Metasurfaces with bound states in the continuum (BICs) have proven to be a powerful platform for drastically enhancing light-matter interactions, improving biosensing, and precisely manipulating near- and far-fields. However, engineering metasurfaces to provide an on-demand spectral and angular position for a BIC remains a prime challenge. A conventional solution involves a fine adjustment of geometrical parameters, requiring multiple time-consuming calculations. In this work, to circumvent such tedious processes, we develop a physics-inspired, inverse design method on all-dielectric metasurfaces for an on-demand spectral and angular position of a BIC. Our suggested method predicts the core-shell particles that constitute the unit cell of the metasurface, while considering practical limitations on geometry and available materials. Our method is based on a smart combination of a semi-analytical solution, for predicting the required dipolar Mie coefficients of the meta-atom, and a machine learning algorithm, for finding a practical design of the meta-atom that provides these Mie coefficients. Although our approach is exemplified in designing a metasurface sustaining a BIC, it can, also, be applied to many more objective functions. With that, we pave the way toward a general framework for the inverse design of metasurfaces in specific and nanophotonic structures in general.

INTRODUCTION

Bound states in the continuum (BICs) are non-radiating solutions to the wave equation with a spectrum embedded in the continuum of the propagating modes in the surrounding space. BICs are a general wave phenomenon that can exist in a variety of acoustic, hydrodynamic, quantum mechanical, and electromagnetic systems $(1-3)$. Because of their infinite radiative lifetimes, BICs are actively studied in optics and photonics, opening up enormous opportunities to realize compact planar high-Q metastructures necessary for biosensing, integrated nonlinear nanophotonics, and an enhancement of light-matter interactions (*4*). In photonics, the most promising platform supporting BICs are *metasurfaces* (*5*). Metasurfaces offer a vast number of designs with materials compatible to BIC. In particular, metasurfaces with BICs demonstrated their efficiency for lasing (*6–10*), biosensing (*11–14*), polaritons (*15–18*), and enhancing nonlinear optical effects (*19–22*).

Optical resonances in periodic metasurfaces radiate only into the open diffraction channels, while BICs remain non-radiating due to the vanishing coupling to all open diffraction channels. For subwavelength metasurfaces, there is only one open diffraction channel and, thus, one coupling coefficient. It can vanish due to symmetry reasons or due to a fine-tuning of the system's geometrical or material parameters (*23*). In the first case, the BICs are called *symmetry-protected* and usually exist in high symmetry points of the k-space. In the second case, BICs are called *accidental* or *parametric*, and they can exist at an arbitrary point in the k-space along the high-symmetry directions (*24*). This explains the term "accidental". The accidental BICs are extremely sensitive to changes in the geometry of the unit cell or the material parameters. Such a high sensitivity makes it challenging and time-consuming to design metasurfaces with a pre-required or fixed spectral and angular position of BIC.

As an alternative to the time-consuming and brute-force optimization (*25, 26*), an *inverse design* approach can be used (*27–30*). The term "inverse design", herein, refers to the process of designing a metasurface with optical properties by initially specifying the desired response rather than the structure of the metasurface itself. Such an inverse design involves dedicated algorithms, e.g., from Bayesian inference, topology optimization, or artificial neural networks. The purpose is always to find the optimal metasurface that provides a predefined optical response (*31–34*). Inverse design can offer metasurfaces with a wide range of optical properties, including phase shifts, polarization conversions, and beam steering. It is a powerful tool for designing advanced optical devices and has applications in fields such as imaging, sensing, and telecommunications (*35–38*). Despite the power of inverse design methods based on artificial neural networks, the underlying physics of the found optimum often remains vague.

In this work, we develop a physics-inspired inverse design procedure for all-dielectric metasurfaces sustaining an accidental BIC at a predefined frequency and incidence angle. Our framework is based on a smart combination of a semi-analytical approach and a dedicated machine-learning algorithm. Our procedure includes three steps schematically shown in Fig. [1.](#page-2-0) In the first step, the problem is solved within a "toy" model. Here, we consider all-dielectric meta-atoms in dipole approximation and capture their response using a T-matrix. After representing the meta-atoms utilizing the electric/magnetic (dipole) polarizabilities, or, equivalently, the scattering (dipole) Mie coefficients, the metasurface model is set up. The existence condition for an accidental BIC at a predefined spectral and angular position is derived analytically as a function of the Mie coefficients of the constituting particle through the identification of the system's eigenmodes. At the end of that first step, we know the polarizabilities of the particle such that the metasurface offers the predefined BIC. In the second step, using a dedicated artificial neural network, we identify the geometrical and material parameters of a core-shell, spherical particle that offers the desired and previously identified polarizabilities so that the metasurface sustains the predefined BICs. The neural network accounts for the practical limitations on the sizes of the spherical particle shells and refractive indices of the materials. In this way, a physically feasible meta-atom is found that provides the desired BIC when placed on an infinite 2D array. In the last step, we numerically verify the design. We also test the robustness of the designed BIC position in k -space if higher-order multipoles contribute besides the dipolar one, namely quadrupoles and octupoles. This entire process is described in the following.

