A STATISTICAL FRAMEWORK AND ANALYSIS FOR PERFECT RADAR PULSE COMPRESSION

NEIL K. CHADA, PETTERI PIIROINEN, AND LASSI ROININEN

ABSTRACT. Perfect radar pulse compression coding is a potential emerging field which aims at providing rigorous analysis and fundamental limit radar experiments. It is based on finding non-trivial pulse codes, which we can make statistically equivalent, to the radar experiments carried out with elementary pulses of some shape. A common engineering-based radar experiment design, regarding pulse-compression, often omits the rigorous theory and mathematical limitations. In this work our aim is to develop a mathematical theory which coincides with understanding the radar experiment in terms of the theory of comparison of statistical experiments. We review and generalize some properties of the Itô measure. We estimate the unknown i.e. the structure function in the context of Bayesian statistical inverse problems. We study the posterior for generalized *d*-dimensional inverse problems, where we consider both real-valued and complex-valued inputs for posteriori analysis. Finally this is then extended to the infinite dimensional setting, where our analysis suggests the underlying posterior is non-Gaussian.

1. INTRODUCTION

Developing mathematical theory of comparison of statistical measurements [30] is crucial for understanding fundamental limits of radar experiments [14, 15, 21, 31, 29]. In the specific field of radar coding, one is interested in studying modulation patterns of transmitted radar signals. We are interested in pulse compression coding of incoherent scatter radar experiments [19, 32], where coding schemes play a crucial role in achieving a high range resolution. Pulse codes are a common approach to modelling the underlying target function, which can be thought of as concentrated length pulses with constant amplitude and phase. General pulse codes of length L, which can be viewed as waveforms, can be expressed as

(1.1)
$$\epsilon(t) = \sum_{n=1}^{L} \int \phi_n \delta(t - nl - \tau) b(\tau, l) d\tau$$

where $\delta(\cdot)$ denotes a Dirac delta function and $b(\cdot)$ is a boxcar function. Pulses can be represented through its phase and amplitude, which has motivated various pulse codes. Arguably one of the most common example are binary phase codes which omit a constant amplitude and two phases $\phi \in \{-1, 1\}$. Other examples of codes include Barker codes [1] and alternating codes [1, 11, 17]. Usually these pulses are compressed in such a way, to allow for longer pulses which have low peak power, illustrated in Figure 1. The accuracy of the estimated target function, i.e. the scattering function as used in radar modelling, depends hugely on the pulse compression design. There is a rich literature on coding techniques, see e.g. [8, 9, 11, 14, 35], that discusses how to best optimize radar experiments with various compression

²⁰²⁰ Mathematics Subject Classification. 94A12, 86A22, 60G35, 62M99.

Key words and phrases. Pulse compression, radar experiments, statistical estimation, comparison of experiments.

techniques and assumptions. Given the complexity of these experiments it is important to understand, through a mathematical, and statistical, framework, how we can best formulate these experiments and gain an understanding from them.

Given the level of uncertainty that can arise within radar coding, a useful way to tackle these issues is through a statistical understanding. The work of Lehtinen [11] first considered this problem by modelling the scattering measurements within the signal as a statistical inverse problem [7, 33]. In other words we could characterize our signal through noisy measurements. With this work an important assumption was taken regarding the signal, which is that it is normally distributed. This assumption was made both for practical purposes but also that many signals omit a pulse form similar to a Gaussian density or kernel. Since this initial development there has been a number of papers looking to extend these results in a more rigorous fashion. Much of the current literature has considered a comparison of statistical measurements. This has lead to various pieces of work which have adapted ideas from Le Cam Theory, notably the work by Piiroinen et al. [13, 21, 26]. Other fundamental questions that have been considered in this context is how one can optimize the baud length of the radar. The baud length can be described as the time step which is used to discretize the radar signal. Numerically this was tested in the work of [12] which looked at the simple case for optimizing the baud length to minimise the posteriori variance. This was shown only in the context of specific targets.

FIGURE 1. Left: Long pulse with limited power. Right: Short pulse with more power through pulse compression.

Our motivation behind this work is to bridge the gap between the various communities in radar coding, namely by deriving a first simplified Bayesian statistical analysis for perfect radar pulse compression [25]. In particular we aim to build upon the current theory and develop a better understanding of statistical properties through characterizing a posterior distribution of the radar signal. The underlying mathematics of the posterior signal and its properties pose intriguing questions, such as whether itself is a Gaussian and its behavior, and understanding this for high and infinite dimensions. This question will act as the motivation behind this work.

1.1. **Contributions.** The following bulletpoints summarize the contributions of this work.

- To the best of our knowledge this is the first paper at deriving a statistical framework, and analysis, for the theory of perfect radar pulse compression. Our framework will be largely based on the notion and generalization of Itô measures to scattering functions.
- We aim to analyze perfect radar pulse compression in a Bayesian setting. This motivates studying and understanding statistical properties of our scattering function. We aim to form a posterior distribution of this scattering function. To aidm we first consider a *d*-dimensional case, where $d < \infty$. Related to this we also provide a result related to showing if two posterior

variances coincide, of two different signals. This will be considered for both real valued and complex valued values.

- To conclude our analysis we consider the *d*-dimensional setting, for $d = \infty$, where we show our underlying posterior is non-Gaussian which follows an inverse Wishart distribution. Here we use the notion of rapidly decreasing functions for our function spaces setting, to characterize the posterior.
- We discuss and review a number of key open questions which are still very much at the core of this field. These problems are motivated through both a mathematical and engineering perspective. Much of these questions follow on from the results obtained in this work.

