ABSTRACT

We propose an automated lowest floor elevation (LFE) estimation algorithm based on computer vision techniques to leverage the latent information in street view images. Flood depth-damage models use a combination of LFE and flood depth for determining flood risk and extent of damage to properties. We used image segmentation for detecting door bottoms and roadside edges from Google Street View images. The characteristic of equirectangular projection with constant spacing representation of horizontal and vertical angles allows extraction of the pitch angle from the camera to the door bottom. The depth from the camera to the door bottom was obtained from the depthmap paired with the Google Street View image. LFEs were calculated from the pitch angle and the depth. The testbed for application of the proposed method is Meyerland (Harris County, Texas). The results show that the proposed method achieved mean absolute error of 0.190 m (1.18 %) in estimating LFE. The height difference between the street and the lowest floor (HDSL) was estimated to provide information for flood damage estimation. The proposed automatic LFE estimation algorithm using Street View images and image segmentation provides a rapid and cost-effective method for LFE estimation compared with the surveys using total station theodolite and unmanned aerial systems. By obtaining more accurate and up-to-date LFE data using the proposed method, city planners, emergency planners and insurance companies could make a more precise estimation of flood damage.

Keywords Lowest floor elevation · Street view images · Flood Inundation · Flood damage · Image segmentation

1 Introduction

Floods are among the most costly natural disasters, especially in coastal areas (J. C. J. H. Aerts et al., 2014; Guo et al., 2022; Michel-Kerjan, 2015; Strömberg, 2007). In the United States, floods accounted for 40% of natural disasters between 1900 and 2015 (Cigler, 2017). Besides weather and terrain, flood damage is also influenced by human development. Urban built environment has been identified to exacerbate flood damage (Brody et al., 2008). The cost of flood damage can be enormous, with more than \$72 billion USD in claims filed by National Flood Insurance Program (NFIP) policyholders between 1990 and 2022 (FEMA, 2023). The ability to estimate flood damages is critical for mitigation and response actions (J. C. Aerts et al., 2018). One key factor for estimating flood damage is the lowest floor elevation (LFE) (Bodoque et al., 2016; Taghinezhad et al., 2020; Xian et al., 2017; Zarekarizi et al., 2020). Flood depth-damage models use a combination of LFE and flood depth for determining flood risk and projecting extent of damages to properties. The absence of reliable and up-to-date LFE data is a major roadblock in proper assessment of flood risk to properties and rapid assessment of flood damages.

The current methods of estimating and measuring are costly, time consuming, and resource intensive. One approach is direct measurement by survey contractors using a total station theodolite. The resulting elevation certificate must

be completed, sealed, and submitted to the jurisdiction’s building code department by a licensed surveyor, engineer, or architect (FEMA, 2020). This type of manual inspection, however, is costly and labor-intensive. Previous literature has shown the use of drones and street view images to estimate LFE. For example, Diaz et al. (2022) used drones and photogrammetric methods to derive LFE in coastal areas; drone aviation, however, is subject to regulatory and training limitations. Mapping LFE at a larger scale (such as an entire city) using drones could be costly due to the aforementioned limitations. LiDAR (light detection and ranging) data has been used for similar measurement in previous literature (Bonczak & Kontokosta, 2019; Feng et al., 2022; Meesuk et al., 2017). Feng et al. (2022) used LiDAR data captured by vehicles for detecting building openings, such as doors and windows, for mapping building flood risk. Capturing LiDAR data, however, is more expensive than capturing images. Another approach is the use of street view images (SVI), such as Google Street View, are publicly available. Ning et al. (2022) used Google Street View images and a computer vision algorithm, YOLO-v5, to estimate LFE. G. Gao et al. (2023) analyzed flood mitigation governance based on Ning et al. (2022)’s LFE estimation method; however, these studies lacked estimation of the height difference between the street and the lowest floor (HDSL), which is critical information for flood vulnerability estimation. In addition, the previous studies used bounding boxes, rectangles to frame objects in images, to mark door shapes. Bounding boxes, however, are not able to discern precise object shapes in some situations, such as variation in viewpoints and distortion in projection, since shapes are perceived only as rectangles. When the viewpoint of an image is not perfectly aligned with the target door, the door shape will be a parallelogram instead of a rectangle. When a panorama is presented on a plane, inherent distortion causes door edges to appear as non-straight. To address the limitation of bounding boxes to delineate door shapes from the images with viewpoint variation and projection distortion, the previous method reprojects street view equirectangular panoramas to perspective images before object detection. Image reprojection, however, results in loss of information. Furthermore, bounding boxes can provide only straight lines, yet streets are not always straight, making this method unsuitable for HDSL estimation. To address these limitations, we propose an automated LFE and HDSL estimation algorithm using computer-vision techniques directly on street view panoramas without image reprojection and demonstrate the application of the proposed algorithm using data from Meyerland in Harris County, Texas (USA).