Figure 1: The concept of our proposed framework. Beginning from the top left, an accidental BIC sustained by a metasurface is desired at a specific normalized frequency and incidence angle given by $(\tilde{\omega}_d, \theta_d)$. Then, the metasurface is analytically modeled via the multipolar expansion up to dipolar order. The predefined BIC is supported when the isotropic meta-atom decorating the unit cell of the metasurface has a specific electric and magnetic dipolar polarizability. Following that, a realistic core-shell particle that provides the desired polarizabilities is designed via a machine-learning algorithm in the second step. Finally, the proposed, realistic metasurface is numerically validated concerning its performance and robustness in the third step. By the latest at that stage, a realistic metasurface is described in all its details.

RESULTS

Step 1: BIC in dipolar metasurface

Let us consider in our "toy" model a metasurface consisting of isotropic and non-absorbing particles described in dipole approximation. The particles are arranged on a square lattice with a subwavelength period, i.e. for any incidence angle, there is only a zeroth diffraction order. The considered unit cell is shown in Fig. [2\(](#page-4-0)a). The surrounding medium is a vacuum. The metasurface is illuminated by a timeharmonic linearly polarized plane wave in either TE (or s) or TM (or p) polarization.

Considering the renormalization of the particle's polarizability due to the lattice interaction and imposing a condition that expresses the existence of a resonance, i.e., a denominator in the renormalized polarizability has to be zero, allows for the analytical identification of an equation that must be satisfied for the existence of a BIC. For a given lattice, frequency, polarization, and incidence angle, this equation expresses the necessary relation between the dipolar magnetic b_1 and electric a_1 Mie coefficients to encounter a BIC. A derivation is given in the METHODS section, but the final expressions read

$$
b_1 = -\frac{1 + a_1 (C_1 + C_3)}{C_2 + a_1 (C_1 C_2 + C_2 C_3 - 2 C_5^2)} = F(a_1),
$$
 (TE/s-polarized incidence) (1a)

$$
a_1 = -\frac{1 + b_1 (C_1 + C_3)}{C_1 + b_1 (C_1 C_2 + C_2 C_3 - 2 C_5^2)},
$$
 (TM/s-polarized incidence) (1b)

$$
a_1 = -\frac{1 + \sigma_1(\sigma_1 + \sigma_3)}{C_2 + b_1 (C_1 C_2 + C_2 C_3 - 2 C_5^2)},
$$
 (TM / p-polarized incidence) (1b)

where C_i ($i = 1, ..., 5$) are the elements of the lattice interaction coefficients matrix \bar{C}_s (see Supplementary Material, Sec. S5). These interaction coefficients are calculated via an Ewald summation methods (*39–41*).

The elements of $\bar{\bar{C}}_s$ depend on the lattice constant d, frequency ω , and Bloch wavevector. Therefore, they carry the information about the desired point of operation. Once they are fixed, the Mie coefficients can be identified such that a BIC is supported. Note that the equations for s- and p-polarization are similar. Only the coefficients a_1 and b_1 are swapped, as anticipated, due to symmetry. One should notice from [\(1\)](#page-3-0) that the electric-magnetic lattice coupling coefficient is crucial for the existence of a simultaneous solution for (a_1, b_1) , indicating the importance of multipolar, electromagnetic coupling to realize BICs. The analytical derivation of Eqs. [\(1\)](#page-3-0) is further elaborated in the *Supplementary Material*.

Hence, for the specific scenario considered, Eqs [\(1\)](#page-3-0) provides the exact condition to encounter a BIC for s- or p-polarized incidences, respectively. To further simplify the design, the Mie coefficients are parametrized using what is called the Mie angles (*42*). For a lossless particle, a single angle bound between $-\pi/2$ and $\pi/2$ is sufficient to express any possible value a Mie coefficient might attain. A representation of the Mie coefficients in terms of these Mie angles is highly beneficial for the further design. For example, for the s-polarized incidence case, by substituting dipole electric and magnetic Mie angles, θ_{E1} and θ_{M1} (see METHODS) into Eq. [\(1a\)](#page-3-1), the exact solution can be easily obtained via a non-linear equation solver for a given wavelength, incidence angle, and lattice dimension.