1.2. **Outline.** Our work will be split into the following sections: we begin Section 2 with a review of radar signaling, and in particular pulse compression. Section 3 will be dedicated to understanding posterior distribution of the signal that is defined through the previous section, which highlights our main results. Appendix A and B will be devoted to the analysis of the *d*-dimensional and infinite-dimensional analysis, which ultimately shows the proof of our main theorem. Finally we review and discuss a number of questions still to be answered while concluding our findings, in Section 4.

2. RADAR CODING

In radar modelling commonly a signal of interest μ corresponds to a transmitted code, which can be defined as an uninterrupted sine wave multiplied with some envelope $\epsilon^q(t)$, by the following integral equation

(2.1)
$$z^{q}(t) = \int_{r \in \mathbb{R}^{3}} \epsilon^{q}(t - S(r)) \mu^{q}(d^{3}r) + \sqrt{T}\xi^{q}(t).$$

The notation S(r) denotes the total travel time of the signal from the transmission through to the scattering point r to the receiver. This implies that (2.1) sums up all elementary scatterings which takes into account the phase of the signal. The final term is related to thermal noise, where T denotes the temperature and $\xi(t) \sim \mathcal{N}(0, I)$ is complex additive Gaussian white noise. While (2.1) holds for a wide class of transmissive and receptive antennas in this work we consider a slightly different model. For simplicity we will assume that we have a mono-static single beam radar. To be more precise, if the back and forth signal time along the beam is denoted by r, then S(r) = r and we describe the signal model as a different integral equation

(2.2)
$$z^q(t) = \int_0^\infty \epsilon^q(t-r)\mu^q(dr) + \sqrt{T}\xi^q(t).$$

We can rewrite (2.2) as the formal equation

$$\langle \mu(dr), \overline{\mu(dr')} \rangle = X(r)\varphi(r-r')drdr',$$

where X(r) is known as the structure function or simply the target density and its corresponding covariance can be explicitly determined as

$$\langle \mu(dr), \overline{\mu(dr')} \rangle = \int_{r \ge 0} \int_{r' \ge 0} \epsilon^q (t-r) \overline{\epsilon^q(t'-r)} + T\varphi(t-t')$$

=
$$\int X(r) \epsilon^q (t-r) \overline{\epsilon^q(t'-r)} + T\varphi(t-t')$$

=
$$\int A_{tt'} X(r) dr + T\varphi(t-t'),$$

where $A_{tt'} = \epsilon^q (t-r) \overline{\epsilon^q (t'-r)}$. Both (2.1) and (2.2) assume that we have a time-incoherent signal, whereas in the case if the signal was time dependent our signal would be modified to

(2.3)
$$z^{q}(t) = \int_{0}^{\infty} \epsilon^{q}(t-r)\mu^{q}(dr;t) + \sqrt{T}\xi^{q}(t),$$

so that now t can be treated as either the scattering time or the reception time. However as already stated our focus will be on analyzing signals which are timeincoherent. Our quantity of interest in this model is the signal denoted by $\mu(\cdot)$. In radar signaling this unknown we are aiming to estimate is known as an incoherent scattering target. A fundamental question that arises is how to best estimate or model the underlying signal? In order to answer this question, below we provide some useful definitions to give understanding to quantities, and concepts, in pulse compression.

We will introduce specific way of modeling the signal, which we refer to as an Itô measure. Throughout we will assume that our unknown takes the form of a Gaussian distribution.

Definition 2.1. Assume we have two measurements defined as

(2.4)
$$(m_1^q)_{q=1}^{N_q} = \epsilon_1 * (S(\sigma)^q)_{q=1}^{N_q} + (\xi_1^q)_{q=1}^{N_q},$$

(2.5)
$$(m_2^q)_{q=1}^{N_q} = \epsilon_2 * (S(\sigma)^q)_{q=1}^{N_q} + (\xi_2^q)_{q=1}^{N_q},$$

where $\xi_1 \sim \xi_2$ are of a complex Gaussian form, ϵ is a transmitted waveform and $S(\sigma)$ is the scattering function such that $S(\sigma) \sim \mathcal{N}(0, \sigma)$.

We now provide some definitions related to the notion of an Itô measure, which represents our signal, as within mathematics. A physical interpretation is that is it the spatially incoherent scatter.

Definition 2.2. Let \mathcal{B}_0 be the Borel field of $\mathcal{D} \subset \mathbb{R}^n$ a random set function $\mu : \mathcal{B}_0 \to L^2(\Omega, \mathcal{F}, \mathbb{P})$ is called an Itô measure on \mathcal{D} with a structure measure X if

- 1. X is a σ -finite Borel measure on \mathcal{D} .
- 2. $\mu(\emptyset) = 0.$
- 3. For all pairwise disjoint sets $B_k \in \mathcal{B}_0$ it holds that

$$\mu\big(\cup_{k=1}^{\infty} B_k\big) = \sum_{k=1}^{\infty} \mu(B_k).$$

4. $\mathbb{E}[\mu(B_1)\overline{\mu(B_2)}] = X(B_1 \cap B_2).$

Definition 2.3. An Itô measure $\mu(\cdot)$ is a signal with the following satisfying properties:

- 1. Complexity: $\mu(\cdot) \in \mathbb{C}$ given the phase and amplitude of the signal.
- 2. Additivity: $\mu(B_1 \cup B_2) = \mu(B_1) + \mu(B_2)$, if $B_1 \cap B_2 = \emptyset$.
- 3. Gaussian: the measure is taken as a mean zero Gaussian measure with covariance structure C i.e. $\mu \sim \mathcal{N}(0, C)$.
- 4. Incoherence: $\mathbb{E}[\mu(B_1)\overline{\mu(B_2)}] = X(B_1 \cap B_2) = 0$ if $B_1 \cap B_2 = \emptyset$.