Figure 1 depicts an overview of the proposed method. The first step involves collecting images and depthmaps from Google Street View, which are then preprocessed to align with each building in the study area. Image segmentation techniques are then utilized to detect doors, which can be used to determine LFEs. Similarly, objects such as roads, grass, and dirt are used to determine the elevation of the roadside, providing information necessary to calculate HDSL. The data and methods section describes the data sources and the methodology used in this research. The results and discussion section presents the estimation of the two measurements when implementing computer-vision techniques on street view images. It discusses the corresponding error then provides an in-depth analysis of the developed estimation algorithm. The closing remarks section summarizes the contributions, limitations, and suggestions for future works of this study.

2 Data and Methods

2.1 Study Area and Ground Truth Data

In this study, we used the LFE measured by an unmanned aerial system-based photogrammetry as ground truth to evaluate the LFE derived by our proposed street view image-based method. The drone-based LFE measurements achieved 0.16 m (6.3 in) mean absolute error (MAE) to elevation certificates (ECs) from the Federal Emergency Management Agency (FEMA). Detailed description of drone measurement is in Diaz et al. (2022). The drone-based LFE was measured using the bottom of front, side, and back doors. On the other hand, the LFE determined in ECs is the lowest enclosed area, including garages and basements (FEMA, 2020). Since the drone-based LFE is the available data whose definition of LFE is the closest to our definition, the bottom of front doors, the drone-based LFE is adopted as ground truth in this study. The inconsistency between the LFE in ECs and the LFE derived by image-based methods has been indicated in several studies (Diaz et al., 2022; Ning et al., 2022). The study area is in Meyerland, a flood-prone community in Harris County, Texas. About \$0.68 billion USD in claims was filed by National Flood Insurance Program (NFIP) policyholders in Meyerland between 1990 and 2022 (FEMA, 2023). In recent years, lots of buildings in this community were reconstructed or elevated to avoid being flooded. An example of a house in Meyerland elevated after Hurricane Harvey is shown in Figure 3. The flood vulnerability of Meyerland, however, is deteriorating with the expansion of the floodplain extent (Juan et al., 2020). The need for flood risk evaluation and the LFE difference among new and old buildings make this community a suitable testbed for evaluating the Elev-Vision method. Figure 2 shows the study area.