The process of identifying the BIC graphically can be demonstrated by assuming an s-polarized incidence, as depicted in Fig. [2\(](#page-4-0)a). After expressing the right hand side of Eq. [\(1a\)](#page-3-1) as $F(a_1)$,All possible Mie angles in the range of $[-\pi/2, \pi/2]$, which parametrize the magnetic and electric dipolar coefficients, are swept through. The left-hand side (only the b_1 coefficient) and the right-hand side of Eq. [\(1a\)](#page-3-1) are shown in the complex plane in Fig. [2\(](#page-4-0)b). between $-\pi/2$ and $\pi/2$ that parametrize the magnetic and

Figure 2: The toy model: (a) A unit cell of a metasurface made from a periodic arrangement of scatterers with electric and magentic dipole polarizabilities in a square lattice. (b) A graphical representation of how the Mie coefficients are identified that lead to the desired response. The analytical expression for the Mie coefficient that needs to be satisfied to sustain a BIC at a predefined normalized frequency and incidence angle for a given period is plotted separately concerning its left- and right-handed sides. Each side depends only on one Mie coefficient. By parametrizing the Mie coefficients with the Mie angles, both sides of the expression in the complex plane have been plotted. From the point of crossing, the Mie coefficients that provide the desired BIC are identified. (c) The reflection R as a function of dimensionless frequency $\omega d/2\pi c$ and angle of incidence θ for a square lattice with period $d = 450$ nm. The lattice is decorated with particles that offer the previously identified Mie coefficients. The appearance of the BIC at the predefined frequency and incidence angle can be seen. (d) The reflection R as a function of dimensionless frequency $\omega d/2\pi c$ in close proximity to the off-Γ BIC.

electric dipolar coefficients. The left-hand side, i.e. only the b_1 coefficient, and the right-hand side of [\(1a\)](#page-3-1) are shown in the complex plane in Fig. [2\(](#page-4-0)b). As required by lossless scatterers, all possible Mie

coefficients, including the ones of b_1 , lie on a circle in the complex plane with a center at the $(0.5, 0)$ point and a radius of 1. It can be identified that the BIC is located where $\text{Re}\{b_1\} = \text{Re}\{\text{F}(a_1)\}$ and $\text{Im}\{b_1\}$ = $\text{Im}\{F(a_1)\}$ for a specific wavelength, incidence angle, and lattice constant. Once the b_1 coefficient is known, the a_1 value can be explicitly calculated.

As an example, we find a combination of Mie angles $(\theta_{E1}, \theta_{M1})$, or, in other words, \bar{T}_0 matrix, for which a BIC exists for the desired normalized frequency $\tilde{\omega}_d = \omega d/2\pi c = 0.517$ and incident angle $\theta_d = 55^\circ$ in TE- / s-polarization. The reflection from a metasurface formed by the 2D array of dipolar particles, corresponding to the calculated (a_1, b_1) values, is shown in Fig. [2\(](#page-4-0)c). The reflection is shown as a function of the normalized frequency, $\omega d/2\pi c$, and the incidence angle, θ . Additionally, we have been assuming here that the T-matrix is non-dispersive.

For the selected a_1 and b_1 dipole moments, a narrow resonant band is formed. This resonant band disappears precisely at the target parameters $(\tilde{\omega}_d, \theta_d)$, thus, hailing a BIC. To make the success of the proposed methodology more explicit, in Fig. [2\(](#page-4-0)d), we illustrate the change in resonance shape for the reflection coefficient, R, as a function of $\omega d/2\pi c$, for different incident angles θ from 52° to 57°. The resonance becomes infinitely narrow at an angle of θ_d at $\tilde{\omega}_d$, or the Q-factor becomes infinite. It implies that the incident wave does not interact with the metasurface that gets fully transparent. Therefore, the presented methodology succeeds in providing the Mie coefficients for a spherical particle to observe a BIC at a specific frequency and an angle of incidence of a plane wave upon a periodic arrangement of the particle.