Definition 2.4. Given a transmitted waveform of the form

(2.6)
$$\epsilon(t) = \sum_{j} \epsilon_{j} \phi(t - j \Delta t),$$

such that $e_j \in \mathbb{C}$ with the index $j \in \mathbb{Z}$. Δt is known as the baud length and ϕ is the pulse form. We can define it corresponding Fourier transformation as

(2.7)
$$\hat{\epsilon}^q(t) = \int \epsilon(s) \exp(ist) dt.$$

Our final definition is related to the scattering function.

Definition 2.5. We say the scattering function $S(\sigma)$, or its structure σ , are a set of admissible priors if satisfies the conditions

- 1. The state space of the random variable $S(u) = S(\omega, u)$ is $L^1(\mathbb{R}^N)$ for every $u \in \mathcal{U}$ where \mathcal{U} is the state space of the structure σ .
- 2. The mapping $S(\sigma)(\omega) = S(\omega, \sigma(\omega))$ is a random variable.

3. Posterior analysis

In this section we provide a statistical analysis on signals arising from perfect radar pulse compression. In particular the focus will be on understanding the posterior distribution of σ , when we assume a fully Gaussian system, related to the prior and noise level. The derived analysis will form a basis for the higher and infinite dimensional setting, in succeeding sections.

All the definitions what is meant by densities and conditioning of the generalised random variables are reviewed in the Appendix. By the posterior distribution we mean the regular conditional distribution of the generalised random variable given the data random variable, and when it possesses a density we will refer to its density. Specifically the characteristic functions are defined in Appendix A.1, and densities are defined in Appendix A.2.

We now present our main theorem of the paper, which is the characterization of the posterior variance, related to the scattering function. This is given through the follow result, whose proof is divided up into multiple results used in the Appendix.

Theorem 3.1. Assume the priori distribution of $|\sigma|^2$ is interpretable as an affine transform of inverse Wishart distribution, then the posteriori distribution of $|\sigma|^2$ is a generalized limit of affine transforms of inverse Wishart distributions of the similar type.

The above result in Theorem 3.1 highlights that the underlying posterior is not Gaussian, with the assumption that the prior is. The proof follows the results obtained from Appendix B, which is extended from the analysis conducted in Appendix A.

For the infinite dimensional setting the underlying spaces are taken to be the rapidly decreasing functions, or Schwartz functions. These are defined by $\mathscr{S}(\mathcal{C}^n)$ (or the compactly supported test functions $\mathscr{D}(\Omega)$) and their dual spaces $\mathscr{S}'(\mathcal{C}^n)$ of tempered distributions (or the distributions $\mathscr{D}'(\Omega)$).

Our next main result, is related to characterizing a relationship between two signals in relation to their posterior variance of the scattering function. This is provided through the following theorem.

Theorem 3.2. Suppose the prior covariance structure $X(\sigma)$ is a complex Gaussian¹ with constant $|\sigma|^2 > 0$. If the moduli of the Fourier transforms of the transmitted waveforms coincide, i.e. if

 $|\widehat{\epsilon}_1| = |\widehat{\epsilon}_2|,$

¹see Appendix A

as Schwartz distributions², then the posterior variances $var(|\sigma|^2 | m_1)$ and $var(|\sigma|^2 | m_2)$ of the σ given m_1 and m_2 are equal, i.e.

$$\operatorname{rar}(|\sigma|^2 | m_1) = \operatorname{var}(|\sigma|^2 | m_2)$$

Proof. We show in Appendix A that if the covariance structure corresponds to a constant multiplier, then

$$\operatorname{var}(m_j \mid \mid \sigma \mid^2) = \phi \mapsto \mid \phi \mid^2 \left(\mid \sigma \mid^2 \mid A_j \mid^2 + T \right),$$

where $|A_j|^2 = |\hat{\epsilon}_j|^2$. Using the assumption of equal moduli of Fourier transforms of the transmitted waveforms, we see that

$$\operatorname{var}(m_1 | |\sigma|^2) = \operatorname{var}(m_2 | |\sigma|^2),$$

and therefore by the results of Appendix A, we obtain that this implies that the conditional characteristic functions

$$J_{m_1 \, | \, | \, \sigma \, |^2} = J_{m_2 \, | \, | \, \sigma \, |^2},$$

as generalized functions. Since the prior was constant, we obtain that the conditional densities of $|\sigma|^2$ given m_1 and m_2 are both following the same inverse Wishart distribution under the same spatial discretisation. Therefore, they have the same discretisation limits and hence also their posterior variances coincide. \Box

4. CONCLUSION & DISCUSSION

Pulse compression has been a cornerstone of modern applied mathematics incorporating tools from information theory, Fourier analysis and harmonic analysis. Recently statistical methodologies have gained interest most notably for enabling some form of uncertainty quantification. This papers motivation is exactly in this where our aim is to understand perfect pulse compression through a statistical framework. What we showed was that, through the introduction of Itô measures where we assume our signal is distributed according to a Gaussian, we were able to characterize a posterior distribution of the signal σ . As our results suggest, the resulting posterior is indeed non-Gaussian specifically an inverse Wishart distirbution. This was achieved through analysis in both a finite-dimensional setting and infinite-dimensions, where we introduced Gaussian measures and the concept of Schwartz functions for our function-space setting.

As this is the first instance in understanding perfect radar pulse compression in a statistical manner, there are numerous directions to take for future work. One direction to consider is to understand the relationship between different pulses. To do so one can consider using various probabilistic metrics for Gaussian measures. A natural one to consider is the Kullback-Liebler divergence which has been analyzed in infinite dimensions [22, 23, 34]. However given how this is not an actual metric per say one could consider extensions to the Wasserstein distance and also the Le Cam distance [3], which has been used for statistical experiments.