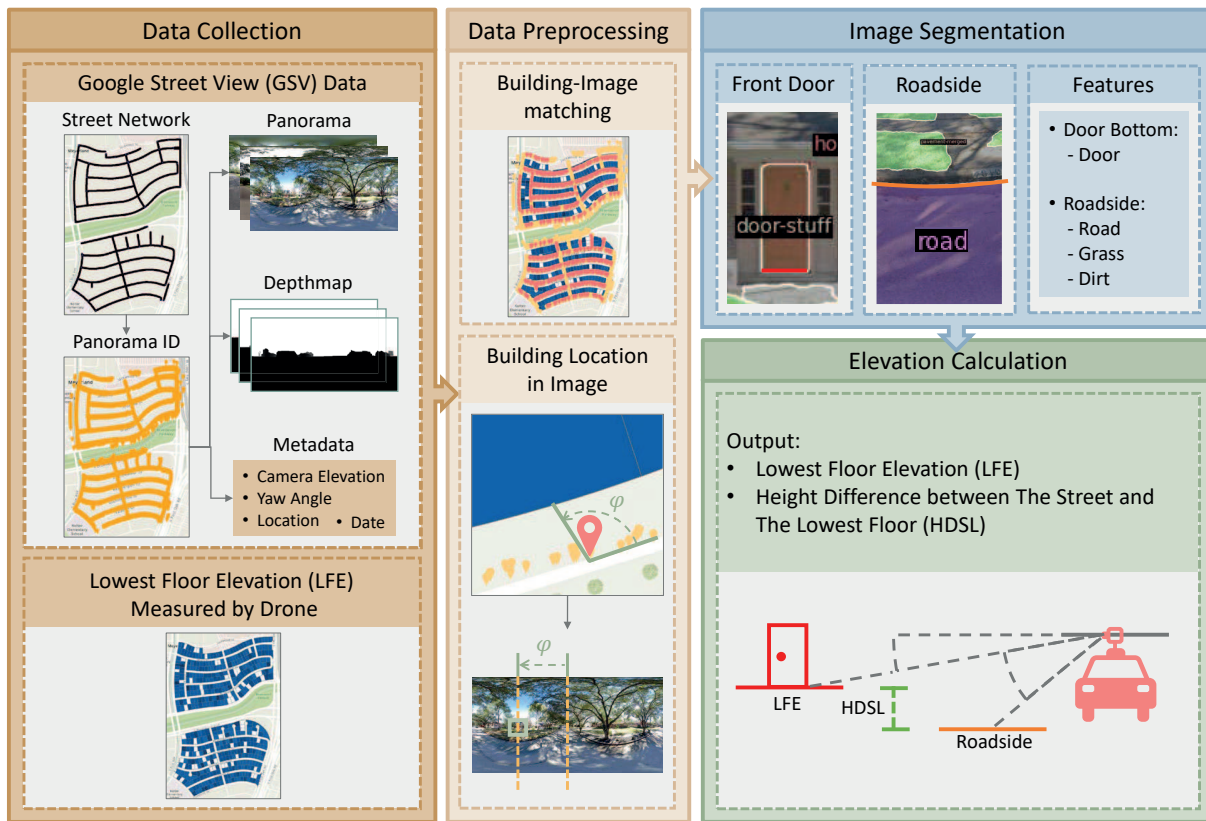

Figure 1: Overview of the Elev-Vision method to estimate LFE and HDSL. The elevation estimation method comprises four steps: data collection, data preprocessing, image segmentation, and elevation calculation. Data collection: the street map should be downloaded first to determine the required street view images on the streets of interest; street view panoramas, depthmaps, and metadata are collected based on the collected panorama IDs. Data preprocessing: street view images are matched with houses based on addresses; the image with the most visible front door is selected for each house; the house of interest is automatically located in the image based on the bearing angle from the camera to the house. Image segmentation: the front door bottom and the road elevation are detected. If the road is not detected, the grass and the dirt are used as the secondary feature for roadside extraction. Elevation calculation: LFE and HDSL are calculated by the depth and the pitch angle.

2.2 Street View Images

Street view imagery, an accessible urban data source, makes available easily accessible high-quality images. Perrett et al. (2023) developed a roadside verge biodiversity classification model using street view images for roadside verge surveys. D. Liu et al. (2023) used street view images and a street tree classification model to establish street tree inventories. Alizadeh et al. (2022) combined flood gauge data and flooded street view images for flood depth estimation. L. Liu et al. (2023) used street view images for three-dimensional streetscape-feature estimation to explore the relationship between three-dimensional streetscapes and vehicle use. Biljecki and Ito (2021) provides a comprehensive review on the applications of street view images in studies related to spatial and urban analysis.

The road network of Meyerland was first downloaded from OpenStreetMap (OpenStreetMap contributors, 2017) for street view image collection. Google Street View images, with available related depthmaps and metadata, offer stable quality across the desired area and time period. Google Street View panoramas and their metadata were collected based on streetview (Letchford, 2023), a Python module for downloading Google Street View images. The depthmaps were decoded based on GSVPanoDepth (Häußler, 2023). The resolutions of most panoramas are 8192 x 16384 pixels and 6656 x 13312 pixels. The resolution of depthmaps is 256 x 512 pixels. Collected metadata includes image location, address, camera elevation, camera yaw angle, and image captured date. Camera elevations are in WGS84 (World Geodetic System 1984) meters above mean sea level (MSL), the same as drone-based LFEs.

Figure 2: Meyerland, a flood-prone community in southern Harris County, Texas, was the testbed for this research.

Figure 3: Example of a house elevated after Hurricane Harvey. (a) The house in 2016 (Before Hurricane Harvey). (b) The house in 2022 (After Hurricane Harvey).

The research area contains 483 houses. Due to house reconstruction during LFE measurement time, ground truth data for only 424 LFE (87.78%) were available for the analysis. Among the houses with LFE ground truth, 409 (96.46%) of houses' street view images were available. Among these street view images, 197 (48.17%) houses' front doors were visible. Some of the images, however, were not matched with the LFE ground truth because of reconstruction. Specifically, some street view images showed newly constructed houses, whereas the LFE ground truth was for the houses before reconstruction. Despite the availability of older images, only the images taken after 2015 were used in this study with consideration of image resolution. After removal of unmatched images, 185 (93.91%) images were available. The numbers of houses passing the data filter in each step are listed in Table 1.

Table 1: Number of houses passing the filter in each step.

Step	Data Filter	Number of Houses
1	Houses with LFE ground truth	424
2	Houses with an SVI	409
3	Houses with a visible front door in the SVI	197
4	Houses with matched LFE ground truth and the SVI	185
5	Houses with the detected door bottom in the SVI*	136

* Detailed explanation of the number of houses in Step 5 is provided in Section 2.3

2.3 Image Segmentation

The computer vision-based method is used extensively in civil infrastructure inspection (Lee & Gharaibeh, 2022; Zhang et al., 2020), building damage assessment (Y. Gao & Mosalam, 2018; Kaur et al., 2023; Sajedi & Liang, 2020), and other related applications. In this study, we used image segmentation, a computer vision technique that involves pixel classification, to detect building objects that could be used for finding lowest floor elevation. Image segmentation comprises three categories: semantic segmentation, instance segmentation, and panoptic segmentation (Minaee et al., 2022). Semantic segmentation is categorical labeling for each pixel to create a categorical mask for each category. Instance segmentation creates an individual mask for each object, which can be view as the combination of object detection and semantic segmentation. Panoptic segmentation is a combination of the semantic and image segmentation; for object categories, instance segmentation is conducted; for background categories, semantic segmentation is conducted.