Step 2: Deep learning-assisted engineering of spherical particles for BIC realization

In the previous subsection, a method was presented that provides the T-matrix for an isotropic particle to achieve an accidental BIC for a specific normalized frequency and incidence angle.. Although this approach was successful, if one wants to provide a practical design of a metasurface that exhibits BICs, the calculated (a_1, b_1) values must be linked to a realistic scatterer. In this work, we employ a deep-learning scheme to assign the calculated Mie coefficients to a spherical core-shell nano-particle of realistic dimensions and made from existing materials for an operation at optical wavelengths.

To find a suitable scatterer that provides desired Mie angles, a gradient-based deep learning-assisted approach is performed, schematically explained in Fig. [3\(](#page-6-0)a). More details on the Artificial Neural Networks (ANNs) can be found in the article (*43*). Initially, we train a set of ANNs to predict the Mie angles of coated dielectric spheres made from one to five shells and at 200 distinct wavelengths, between 800 nm - 1200 nm. A part of the ANNs is also a classifier that predicts the most probable number of shells to provide the requested Mie angles. Actually, the exemplarily shown core-shell particle in Fig. [3\(](#page-6-0)a) has only three shells. Our trained ANN simply predicted at the end a core-shell particle with three shells only as the most appropriate, which is illustrated here. The materials of the layers are restricted to discrete refractive indices classes ranging from $1.4 - 3.5$, values that are realistic at optical wavelengths for specific materials (see table [1\)](#page-7-0). The radius of the core is limited to 20 nm - 50 nm. The dimension of each shell is restricted to 20 nm - 40 nm. The ANNs are used as a fully differentiable surrogate model in a gradient-based optimization algorithm, namely the limited-memory Broyden-Fletcher-Goldfarb-Shanno algorithm including boundary constraints, or L-BFGS-B (*44*).

The actual solution to the inverse problem starts from random particle parameters as network input, for which we predict the spectral dependencies of the Mie angles with the trained ANN. From that output,

Figure 3: Inverse design: (a) Scheme to find the geometrical and material parameters of a meta-atom (core-shell particle) with a target optical response. In the central part, there is a fully differentiable artificial neural network that can predict the Mie angles for a given core-shell particle. The network was trained within a given spectral region using discrete material classes and constrained geometrical dimensions for the core and the shell that make the design feasible for realization. A gradient descent is then used to identify the parameters characterizing the core-shell particle such that predefined dipolar Mie angles are provided at a design wavelength. At the very end, a second optimization is performed where the refractive indices of the considered materials are fine-tuned to reach an absolute precision. The table shows the design parameters for the example considered in the text. (b) Contribution of each multipole moment (up to quadrupolar order) to the scattering cross-section of the core-shell particle σ_{sc} as a function of the wavelength λ for the final design. (c) Mie angles as a function of wavelength: the dotted line refers to the Mie angles of the optimized toy model, and the solid line refers to the Mie angles of the final design. The intersection of the dotted and solid lines in the $\lambda_d = 870$ nm.

we compute an objective function f, the Mean Absolute Error (MAE) of the ANN output and the target

Class							
Refractive index	1.4649	\pm 1.7196	1.9447	2.0745	$\vert 2.4317 \vert$		
Material	SiO ₂	MgO	ZnO	ZrO2	TiO2	AlAs	GaAs

Table 1: Diferent materials, associated classes and refractive indices.

Mie angles at the desired wavelength, λ_d , as

$$
f(\theta_{\text{target}}, \theta_{\text{NN}}; \lambda_{\text{d}}) = \frac{1}{2} \sum_{i \in \{\text{E1}, \text{M1}\}} |\theta_{i,\text{target}}(\lambda_{\text{d}}) - \theta_{i,\text{NN}}(\lambda_{\text{d}})|. \tag{2}
$$

Subsequently, the gradients of f with respect to the particle parameters $\frac{\partial f}{\partial (r,n)}$ are computed, and they are adjusted iteratively to minimize the MAE. This procedure is repeated for several initial parameters until we find a core-shell particle that provides the target Mie angles with high accuracy.

Unfortunately, the discretization of the refractive index values naturally leads to a restriction of the possible design space. Thus, the design Mie angles and those of the optimized stricture do not match in a perfect sense after that procedure, i.e., we found an agreement only up to two digits after the comma. However, the BIC is very sensitive to slight changes in the Mie angles. Hence, we perform a second optimization using the actual analytical computation of the Mie angles and varied the refractive index of the involved materials slightly for fine-tuning. This approach alone is significantly slower than ANNassisted design, especially for several initial trials. Fortunately, in this work, the designed particle can be fine-tuned to achieve the required accuracy (eight digits after the comma) and grant the appearance of the BIC, given the results of the first ANN-assisted optimization approach as a single starting point. The fine-tuning of the refractive index of the shells could be carefully done by suitable doping of the respective material, which should be within reach with existing technology (*45–47*). In summary, this procedure provides a physical particle that can be used to form a metasurface that offers the BIC at the predefined frequency and incidence angle.