Another more applied direction is to consider a better way to model the pulses as usually they take the form of box-car functions or piecewise constant functions, where imposing Gaussian [18] modeling assumptions can hinder performance. Recent work has shown that α -stable processes [5] can be used in place which can be used for edge-preserving inversion. This would imply the prior random field has the particular form

$$U(x) = \int_{[0,1]^d} f(x, x') M(dx'), \ x \in [0,1]^d,$$

²in most cases just as function pointwise for almost every point

where

$$f(x, x') = \begin{cases} 1 \text{ when } x'_i \leq x_i \text{ for all } i = 1, \dots, d \\ 0 \text{ otherwise,} \end{cases}$$

and M is symmetric α -stable random measure. An example of a non-Gaussian α -stable process are Cauchy processes [4, 16, 24, 27, 28] which have already been tested within inverse problems. This could be a natural direction for using more advanced non-Gaussian priors.

More specific to the pulse compression an important question to quantify, is the relationship of the pulses and the temperature T. Specifically what occurs in the limit $T \to 0$. For the case of T = 0 let us assume the code is modeled as a boxcar of width a > 0 and unit L^2 norm

$$\epsilon(t) = \epsilon_a(t) = a^{-1/2} \chi_{[0,a)}(t)$$

Then choosing a = 1/2N results in the following expression for the signal

$$z^{q}(n/N+t) = \int_{0}^{1} \epsilon_{1/2N}(n/N+t - r(\text{mod } 1)) \,\mu^{q}(dr) + \sqrt{T}\xi^{q}$$

with $0 \le t < 1/2N$ and $n = 0 \dots N - 1$,

are all mutually independent and equally informative measurements of σ , each separately adding the same amount of information to σ , independent of N. It follows that the posteriori variance of σ approaches 0, when $N \longrightarrow \infty$. This is in contradiction with a rather common engineer understanding saying that increasing radar power (equivalent to decreasing additional noise) will give no extra benefit after some level is reached. One will naturally benefit by choosing increasingly narrow pulses as extra power becomes available.

However for the case of T > 0, where T is close to 0, what is explained above it seems plausible that the optimal radar code might be a narrow pulse. If true then the width would approach 0 as $T \longrightarrow 0$.

Conjecture 4.1. For each T it is possible to find an optimal code $\epsilon_T(t)$ so that

$$\lim_{T \longrightarrow 0} \sqrt{T} \epsilon_T(t/T),$$

defines a well-defined limiting shape: a fundamental typical shape of optimal radar baud.

Related to this a final direction to consider is to quantify whether the optimal code, discussed in the above conjecture is unique or not. This of course could be related to how one defined the prior form, or the scattering function. These and other directions will be considered for future work.

APPENDIX A. FINITE DIMENSIONAL ANALYSIS

In this appendix we consider a generalized setting, which is the *d*-dimensional case. For our analysis we will consider four separate cases namely; (i) real valued Gaussian random vector, (ii) complex valued Gaussian random vector, (iii) real valued white noise and (iv) complex valued white noise. In order to do so we recall a number of key definitions which we will use for our analysis. Our analysis will be based on the notion of computing means and covariances through moment generating functions.

Definition A.1. (Gaussian random vector) Assume $X := (X_1, \ldots, X_n)$ is a real finite dimensional random vector. We say X is a Gaussian random vector if it can be expressed in the form

$$X = \mu + AY,$$

where $\mu \in \mathbb{R}^n$, $A \in \mathbb{R}^{n \times k}$ and $Y = (Y_1, \ldots, Y_k)$ is a vector of independent standard Gaussian random variables. Such a vector Y is called standard multinormal random vector or discrete real white noise vector.

Definition A.2. (Complex Gaussian random vector) Assume $X = (X_1, \ldots, X_n)$ is a complex finite dimensional random vector. We say X is a complex Gaussian random vector if it can be expressed in the form

$$X = \mu + AY,$$

where $\mu \in \mathbb{R}^n$, $A \in \mathbb{C}^{n \times k}$ and $Y = (Y_1, \ldots, Y_k)$ is a discrete complex white noise vector. We say a complex random vector $Y = Y_R + iI_I \in \mathbb{C}^k$ is a discrete complex white noise, if $(Y_R, Y_I)/\sqrt{2}$ is a discrete 2k-dimensional real white noise.

Let us list some properties that hold for complex and real Gaussian vector.

Proposition A.3. Assume that $X \in \mathbb{K}^k$ is a k-dimensional complex ($\mathbb{K} = \mathbb{C}$) or real ($\mathbb{K} = \mathbb{R}$) Gaussian random vector. Suppose $A \in \mathbb{K}^{n \times k}$ and $\mu \in \mathbb{K}^n$. Then $Z = \mu + AX$ is a \mathbb{K} -Gaussian random vector with \mathbb{K} -expectation

$$\mathbb{E}(Z) = \mu + \mathbb{E}(X),$$

and its \mathbb{K} -covariance matrix is

$$\operatorname{Cov}(Z) = A\operatorname{Cov}(X)A',$$

where $A' = A^{\top}$, when $\mathbb{K} = \mathbb{R}$ and $A' = \overline{A}^{\top}$, when $\mathbb{K} = \mathbb{C}$

Proof. The expectation of Z is defined as a mapping $\phi \mapsto \mathbb{E}(Z'\phi)$. Since $X = \lambda + BY$ for some K-Gaussian random vector, we have

$$Z'\phi = \mu'\phi + (A\lambda)'\phi + Y'B'A'\phi.$$

Since the expectation of Y is a zero mapping, we see that

$$\mathbb{E}(Z) = \mu + (A\lambda),$$

where μ is identified with the mapping $\phi \mapsto \mu' \phi$. When $\mu = 0$ and A is identity, this gives also that

$$\mathbb{E}(X) = \lambda_{1}$$

so the first claim follows.