Image segmentation has been applied to street view images in city environmental research applications, such as built environment (S. Chen & Biljecki, 2023; Chiang et al., 2023; He et al., 2023; Jeon & Woo, 2023; Ki & Lee, 2021; Ma et al., 2021; Middel et al., 2019), acoustic environment (Zhao et al., 2023), air pollution (Qi & Hankey, 2021), and route planning (Guan et al., 2023; Li et al., 2019). Jeon and Woo (2023) assessed walking environments of public housing using street view images and image segmentation; Qi and Hankey (2021) applied image segmentation to street view images with a combination of land-use regression models for air pollution prediction; S. Chen and Biljecki (2023) adopted image segmentation and street view images to assess public open spaces; Chiang et al. (2023) applied image segmentation to street view images for estimating sky view factor and green view index; Guan et al. (2023) analyzed the complexity involved in decision-making at road intersections by the application of street view images and image segmentation; He et al. (2023) employed image segmentation on street view images for extracting human perceptions to built environment and evaluating the potential in urban renewal; Zhao et al. (2023) combined image processing, object detection, image segmentation, and scene recognition to explore urban soundscapes. Image segmentation has also been utilized in other urban and structural studies (Czerniawski & Leite, 2020; Hosseini et al., 2023; Kido et al., 2021; Pan et al., 2022; Wu et al., 2019; Zou et al., 2021). Pan et al. (2022) used image segmentation on structure facades for identifying thermal anomalies. Kido et al. (2021) applied image segmentation and enhanced mixed reality to estimating designed landscapes to assess environmental impact of construction projects. Wu et al. (2019) used image segmentation and point cloud to extract road pothole data.

Different image segmentation models have been developed in recent years (L.-C. Chen et al., 2017; Long et al., 2015). In this study, we adopted OneFormer (Jain et al., 2023) , a transformer-based multi-task image segmentation framework, to detect door bottoms and roadsides. OneFormer was selected because of its good segmentation performance on COCO-stuff dataset (Caesar et al., 2018). The OneFormer model pretrained by COCO-stuff dataset is utilized. We also experimented with other datasets for door segmentation, but the COCO-stuff dataset was the only dataset on which front doors were able to be segmented. Most datasets could only be used for indoor door segmentation.

Through COCO-stuff pretrained OneFormer, 136 (73.51%) of these visible door bottoms in the aforementioned 185 street view images were correctly segmented while 100% of roadsides were segmented.

2.4 LFE Estimation

2.4.1 House Localization in Panorama

The house of interest needs to be located from among the many houses in the panorama. First, the bearing angle from the camera to the house β_{house} (*radian*) is calculated using Eq. 1,

$$\beta_{house} = atan2(X, Y) \quad (1)$$

$$X = \sin(lon_{house} - lon_c) \cdot \cos(lat_{house}) \quad (2)$$

$$Y = \cos(lat_c) \cdot \sin(lat_{house}) - \sin(lat_c) \cdot \cos(lat_{house}) \cdot \cos(lon_{house} - lon_c) \quad (3)$$

in which (lat_c, lon_c) is the camera location and $(lat_{house}, lon_{house})$ is the house location. Since Google street view panoramas are equirectangular projection images, for the property upon which vertical and horizontal angles are projected, constant spacing lines can be utilized to transform between angles and pixels. The horizontal pixel p_x of the house is calculated by Eq. 4,

$$p_x = \begin{cases} \frac{W_{img}}{2} + \frac{\Delta\beta}{180} \cdot \frac{W_{img}}{2} & \beta_{yaw} \leq \beta_{house} \leq \beta_{yaw} + 180 \\ \frac{W_{img}}{2} - \frac{\Delta\beta}{180} \cdot \frac{W_{img}}{2} & else \end{cases} \quad (4)$$

in which β_{yaw} (degree) is the yaw angle of the camera, β_{house} (degree) is the bearing angle from the camera to the house, $\Delta\beta$ is the angle between the yaw direction the direction from the camera to the house, and W_{img} is the width of the panorama.

From house location, the possible location range of the front door can be determined. We set the possible location range of the front door for image segmentation as ± 45 degrees from the bearing angle of the house, $[\beta_{house} - 45^\circ, \beta_{house} + 45^\circ]$. If the front door is not detected, the possible location range is horizontally translated ± 22.5 degrees. House localization not only prevents house mismatching but also accelerates the process time of image segmentation.

2.4.2 Door-bottom Extraction

Next, we conduct image segmentation to get the category matrix. Eq. 5 extracts pixels of the door bottom from the door mask. The pixel

$$(p_x, p_y) \in P_{db} \quad \forall \quad [p_x \in P_{x,door} \quad and \quad (p_y = \max p'_y \quad \forall \quad p'_y \in P_{y,door}(p_x))] \quad (5)$$

in which P_{db} is the set of the door bottom pixels, $P_{x,door}$ is the set of the door's horizontal pixels, and $P_{y,door}(p_x)$ is the set of the door's vertical pixels given the horizontal pixel.

2.4.3 Elevation Calculation

To obtain LFE, we first calculate the height difference between the camera and the door bottom $\Delta h_{db,c}$ with the pitch angle from the camera to the door bottom $\Delta\theta_{db,c}$ and the depth from the camera to the door bottom $d_{db,c}$ by Eq. 6.

$$\Delta h_{db,c} = d_{db,c} \cdot \sin(\Delta\theta_{db,c}) \quad (6)$$

The depth from the camera to the door bottom $d_{db,c}$ is extracted from the depthmap based on the door bottom pixels obtained in the previous step and the pitch angle from the camera to the door bottom $\Delta\theta_{db,c}$ is calculated by Eq. 7,

$$\Delta\theta_{db,c} = \left(\frac{H_{img}}{2} - p_y \right) \cdot \frac{180}{H_{img}} \quad (7)$$

in which H_{img} is the height of the panorama and p_y is the vertical pixel of the door bottom. The depth and the pitch angle are demonstrated in Figure 4.