Step 3: Application of the design methodology

The procedure presented above will now be applied to propose a metasurface with a square unit cell decorated by core-shell dielectric spheres that realize a BIC for a predefined lattice, frequency, and incidence angle. For this purpose, let us begin with the theoretical setup depicted in Fig. [2](#page-4-0) with the resulting Mie coefficients from [\(1\)](#page-3-0), $a_1 = -0.4046 + 0.4908$ i and $b_1 = -0.5508 + 0.4974$ i for $\tilde{\omega}_d =$ 0.517 and $\theta_d = 55^\circ$. Afterward, the algorithm presented in the previous section will be utilized to design a realistic core-shell spherical particle that provides the calculated Mie coefficients a_1 and b_1 . We define the dimension of the square lattice as $d = 450$ nm, thus, the desired operational wavelength is $\lambda_d = 870$ nm. The obtained set of parameters of the core-shell particle, i.e., the refractive indices and the geometric dimensions of the shells and core, of which the square array should consist, is shown in Fig. [3\(](#page-6-0)a). Next, we perform a multipolar decomposition of the scattered field (*48*) from the designed spherical particle upon illumination with a linearly polarized plane wave. As depicted in Fig. [3\(](#page-6-0)b), it possesses predominantly a dipolar response around the operational wavelength, λ_d . Moreover, the Mie angles of the designed core-shell particle are calculated (*42*) and presented for the wavelength spectrum 500−1200 nm in Fig. [3\(](#page-6-0)c). Although the Mie angles are dispersive within the considered spectrum, they possess at the $\tilde{\omega}_d$ the required values for the designed operation, equal those requested by the theoretical model.

Figure 4: (a) The square lattice of core-shell particles. (b,d) Reflection coefficients of the actual metasurface as calculated with a full-wave Maxwell solver that exploits the T-matrix formalism. The reflection is shown as a function of the frequency and the incidence angle for a lattice dimension $d = 450$ nm. (b) Calculation in dipole approximation. (d) Calculation in octupole approximation. (c,e) The reflection coefficient versus the normalized frequency in proximity to the off-Γ BIC for a lattice dimension d and using the dipole or the octupole approximation, respectively.

Finally, the designed core-shell spherical particle is placed on a 2D square array (Fig. [4\(](#page-8-0)a)) and the optical response from the metasurface is analyzed with a dedicated T-matrix based full-wave solver (See *Supplementary Material*) (*39, 40*). In Figs. [4\(](#page-8-0)b) and (d), the reflection depending on the normalized frequency, $\omega d/2\pi c$, and the incidence angle, θ , are shown when only dipole (first order) and up to octupole (third order) multipoles are considered in the response calculation, respectively (*40*). Please note, the dipolar approximation would correspond to the assumption in the design process. However, the actual particle does not, of course, have a purely dipolar response, but also small, yet non-negligible, higher-order multipolar coefficients. These higher-order multipolar contributions usually need to be considered when the response from an actual metasurface is predicted.

Specifically, when only the dipolar response of the particle is considered (Fig. [4\(](#page-8-0)b)), a BIC is observed at the $(\tilde{\omega}, \theta) = (0.518, 54.5^{\circ})$, almost exactly on the desired location in the parameter space. A

Figure 5: Robustness of the BICs. (a) the positions of the BICs for different angles θ (deg.) and normalized frequency $\tilde{\omega}$ values: circles and contour in the form of a rectangle $ABCD$. (b) the values of the Mie angles for BICs from panel a.

more clear view of the reported BIC point is given in Fig. [4\(](#page-8-0)c), where the reflection coefficient of the corresponding metasurface is plotted versus the normalized frequency for various angles of incidence. Thus, the deviation of the obtained core-shell particle metasurface from the desired BIC point in the theoretical dipole analysis is 1%. The discrepancy can easily be explained by the fact that the realistic structure does not provide exactly the desired Mie coefficients. In other words, the consideration of actual materials causes these small deviations. Finally, to verify that the proposed design still fulfills the set goals when higher order multipoles are taken into account, the reflection coefficient from the core-shell particle metasurface is calculated when considering multipoles up to octupolar order, i.e., $j = 3 (39, 40)$. One can observe in Fig. [4\(](#page-8-0)d) and (e) that the resulting BIC position at $(\tilde{\omega}, \theta) = (0.516, 55.5^{\circ})$ does not differ much from the desired one. Therefore, it can be safely deduced that the performance of the designed metasurface will remain the same in realistic conditions.