The K-covariance of Z is defined as a the covariance of $W = Z - \mathbb{E}(Z) = ABY$ which is in turn the mapping

$$\phi \mapsto \mathbb{E}(W'\phi)'(W'\phi) = \mathbb{E}(\phi'WW'\phi).$$

Since

$$W'\phi = Y'(AB)'\phi$$

we have

$$(W'\phi)'(W'\phi) = \phi'ABYY'B'A'\phi$$

This implies since the covariance of Y is an \mathbb{K} -identity operator, that

$$\operatorname{Cov}(Z) = AB\operatorname{Cov}(Y)B'A' = ABB'A'.$$

Again, when A is an identity, this gives that the covariance of X is BB' so the latter claim follows.

Remark A.4. Note that this proof generalizes immediately to infinite dimensional setting, as we will see in the succeeding section. The reason that the covariance of Y is an identity in both real and complex case is the following.

When $\mathbb{K} = \mathbb{R}$ this is well-known, however for $\mathbb{K} = \mathbb{C}$ we can argue as follows. For any complex vector z then z'z is real-valued and its real part is $z_R^{\top} z_R + z_I^{\top} z_I$, where R denotes real and I denotes imaginary. Now let X and Z be the real and imaginary part of $Y'\phi$.

$$X = (Y'\phi)_R = ((Y_R + iY_I)'(\phi_R + i\phi_I))_R = Y_R^{\top}\phi_R + Y_I^{\top}\phi_I,$$

$$Z = (Y'\phi)_I = ((Y_R + iY_I)'(\phi_R + i\phi_I))_I = Y_R^{\top}\phi_I + Y_I^{\top}\phi_R,$$

so both are \mathbb{R} -linear transformations of real Gaussian random vector (Y_R, Y_I) . Therefore, the expectation of (X, Z) is $\mathbb{E}[(X, Z)] = 0$ and the variance of X is

$$\operatorname{var}(X) = B\operatorname{Cov}((Y_R, Y_I))B^{\top} = \frac{1}{2}BB^{\top},$$

where the matrix B is

$$B = \begin{pmatrix} \phi_R^\top & \phi_I^\top \end{pmatrix},$$

therefore we have $\operatorname{var}(X) = \frac{1}{2}\phi'\phi$. We can similarly verify, that $\operatorname{var}(Z) = \frac{1}{2}\phi'\phi$. Since $\mathbb{E}(Y'\phi)'(Y'\phi) = \operatorname{var}(X) + \operatorname{var}(Z) = \phi'\phi$, we see that the covariance of Y is complex identity. We used the real version to make the calculation easier.

A.1. Characteristic functions. Since the complex Gaussian random vectors is defined as an affine transformations of complex Gaussian white noise and the k-dimensional complex Gaussian white noise is isomorphic with scaled 2k-dimensional real white noise, we can define the characteristic function via the following idea.

If Y is a discrete k-dimensional complex white noise, then $\tilde{Y} = (Y_R, Y_I)/\sqrt{2}$ is discrete 2k-dimensional real white noise and its characteristic function is

$$J_{\widetilde{Y}}(\widetilde{\phi}) = \mathbb{E}\exp(i(\widetilde{\phi}^{\top}\widetilde{Y})) = \mathbb{E}\exp(i(\phi_R^{\top}Y_R + \phi_I^{\top}Y_I)/\sqrt{2}) = \mathbb{E}\exp(i\operatorname{Re}(Y'\phi)),$$

where again $\operatorname{Re}(\cdot)$, denotes the real component.

Definition A.5. (Characteristic function of complex Gaussian random vector) Assume $X := (X_1, \ldots, X_n)$ is a complex finite dimensional random vector. The function

$$J_X(\phi) = \mathbb{E} \exp(i \operatorname{Re}(X'\phi))_{i}$$

where $\phi \in \mathbb{C}^n$ is the characteristic function of complex Gaussian random vector.

Note that via isomorphicity, the characteristic function fully determines the distribution [2].

Proposition A.6. The characteristic function of discrete k-dimensional complex white noise Y is

$$J_Y(\phi) = \exp(-\frac{1}{4}\phi'\phi), = \exp(-\frac{1}{4}|\phi|^2),$$

where
$$|\phi|^2 = \phi'\phi = |\phi_1|^2 + \dots + |\phi_k|^2$$

Proof. This follows with a straightforward computation. The \mathbb{C} -covariance $\operatorname{Cov}(Y)$ of $Y = Y_R + iY_I$ is by definition $\frac{1}{2}I_{\mathbb{C}}$, so Y_R and Y_I are independent and $\operatorname{Cov}(Y_R) = \operatorname{Cov}(Y_I) = \frac{1}{2}I_{\mathbb{R}}$. Therefore

$$J_Y(\phi) = \mathbb{E} \exp(iY_R^\top \phi_R) \mathbb{E} \exp(iY_I^\top \phi_I) = \exp(-\frac{1}{4}\phi_R^\top \phi_R) \exp(-\frac{1}{4}\phi_I^\top \phi_I)$$
$$= \exp(-\frac{1}{4}|\phi|^2).$$

Proposition A.7. The characteristic function of $X = AY + \mu$, where Y is kdimensional complex white noise, $A \in \mathbb{C}^{n \times k}$ and $\mu \in \mathbb{C}^n$ is

$$J_X(\phi) = \exp(i \operatorname{Re}(\mu' \phi) - \frac{1}{4} \phi' \Sigma \phi),$$

where $\Sigma = AA'$ is an self-adjoint matrix in $\mathbb{C}^{n \times n}$.

Proof. Since $i \operatorname{Re}(X'\phi) = i \operatorname{Re}(\mu'\phi) + i \operatorname{Re}((AY)'\phi)$, we may assume that $\mu = 0$ without a restriction. Since $(AY)'\phi = Y'A'\phi = Y'\psi$, where $\phi = A'\phi$, the previous proposition gives that

$$J_X(\phi) = J_Y(\psi) = \exp(-\frac{1}{4}\psi'\psi) = \exp(-\frac{1}{4}(A'\phi)'A\phi) = \exp(-\frac{1}{4}\phi'\Sigma\phi),$$

which proves the claim.