Then, the estimated LFE is performed using

$$LFE = CE + \Delta h_{db,c} \quad (8)$$

in which CE represents camera elevation.

To provide more robust estimation, we use the median of the set of the door bottom elevations $\{E_{db}\}$ derived from the set of the door bottom pixels P_{db} as the estimated LFE instead of using only one point (p_x, p_y) . However, due to the

Figure 4: The example of the depthmap with the spherical coordinate system demonstration. Pixels with darker masks represent shorter depths. β_{yaw} (degree) is the yaw angle of the camera, β_{house} (degree) is the bearing angle from the camera to the house, $\Delta\theta_{db,c}$ is the pitch angle from the camera to the door bottom, $\Delta\theta_{rs,c}$ is the pitch angle from the camera to the roadside, $d_{db,c}$ is the depth from the camera to the door bottom, $d_{rs,c}$ is the depth from the camera to the roadside. Google Street View panoramas are equirectangular projection images, of which vertical and horizontal angles are projected to constant spacing lines. This characteristic makes it simple to transform between angles and pixels.

view angle of images, the door in the image is a quadrilateral rather than a perfect square. LFE will be overestimated if we simply use the median of elevations derived from the set of the door bottom pixels P_{db} as the estimated LFE. To solve this problem, the outliers of door bottom elevations are removed from the set of the door bottom elevations $\{E_{db}\}$ first. Then, as shown in 5, the detected front doors are labeled as completely detected or partially detected. Specifically, we labeled the detected door bottoms for all houses at the subset $\{E'_{db}\}$ containing only the 25%, 50%, or 75% lowest door bottom elevations. For completely detected front doors, $\{E'_{db}\} = \{E_{db}\}$. Last, we further removed the elevations higher than the median of the subset of door bottom elevations $\{E'_{db}\}$ to construct another subset $\{E''_{db}\}$ then calculated the median of $\{E''_{db}\}$ as the estimated LFE.

2.5 Height Difference between the Street and the Lowest Floor Estimation

To estimate HDSL, we first calculated the elevation of the roadside RE near the house with the pitch angle from the camera to the roadside $\Delta\theta_{rs,c}$ and the depth from the camera to the roadside $d_{rs,c}$. The calculation of RE is similar to the calculation of LFE. Roads, grass, and dirt are the features used to detect roadsides. Grass, and dirt are secondary features for roadside detection because roads are not always correctly segmented. When using secondary features to detect roadsides, we selected pixels which were 20 pixels vertically lower than the edge of the feature mask to represent the roadside more accurately. Then, HDSL was calculated using Eq. 9.

$$HDSL = LFE - RE \quad (9)$$

3 Results and Discussion

SVI-estimated LFSs were compared to drone-measured LFE as the ground truth. The error distribution is shown in Figure 5. As the front doors of houses are not always completely visible, the data were classified as door bottom completely visible or partially visible to evaluate the influence of image segmentation performance on LFE estimation. Figure 5 demonstrates that the LFE error range is narrower for completely detected door bottoms than for partially detected ones, even though there are more outliers among the former. However, there is no significant difference in terms