DISCUSSION

The sensitivity of the BIC against deviations in the Mie angles parameterizing the optical response of the scatterers will now be discussed. Figure [5](#page-9-0) demonstrates how the position of the BIC for different angles θ and frequency $\tilde{\omega}$ values translates to values of the required Mie angles. The bounding box as a rectangle ABCD is transformed very strongly in the plane of the Mie angles. That can also be seen in the individual circles that provide some insights into the robustness. Generally, for a robust BIC, we require each area in the plane of the Mie angles to be as large as possible and as circular as possible. That

would suggest that a given Mie coefficient only needs to be roughly hit to ensure that a BIC appears in the target area given by the circles in the plane spanned by the frequency and incident angle. However, the BIC is extremely sensitive for a strongly reduced area of the surface in the plane of the Mie angles. Thus, for that case, the Mie angles must be precisely met to cause a BIC at predefined frequencies and angles. Moreover, we notice that some circles are stretched and elongated in the plane of the Mie angles. Here, we will speak about conditional robustness. In this case, many Mie angles, for, let's say, the electric dipole moment, permit the observation of the BIC in the target range of parameters. However, the other Mie angle must be carefully tuned to be within the stretched circle. One can roughly conclude that the most robust region is in the zone of lower frequencies and shorter angles (close to the corner A). However, the excitations of BICs in the related parameter regime are difficult for practical systems. The sizes of realistic spheres, obtained as a result of the deep learning-assisted engineering step, compare already very well to the period of the metasurface. Therefore, the BIC position could shift a lot relative to the desired angles and frequencies since the renormalization is substantial in that parameter domain.

In Fig. [5\(](#page-9-0)b), the intersection of two lines of the bounding box occurs as a further interesting phenomenon. It means that for these Mie angles at the point of intersection, the metasurface sustains two distinct BICs for different pairs of frequency and incidence angles. This case is discussed in more detail in the *Supplementary Material*.

Although, in this work, we have utilized the dipole approximation to design the meta-atoms, i.e., only up to the first multipolar order, the core idea behind the presented methodology is general and can be applied to higher-order multipoles or more complex scatterers. Provided that the general eigenvalue problem (see [\(6\)](#page-12-0) in METHODS) can be solved under some approximations and the solutions corresponding to the BIC resonances can be recognized, the Mie angles that lead to the desired BIC can be expressed. For example, in (*40*), for a square metasurface illuminated by a normally-incident plane wave and consisting of an isotropic particle with only a magnetic dipole and an electric quadrupole excited, a BIC point was identified, or the required (b_1, a_2) values. Then, a suitable inverse design technique can be used to identify an actual meta-atom that offers these desired Mie angles. In the work at hand, the acquired Mie coefficients were assigned to a core-shell particle via the deep learning algorithm. These considerations can be extended to more complex, e.g., anisotropic or bi-anisotropic scatterers and can accommodate an increasing number of multipolar orders. Approximate models for the T matrix could be utilized for that purpose (*49, 50*) or more advanced neural networks can be trained (*51*).

In summary, the physics-inspired inverse design procedure for all-dielectric metasurfaces sustaining an accidental BIC at a certain frequency and angle of incidence was developed in this work. The methodology utilized a smart combination of a semi-analytical approach and a dedicated machine-learning algorithm. Firstly, the problem was solved within a theoretical model considering all-dielectric meta-atoms using the dipole approximation and the T-matrix technique. The existence condition for an accidental BIC was derived in terms of Mie angles. Secondly, using a dedicated artificial neural network, the geometrical and material parameters of a core-shell, spherical particle that offered the desired optical response provided by the BIC condition were identified. In this way, a physically feasible meta-atom was found that provided the desired BIC when placed on an infinite 2D array. Finally, the design was numerically verified, and the robustness of the designed position BIC in k -space was tested by considering higher-order multipoles.

METHODS

The T-matrix formulation for 2D arrays and BIC identification

Considering a metasurface composed of a square array of isotropic and non-absorbing particles, as shown in Figure [2\(](#page-4-0)a). The surrounding medium is a vacuum.