Corollary A.8. The characteristic function of a complex Gaussian vector X is

$$J_X(\phi) = \exp(i\operatorname{Re}(\mathbb{E}(X)'\phi) - \frac{1}{2}\phi'\operatorname{Cov}(X)\phi),$$

and the expectation and the complex covariance fully determine the distribution.

Proof. This follows from previous results and the fact that $Cov(Y) = \frac{1}{2}I$ for the complex white noise.

A.2. Densities for complex Gaussian vectors. By stating the density of the complex Gaussian vector X we mean the non-negative function $f \ge 0$ such that

$$\mathbb{P}(X \in A) = \int_{\mathbb{C}^n} [x \in A] f(x) \, \mathrm{d}x,$$

where the integral is understood as a Lebesgue (volume) integral on \mathbb{R}^{2n} . Note that not every complex Gaussian vector has a density in this sense. However, every non-zero complex Gaussian vector has a \mathbb{C} -affine subspace (potentially of lower dimension) of \mathcal{C}^n such that the distribution is supported on this subspace and relative to that the subspace it has a density. The complex white noise itself has a density in this sense.

In order to extend this to other complex Gaussian vectors, we first consider the orthogonal and unitary transformations. These are given through the following propositions.

Proposition A.9. The density function of discrete k-dimensional complex white noise Y is

$$f_Y(z) = \pi^{-n} \exp(-z'z) = \pi^{-n} \exp(-|z|^2),$$

for every $z \in \mathbb{C}^k$.

Proof. Since Y is isomorphic to \mathbb{R}^{2k} -dimensional scaled white noise (Y_R, Y_I) and the latter has a density on \mathbb{R}^{2k} since it is a vector of 2k independent Gaussian random variables with zero mean and $\frac{1}{2}$ variance. Therefore

$$f_{(Y_R,Y_I)}(z_R,z_I) = \prod_{j=1}^n (2\pi(1/2))^{-\frac{1}{2}} (2\pi(1/2))^{-\frac{1}{2}} \exp\left(-\frac{(z_R)_j^2 + (z_I)_j^2}{2 \cdot (\frac{1}{2})}\right)$$
$$= \pi^{-n} \exp(-(z_R^\top z_R + z_I^\top z_I))$$
$$= \pi^{-n} \exp(-z'z).$$

Proposition A.10. Suppose $U \in \mathbb{C}^{k \times k}$ is a unitary and Y is a k-dimensional Gaussian random vector with density. Then X = UY also has density and its density is given by

$$f_X(z) = f_Y(U'z),$$

for every $z \in \mathbb{C}^k$.

Proof. This follows from the isomorphicity and the general transformation rule, since U' is the inverse matrix of U and the Jacobian determinant of the isomorphich copy of U' is identically one, since

$$\mathcal{J}_{\mathbb{C}}(U') = \det \begin{pmatrix} U_R & -U_I \\ U_I & U_R \end{pmatrix} = \det (U_R^\top U_R + U_I^\top U_I) = \det ((U'U)_R) = 1.$$

Proposition A.11. Suppose $U \in \mathbb{C}^{k \times k}$ is a diagonal matrix $U = \text{diag}(\lambda_1, \ldots, \lambda_k)$ and Y is discrete k-dimensional complex white noise Y. Then X = UY has a density if and only if the determinant $D = \lambda_1 \ldots \lambda_k \neq 0$. In this case it is given by

$$f_X(z) = |D|^{-1} f_Y(U^{-1}z),$$

for every $z \in \mathbb{C}^k$.

Proof. Let us first assume $D \neq 0$. In this case $X_j = \lambda_j Y_j$ for each $j = 1, \ldots, k$. Moreover, the random variables X_1, \ldots, X_k are independent. This implies that each X_j has a density function and the joint density is the product of the densities.

Each $Y_j = \lambda_j^{-1} X_j$ which is isomorphic to 2-dimensional real linear transformation: therefore,

$$f_{X_j}(z_j) = \sqrt{|\lambda_j^{-1}|^2} f_{Y_j}(z_j/\lambda_j) = |\lambda_j|^{-1} f_{Y_j}(z_j/\lambda_j).$$

The isomorphicity is inside the first identity, since the Jacobian determinant is

$$\det \begin{pmatrix} (\lambda_j^{-1})_R & -(\lambda_j^{-1})_I \\ (\lambda_j^{-1})_I & (\lambda_j^{-1})_R \end{pmatrix}^{1/2} = |\lambda_j^{-1}|^2,$$

The claim follows by taking the products.

If D = 0, then at least one the λ_j 's is zero. Without a loss of generality, we can for simplicity assume that $\lambda_1 = 0$. Then $Y = (0, Y_2, \ldots, Y_k)$ and hence Y is supported on a hypersurface of at most k - 1 complex dimensions. This already implies that the density cannot exist.

Proposition A.12. Suppose $A \in \mathbb{C}^{n \times n}$ is a matrix, Y is discrete n-dimensional complex white noise Y and $\mu \in \mathbb{C}^n$. The complex Gaussian vector $X = AY + \mu$ has a density if and only if A is invertible. When A is invertible, it is given by

$$f_X(z) = \pi^{-n} |\det(B)|^{-1/2} \exp(-(z-\mu)' B^{-1} (z-\mu)),$$

for every $z \in \mathbb{C}^n$, where B = AA'.

Proof. Without a restriction, we can assume $\mu = 0$. The matrix B is self-adjoint, since B' = (AA')' = AA' = B, so it has a spectral decomposition $B = U\Lambda U'$ and a self-adjoint square root $\sqrt{B} := U\sqrt{\Lambda}U'$, i.e. $(\sqrt{B})' = \sqrt{B}$ and $(\sqrt{B})^2 = B$. Note that det $(\Lambda) = \det A$ so the invertibility encoded into the diagonal matrix.