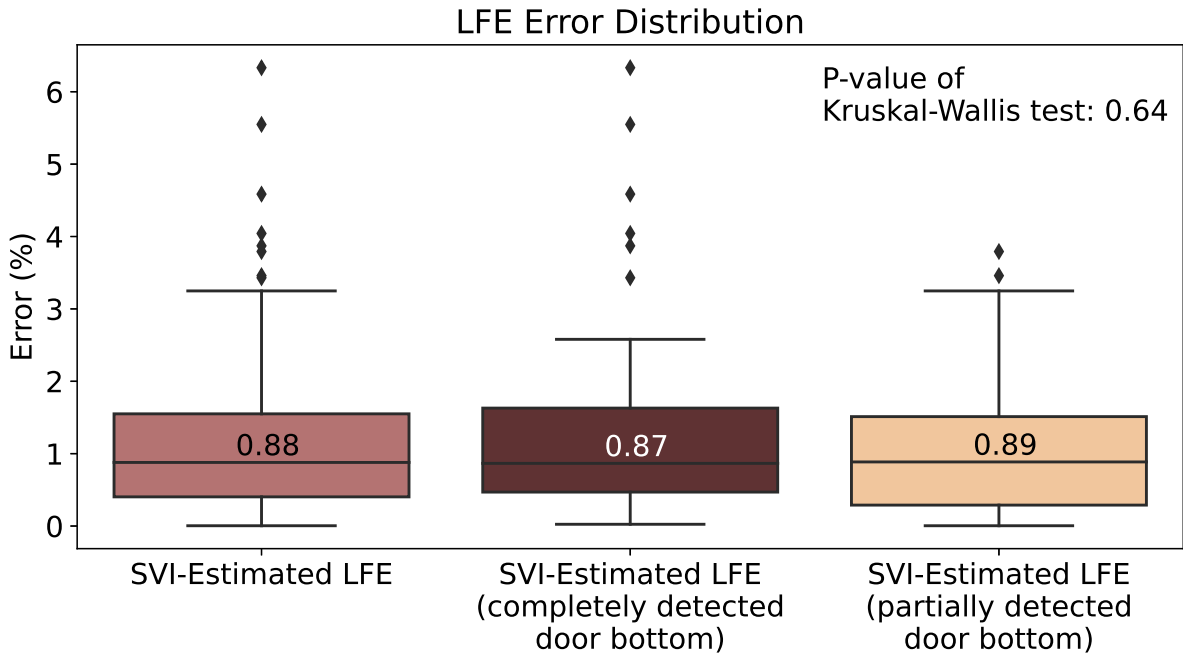

Figure 5: Lowest floor elevation error distribution. The error range of LFE of the completely detected door bottoms is narrower than that of the partially detected door bottoms, despite more outliers in completely detected door bottoms. The medians of error of the three subsets of SVI-estimated LFE show no significant difference. The p-value of a Kruskal-Wallis test among them is 0.64, greater than the significance level of 0.1. The result suggests that partial occlusion of the door bottom has no significant influence on our proposed LFE estimation algorithm. Regardless of whether if the door bottom is completely or partially visible, the algorithm performs well.

of their medians, as indicated by a Kruskal-Wallis test with a p-value of 0.64, which is greater than the significance level of 0.1. In other words, the LFE estimation pipeline developed in this study shows similar performance whether the door bottom is fully visible or not. The mean absolute error of SVI-estimated LFE is 0.190 m (1.18%).

To demonstrate the effectiveness of the Elev-Vision method, we provide examples of two adjacent houses with significantly different LFEs on Imogene Street, a flat street within the study area, in Figure 6, along with the corresponding LFE estimates obtained via SVI. Thus, the difference in their LFEs is due mainly to the height of their lowest floor. Specifically, the house in Figure 6a has a staircase in front of its front door, indicating that the lowest floor is significantly elevated, while the house in Figure 6b has a front door closer to the ground, indicating a lower LFE. The proposed method using SVI allows observation of this difference and effectively estimate the LFE for each building.

Figure 7 compares the SVI-estimated LFE with the drone-measured LFE, revealing that most outliers are underestimated cases. Specifically, when there are large errors, the SVI estimations tends to provide lower LFE values than the drone measurement. Since a lower LFE value is more likely to be evaluated as at-risk of flood damage, it is a more conservative result in the context of flood damage estimation. A possible reason of outliers is low resolution of depthmaps. The resolution of the depthmap is only 256 x 512 pixels, which may not be sufficient to distinguish the depth difference for objects at longer distance. It reveals that the resolution of depthmaps is critical for elevation estimation.

In addition to LFE, this study estimates HDSL to provide information regarding the risk of flood damage when juxtaposed with inundation depth information. Figure 8 shows the distribution of the estimated HDSL. The average HDSL in this study area is 1.074 m (3.524 ft), while the median of HDSL is 0.874 m (2.867 ft). In the study area, 70% of houses have HDSLs higher than 0.536 m (1.759 ft), indicating that they may avoid severe flood damage if the flood inundation depth is less than 0.536 m (1.759 ft). However, 7.30% of houses have an HDSL lower than 0.305 m (1 ft), indicating higher potential for damage during flood events.

Due to the unavailability of ground truth for roadside elevations, we selected three streets with SVIs obtained from several time periods to validate the accuracy of our roadside elevation estimates. Figure 9 shows the estimated roadside

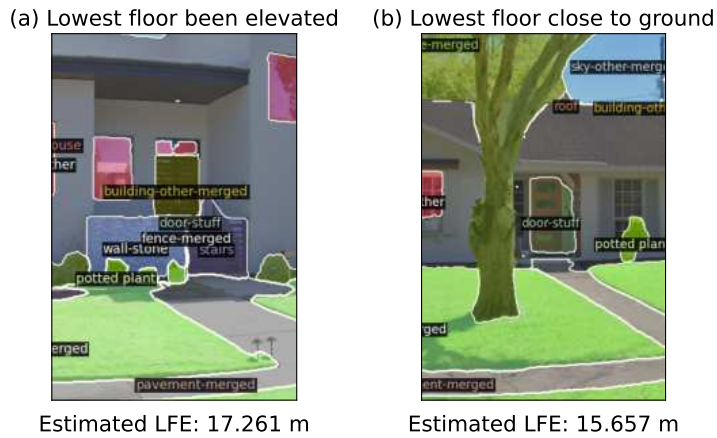

Figure 6: The examples of estimated LFEs for two adjacent houses. (a) The house with a staircase in front of its front door. (b) The house with a front door closer to the ground. The lowest floor of (a) are significantly elevated, resulting in a higher LFE. Conversely, the lowest floor of (b) is closer to the ground level, resulting in a lower LFE. The distinction between the two can be effectively captured by the proposed SVI method.