If an arbitrary scatterer is placed in an infinite homogeneous background and the vector spherical harmonics (VSH) basis is employed to expand the fields, the scattering response to an incident electromagnetic wave can be described using the T matrix, or $\bar{\bar{T}}_0$, as

$$
\left[\begin{array}{c}\mathbf{a}^{\mathrm{e}}\\ \mathbf{a}^{\mathrm{m}}\end{array}\right]=\bar{\bar{T}}_{0}\left[\begin{array}{c}\mathbf{q}^{\mathrm{e}}\\ \mathbf{q}^{\mathrm{m}}\end{array}\right]=\left[\begin{array}{c}\bar{\bar{T}}^{\mathrm{ee}} & \bar{\bar{T}}^{\mathrm{em}}\\ \bar{\bar{T}}^{\mathrm{me}} & \bar{\bar{T}}^{\mathrm{mm}}\end{array}\right]\left[\begin{array}{c}\mathbf{q}^{\mathrm{e}}\\ \mathbf{q}^{\mathrm{m}}\end{array}\right].\tag{3}
$$

Vectors $q^{\{e,m\}}$ contain the incident wave electric or magnetic coefficients, respectively, while $a^{\{e,m\}}$ contain the scattering electric or magnetic coefficients, respectively (*52*). For each multipolar expansion order $j \in \mathbb{N}$, the size of the aforementioned vectors increases by $2j + 1$. Prior knowledge of the T matrix can predict the electromagnetic response of a scatterer, since it depends on the scatterer's geometry, constituting materials, and surrounding material. The elements of the T matrix can generally be extracted up to a preset expansion order via numerical simulations (48, 53), while for special geometries, such as spheres, cylinders, etc., the T matrix elements can be calculated analytically. The particular case of isotropic particles, i.e., spherical ones, is very interesting because apart from enabling analytic calculations, the respective T matrices become diagonal, or, $\bar{\bar{T}}^{\text{em}} = \bar{\bar{T}}^{\text{me}} = \bar{\bar{0}}$ and $T_{il}^{\text{ee}} = T_{il}^{\text{mm}} = 0$, for $i \neq l$, with $\{i, l\} \in [-j, j]$, while \bar{T}_j^{ee} and \bar{T}_j^{mm} become scalar matrices for each multipolar order j, or, $\bar{\bar{T}}_j^{\text{ee}} = -a_j \bar{\bar{I}}$ and $\bar{\bar{T}}_j^{\text{mm}} = -b_j \bar{\bar{I}}$. The parameters a_j and b_j are called the *Mie coefficients* (54).

For an isotropic particle, it is convenient to parameterize the coefficients with *Mie angles* (*42*). In particular, for lossless particles and when only dipoles are considered, i.e., $j = 1$, all possible Mie coefficients can be expressed using two parameters θ_{E1} and θ_{M1} , or

$$
a_1 = \frac{1}{1 - i \tan \theta_{\text{E1}}}, \ -\frac{\pi}{2} \le \theta_{\text{E1}} \le \frac{\pi}{2},\tag{4a}
$$

$$
b_1 = \frac{1}{1 - i \tan \theta_{\text{M1}}}, \ -\frac{\pi}{2} \le \theta_{\text{M1}} \le \frac{\pi}{2}.
$$
 (4b)

As a result, the optical response of the corresponding scatterer can be parameterized with the two Mie angles above, while still having a clear physical picture. This formulation is very important because the control parameters, namely θ_{E1} and θ_{M1} , are placed between an upper and lower boundary, which will aid optimization methods and subsequent metasurface design. Furthermore, similar expressions involving Mie angles, like the ones of [\(4\)](#page-11-0) above, exist for higher-order multipoles, the addition of absorption or Lorentzian dispersion for Mie coefficients (see *Supplementary Material*).

Let us now assume an infinite square array composed of arbitrary, identical, absorption-less, spherical particles placed in a homogeneous material, as depicted in Fig. [1.](#page-2-0) The response of the metasurface can be calculated via the T matrix of the particle by employing microscopic models (*39,40,55,56*). An important aspect to be noted herein is that the T matrix of the particle within the metasurface is *re-normalized* due to the particle interaction. Thus, in 2D array models, the isolated particle's T matrix, $\bar{ \bar{T}}_0$, from [\(3\)](#page-11-1) is replaced with the *effective T matrix* calculated via (*55*)

$$
\bar{\bar{T}}_{\text{eff}} = \left(\bar{\bar{I}} - \bar{\bar{T}}_0 \bar{\bar{C}}_s\right)^{-1} \bar{\bar{T}}_0,\tag{5}
$$

where $\bar{\bar{I}}$ is the identity matrix, and $\bar{\bar{C}}_s$ is the *lattice coupling matrix* expressed in spherical coordinates, which is a function of the unit cell dimension, the frequency, and the wavevector, and is calculated, herein, via rapidly converging summations using Ewald's method (*39, 41, 57*). The analytical method based on a multipolar expansion that is used in this work for the calculation of the response of an infinite 2D square array (*40*) is elaborated in the *Supplementary Material*.