Let $Z = \sqrt{BY}$. The characteristic function of Z is

$$J_Z(\phi) = \exp(-\frac{1}{4}\phi'\sqrt{B}(\sqrt{B})'\phi)$$

= $\exp(-\frac{1}{4}\phi'B\phi) = \exp(-\frac{1}{4}\phi'AA'\phi)$
= $J_X(\phi),$

so Z and X are identically distributed. Therefore, X has a density exactly when Z has a density and in that case $f_X = f_Z$. Moreover, since $Z = U\sqrt{\Lambda}U'Y$, we moreover see that Z and $U\sqrt{\Lambda}Y$ are identically distributed. This shows that

$$f_{\sqrt{\Lambda}Y}(z) = \pi^{-n} |D|^{-1} \exp(-(\sqrt{\Lambda}^{-1}z)'(\sqrt{\Lambda}^{-1}z)) = \pi^{-n} |D|^{-1} \exp(-(z'\Lambda^{-1}z)),$$

where $D = \det(B)$ and thus

$$f_Z(z) = \pi^{-n} |D|^{-1} \exp(-((U'z)'\Lambda^{-1}U'z)) = \pi^{-n} |D|^{-1} \exp(-(z'B^{-1}z)),$$

which proves the claim.

Now one can write the previous result directly with the general transformation rule, but then the calculation of the determinant is more involved since we cannot use the independence.

Corollary A.13. If the covariance of a complex Gaussian n-dimensional vector X is invertible, then X has a density which is given by

$$f_X(z) = (2\pi)^{-n} \left(\det(\operatorname{Cov}(X)) \right)^{-1/2} \exp\left(-\frac{1}{2}(z - \mathbb{E}(X))' \operatorname{Cov}(X)^{-1}(z - \mathbb{E}(X))\right),$$

for every $z \in \mathcal{C}^n$.

Proof. When X is discrete n-dimensional complex white noise, the $\text{Cov}(X) = I_{\mathbb{C}}/2$, so $(\det(\text{Cov}(X)))^{-1/2} = 2^n$ and therefore

$$\pi^{-n} = (2\pi)^{-n} (\det(\operatorname{Cov}(X)))^{-1/2},$$

and

$$\exp(-z'z) = \exp(-\frac{1}{2}z'\operatorname{Cov}(X)^{-1}z),$$

so the claim holds for the discrete complex white noise. The remaining case follows from the previous proposition. $\hfill \Box$

APPENDIX B. INFINITE-DIMENSIONAL ANALYSIS

In this Appendix we extend the results of the previous section towards the infinite dimensional case, where the underlying spaces are taken to be the rapidly decreasing functions $\mathscr{S}(\mathcal{C}^n)$ (or the compactly supported test functions $\mathscr{D}(\Omega)$) and their dual spaces $\mathscr{S}'(\mathcal{C}^n)$ of tempered distributions (or the distributions $\mathscr{D}'(\Omega)$). In particular these can be done on the spaces of linear operators $L(\mathscr{S}(\mathcal{C}^n), \mathscr{S}'(\mathcal{C}^n))$ between the dual spaces. For the time being we will denote these as $\mathcal{X}_{\mathbb{C}}$ and $\mathcal{X}'_{\mathbb{C}}$ only to indicate that these are \mathcal{C} -linear vector spaces with regularity in the topology, such that we can rigorously define the concepts. In particular this appendix concludes the result of Theorem 3.1.

By defining a Gaussian random object on $\mathcal{X}_{\mathbb{C}}$ as generalized Gaussian random variable $X : (\Omega, \mathscr{F}, \mathbb{P}) \to (\mathcal{X}'_{\mathbb{C}}, \mathscr{B}(\mathcal{X}'_{\mathbb{C}})$ via

$$\omega \mapsto (\phi \mapsto \langle \phi, X(\omega) \rangle_{\mathcal{X}_{\mathbb{C}} \times \mathcal{X}'_{\mathbb{C}}}).$$

We will drop the spaces from the dual action for simplicity. We define the complex Gaussian noise as Y on the underlying structure as such that for every finite collection of "test functions" ϕ_1, \ldots, ϕ_n the random object

$$Z := (\langle \phi_1, \overline{Y} \rangle, \dots, \langle \phi_n, \overline{Y} \rangle),$$

is a complex Gaussian vector $n \mathbb{C}$ -dimensions. Moreover, the \mathbb{C} -expectation $\mathbb{E}(Z)$ of Z is (isomorphic) to zero vector and Cov(Z) is isomorphic to a $\mathbb{C}^{n \times n}$ -matrix

$$\left(\frac{1}{2}\langle \phi_j, \overline{\iota\phi_i} \rangle\right)_{i,j}$$

where $\iota: \mathcal{X} \to \mathcal{X}'$ is the natural embedding of the "test function" space into its dual space. In order to proceed we first need to "mimic" the definitions, but in infinite dimensions.

Definition B.1. Suppose X is a \mathcal{X}' -valued random object. It has an expectation $\mathbb{E}X \in \mathcal{X}'$ if the following system of equations makes sense and has a unique solution

$$\langle \phi, \overline{\mathbb{E}(X)} \rangle = \mathbb{E} \langle \phi, \overline{X} \rangle,$$

for every $\phi \in \mathcal{X}$.

Definition B.2. Suppose X is a \mathcal{X}' -valued random object. It has a covariance $Cov(X) \in L(\mathcal{X}, \mathcal{X}')$, if it has an expectation, the following system of equations makes sense and has a unique solution

$$\langle \phi, \overline{\operatorname{Cov}(X)\phi} \rangle = \mathbb{E} |\langle \phi, \overline{W} \rangle|^2,$$

for every $\phi \in \mathcal{X}$ and where $W = X - \mathbb{E}X$.