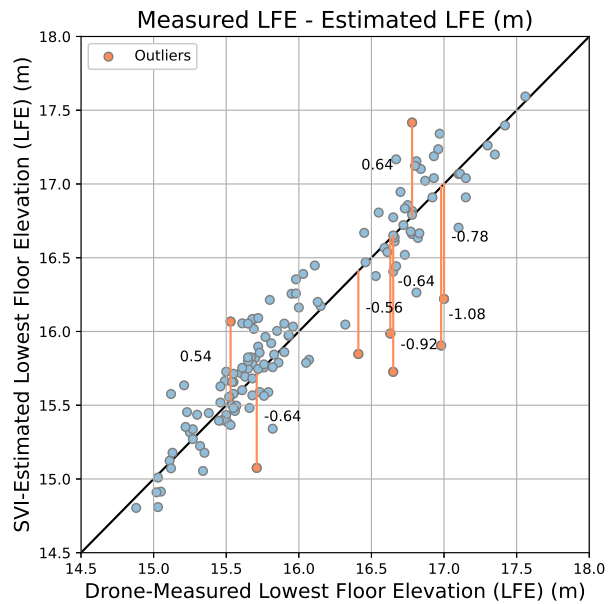

Figure 7: Scatter plot of SVI-estimated LFE by drone-measured LFE. Red scatters are the outliers, of which the error is greater than the upper quartile (Q_3) plus 1.5 times the interquartile range (IQR). The red line shows the difference between SVI-estimated LFE and drone-measured LFE of the outliers. Most of the outliers underestimate LFE compared to drone-measured value, which is conservative for the application to evaluate the risk of flood damage estimation because a lower LFE value is more likely to be evaluated as at the risk of flood damage.

Figure 8: Distribution of height difference between the street and the lowest floor (HDSL). The average HDSL in this research area is 1.074 m (3.524 ft) and the median of HDSL is 0.874 m (2.867 ft). 70% of the buildings in the study area have an HDSL greater than 0.536 m (1.759 ft). 7.30% of houses have an HDSL lower than 1 ft (0.305 m), indicating higher potential for damage during flood events.

elevations for each street. We conducted a pairwise T-test to analyze the estimated roadside elevations from the images captured in different time periods. The p-values of pairwise T-test for three streets are all greater than the significance level of 0.1, indicating no significant difference among the estimated roadside elevations in the same location across different time periods. In addition, the same examples of the two adjacent buildings with significant differences in first floor heights from Figure 6 illustrate SVI-estimated HDSLs (Figure 10). These sample results demonstrate the effectiveness and robustness of the proposed method in estimating HDSL, providing critical information to residents and decision-makers regarding the flood vulnerability of homes.

4 Closing Remarks

This paper presents the Elev-Vision method that integrates Google Street View images and computer vision techniques to estimate the lowest floor elevation (LFE) and the height difference between the street and the lowest floor. To the authors’ best knowledge, this work is the first LFE estimation method based on the application of image segmentation, which can provide precise object shapes from street view images. The proposed method achieves the mean absolute error of 19 cm (7.5 in) for LFEs compared to drone-based ground truth, outperforming the previous method (Ning et al., 2022) based on object detection and street view images, which had an error of 22 cm (8.7 in). The advantage of using image segmentation masks rather than object detection bounding boxes for door bottom detection is that image segmentation maintains good performance even with viewpoint variations and projection distortion. With the application of image segmentation, we were able to maximize the use of the rich information in street view panoramas without loss of information due to image reprojection, filling the gap in the previous LFE estimation method using object detection. In addition, our results suggest that partial occlusion of door bottom has no significant influence on the proposed LFE estimation method (p-value > 0.1). Compared to Ning et al. (2022)’s method treating the door height as the reference height with an assumed value to calculate the height difference between the camera and the door bottom, our proposed method calculates the height difference without any assumed value, reducing the errors from the assumption of reference height. Furthermore, with the advantage of image segmentation in providing masks for objects with any shape, roadsides are able to be identified and marked regardless of curvature and image distortions. Relying on the marked roadside, this study calculates another critical indicator, HDSL, to help mitigate severe flood damage, filling the gap in the extant literature in investigating HDSL and overcoming the limitation in the previous method based on object detection in estimating HDSL. With this indicator, property owners and emergency managers can develop appropriate plans based on the predicted flood inundation depths. The practical contribution of this work lies in providing an efficient and cost-effective approach for estimating lowest floor elevation. Traditional LFE sur-