It should be stressed that, although the scattering response of a single particle and of the subsequent 2D array is provided here using the spherical coordinates and the T matrix approach, the analysis that will follow is valid and interchangeable with the use of multipoles in Cartesian coordinates and the polarizability matrix. In particular, one can obtain the T matrix of a particle from the polarizability matrix, and vice versa using the appropriate transformation matrices for each multipolar order (*40, 58*). Additionally, modifications of the same matrices can transform multipoles of the same type and order from a spherical to a Cartesian basis and vice versa, as presented in the *Supplementary Materials* for multipoles up to the $j = 3$ order.

After defining the multipolar description of the electromagnetic response of 2D arrays composed of isotropic particles, next, we will present the procedure for identifying the presence of BICs after setting certain goals. First, let us theoretically acquire the BIC position using the multipolar expansion technique (*40,59–61*). If we again assume a square array composed of identical and isotropic particles, its response to an incident field can be described by substituting [\(3\)](#page-11-1) and [\(5\)](#page-12-1) into the equations that describe the response of a 2D array (*39, 40*) (see *Supplementary Material*), and, thus, a linear system of equations is formed. Solving the eigenvalue problem leads to the modes of the array, including, in this case, the trapped ones that do not couple with radiation channels, i.e., the BICs. Therefore, if we invert the square matrix of the system to the left side of [\(3\)](#page-11-1) and set the excitation to zero, or $q^{\{e,m\}} = 0$, the resulting homogeneous system will have a non-trivial solution if the determinant of the matrix is zero (*25, 26, 40*). In particular, after some algebra, the BIC condition is reduced to

$$
\left| \bar{\bar{I}} - \bar{\bar{T}}_0 \bar{\bar{C}}_s \right| = 0. \tag{6}
$$

The symmetry of the resonators is tightly related to their mode structure and multipole content, which determine the linear and non-linear response of the resonator. Using group theory, it is possible to classify the eigenmodes into irreducible representations and understand their multipole content (*62–64*). Our model is characterized only by the dipole response. Table 1 shows how the dipole moments correspond to different types of eigenmodes for a square array of particles outside the off-Γ point in a spherical basis. The system is characterized by the C_{2v} symmetry group in direction ΓX . There are only 4 types of modes: A_1 , A_2 , B_1 , and B_2 . Destructive interference of the eigenmodes of one type is necessary for BICs formed by the Friedrich-Wintgen mechanism. It can be concluded that in this model, parametric BIC exists only in modes of types B_1 and B_2 .

The expression [\(6\)](#page-12-0) is general in nature and can be used for any type of lattice or particle in a homogenous medium (*40*). Due to its complexity, [\(6\)](#page-12-0) can only be solved numerically in its general form, i.e., for higher-order multipoles or more diverse lattices. Nevertheless, for specific reduced cases, versatile analytic solutions can be found, as demonstrated in (*40*) for the case of the coupled electric dipole -

Irreducible representation $ A_1 $				
Cartesian basis	p_u	$m_{\rm u}$	p_z, m_x	m_z, p_x
Spherical basis	a_{11}^e, a_{1-1}^e		$\left a_1^{\text{m}}, a_{1-1}^{\text{m}} \right a_{10}^{\text{e}}, a_{11}^{\text{m}}, a_{1-1}^{\text{m}}$	$a_{10}^{\rm m}, a_{11}^{\rm e}, a_{1-1}^{\rm e}$

Table 2: The classification of modes by irreducible representations and the multipole composition of the eigenmode for C_{2v} symmetry group in direction ΓX in the dipole approximation for different bases.

magnetic quadrupole on a square lattice and a normal, TM wave incidence. In this work, we consider a square lattice decorated by isotropic and lossless particles, whose response is expanded only up to dipolar order, or $j = 1$. Then, because the elements of the lattice interaction matrix, $\overline{\overline{C}}_s$, can be pre-calculated for a specific incident wavevector, \mathbf{k}^{inc} , and a normalized lattice dimension, d/λ , eventually, [\(6\)](#page-12-0) can be solved for $j = 1$ with the Mie angles of [\(4\)](#page-11-0) as the unknowns.