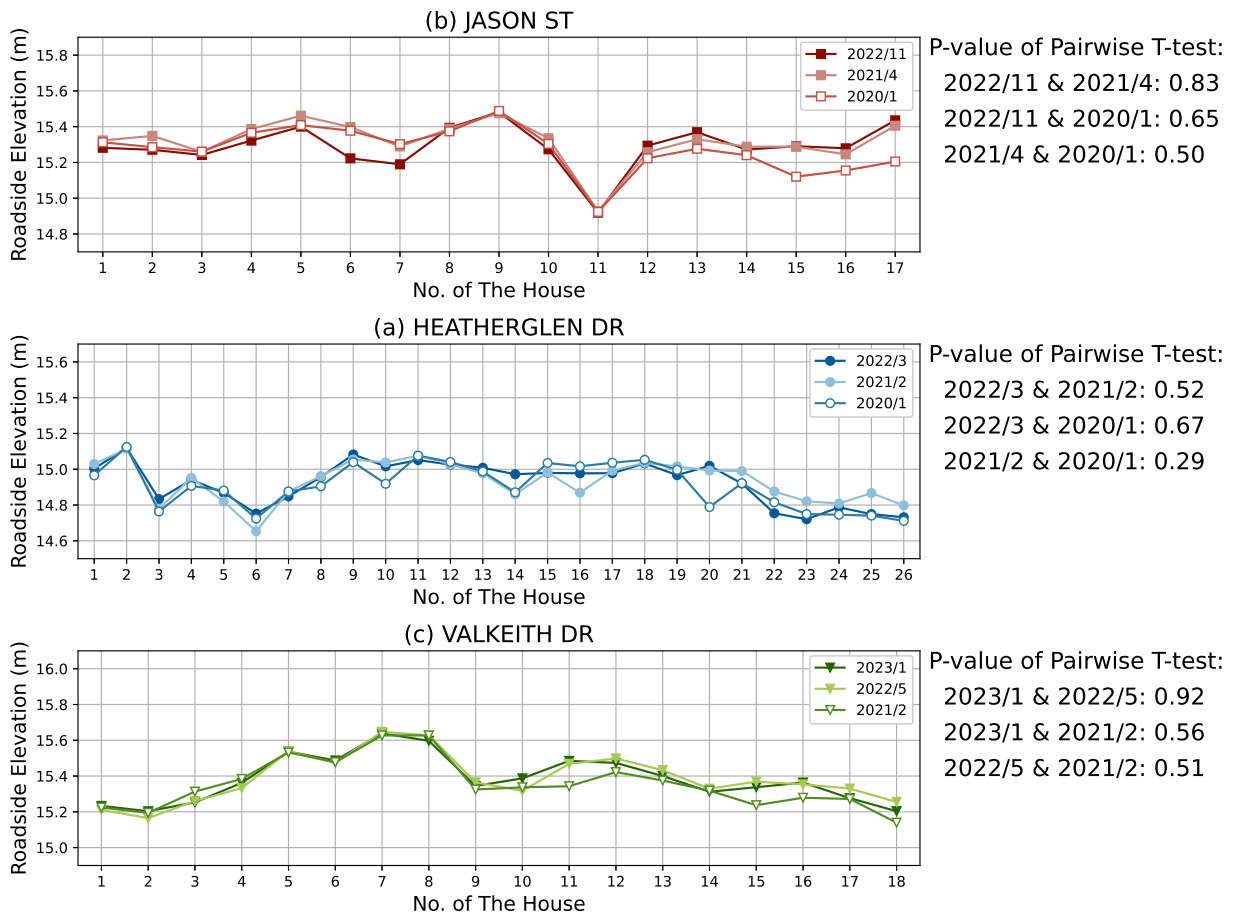

Figure 9: Estimated roadside elevations of three selected streets in three different time periods. Houses are numbered from east to west. The p-values of pairwise T-test for three streets are all greater than the significance level of 0.1, indicating no significant difference among the estimated roadside elevations in the same location across different time periods.

Figure 10: The examples of estimated HDSLs for two adjacent houses. (a) The house with a staircase at its front door. (b) The house with a front door closer to the ground. The LFE of house (a) is higher than the LFE of house (b), resulting in a higher HDSL, since their roadside elevations are similar. The distinction between the two can be effectively captured by the proposed SVI method.

veys employing a total station theodolite are time-consuming, labor-intensive, and costly, while the current measuring technology adopting drones has limitations in regulatory and professional training and it requires manual derivation of LFEs within photogrammetry software for each structure, both of which present hindrances for real-time or large-scale measurement. Moreover, to the best of our knowledge, the height difference between the street and the lowest floor has not been investigated in the extant literature. Our study fills this research gap and offers critical information for the accuracy improvement of LFEs and other flood risk evaluation at the individual structure scale.

It should be noted that there are two limitations in the proposed Elev-Vision method: the resolution of the depthmap and the visibility of the front door. Since the resolution of the depthmap is 256 x 512 pixels, while the vertical and horizontal fields of view are 180 degrees and 360 degrees, the depth difference within 0.7 degrees may not be captured, which is acceptable for close objects but problematic for distant objects. In other words, the applicable distance of the proposed method is limited. On the other hand, as we currently use the door bottom as the lowest floor, the proposed method can be applied only to the street view images in which the front door is visible. For houses whose front doors are hidden, features such as windows and stairs may be utilized as second features for LFE and HDSL estimation. The estimation algorithm, however, would become more complex since the uncertainty of these features' locations is much higher than that of the front door's location.

This work can be furthered in some aspects. Due to the current limitation in the quality of street view depthmaps, depth estimation methods can be applied to street view images to obtain the depthmaps with the same size as the input street view images. In addition, exploring the feasibility of the other building features can be the direction of future works. The proposed Elev-Vision method has many applications on vertical measurements besides LFE estimation. For example, this method can be applied to structure height estimation. It is beneficial to built environment evaluation research and urban canyon effect research. It can also be applied to sidewalk height estimation for sidewalk accessibility assessment research.

5 Data Availability

The data that support the findings of this study are available from Google Street View Data.

6 Code Availability

The code that supports the findings of this study is available from the corresponding author upon request.