Definition B.3. Suppose X is a \mathcal{X}' -valued random object. The characteristic function of X is a mapping $J_X \colon \mathcal{X} \to \mathbb{C}$ given by

$$J_X(\phi) = \mathbb{E} \exp(i \operatorname{Re}(\langle \phi, \overline{X} \rangle)).$$

We can verify that complex white noise Y has the expectation $0 \in \mathcal{X}'$ and its covariance Y is $\operatorname{Cov}(Y) = \frac{1}{2}\iota$ which we will later (incorrectly) call $\frac{1}{2}I$ even though it is not the identity in that sense, it would preserve the space. We can define the general complex Gaussian object on \mathcal{X}' exactly as before.

Definition B.4. (Complex Gaussian object) Assume X is a \mathcal{X}' -valued random object. We say X is a complex Gaussian random object if it can be expressed in the form

(B.1)
$$X = \mu + AY,$$

where $\mu \in \mathcal{X}'$, $A \in L(\mathcal{Y}', \mathcal{X}')$ and Y is a \mathcal{Y}' -valued complex white noise.

The main results generalize nearly verbatim, which are provided through the following propositions,

Proposition B.5. Assume that X is a \mathcal{X}' -valued complex Gaussian object. Suppose $A \in L(\mathcal{X}', \mathcal{Z}')$ and $\mu \in \mathcal{Z}'$. Then $Z = \mu + AX$ is a \mathcal{Z}' -Gaussian random object with expectation

$$\mathbb{E}(Z) = \mu + \mathbb{E}(X).$$

It has covariance

$$\operatorname{Cov}(Z) = A\operatorname{Cov}(X)A',$$

where $A' = \overline{A}^* \in L(\mathcal{Z}, \mathcal{X}).$

Proposition B.6. The characteristic function of a complex Gaussian \mathcal{X}' -valued random object is

$$J_X(\phi) = \exp(i \operatorname{Re}(\langle \phi, \overline{\mathbb{E}(X)} \rangle) - \frac{1}{2} \langle \phi, \overline{\operatorname{Cov}(X)\phi} \rangle),$$

and the expectation and the complex covariance fully determine the distribution.

B.1. Connection to radar equation. Let's recall the radar equation (2.1) that was written as

$$z^{q}(t) = \int_{0}^{1} \epsilon^{q}(t-r) \,\mu^{q}(dr) + \sqrt{T}\xi^{q}(t).$$

In order to be precise, this should be understood as a cyclic convolution

$$z^q = \epsilon_q * \mu^q + \sqrt{T}\xi^q,$$

where given the covariance stucture of the μ^q , then $z^q, \mu^q, \xi^q \in \mathcal{X}'$ are complex Gaussian \mathcal{X}' -valued random objects and $\mathcal{X}' = \mathcal{D}'(\mathbb{T}; \mathcal{C})$, the \mathbb{T} standing for the torus formed out of the interval [0, 1].

More precisely, we assume that the conditional distribution of μ^q given its covariance is known to be X, then $\mu^q | X$ is a complex Gaussian \mathcal{X}' -valued random object with zero mean and random but given covariance X. Writing $A_q \eta = \epsilon_q * \eta$ we see that *provided* the convolution makes sense A_q is a linear mapping form \mathcal{X}' to \mathcal{X}' . Therefore, the conditional characteristic function of z^q is

$$J_{z^q \mid X}(\phi) = \exp(-\frac{1}{2} \langle \phi, \overline{A_q X A'_q \phi} \rangle - \frac{T}{2} |\phi|^2).$$

Note that this is an extension of the simplified model. In order to proceed, we assume that the covariance operators is parametrized. More specifically,

$$X = X(\sigma^2) = \phi \mapsto \sum_{j=1}^N \sigma_j^2 \langle \phi, \iota \chi_j \rangle \iota \chi_j$$

where $\{\chi_j\}_{j=1}^N$ form a periodic, smooth partition of unity normalized in the L^2 -sense.

This turns the bilinear form in the characteristic function into a bilinear matrix form. This corresponds to the idea that the autocovariance function is "piecewise constant", with χ_j acting like a smooth indicator function. We will assume that the set $\{\chi_j\}_{j=1}^N$ is known and the parameter vector $\sigma^2 = (\sigma_1^2, \ldots, \sigma_N^2)$ is the unknown replacing the full covariance operator X.

For this special case, the conditional characteristic (given σ^2) is

$$J_{z^q \mid \sigma^2}(\phi) = \exp(-\frac{1}{2} \langle \phi, \overline{A_q X(\sigma^2) A_q' \phi} \rangle - \frac{T}{2} |\phi|^2).$$

With a straight forward calculation (recalling $A_q \eta = \epsilon_q * \eta$ is understood as a mapping $\mathcal{X}' \to \mathcal{X}'$ and its dual as a mapping $\mathcal{X} \to \mathcal{X}$), we see that

$$\langle \phi, \overline{A_q X(\sigma^2) A'_q \phi} \rangle = \sum_{j=1}^N \sigma_j^2 |\langle \phi, A_q \iota \chi_j \rangle|^2.$$

Using $\phi = \phi_1 \pm \phi_2$ and summing up the previous identity implies

$$\langle \phi_1, \overline{A_q X(\sigma^2) A_q' \phi_2} \rangle = \sum_{j=1}^N \sigma_j^2 \langle \phi_1, A_q \iota \chi_j \rangle \overline{\langle \phi_2, A_q \iota \chi_j \rangle}, = \sum_{j=1}^N \sigma_j^2 \langle \phi_1, A_q \iota \chi_j \rangle \overline{\langle \phi_2, A_q \iota \chi_j \rangle}$$

Therefore, if we use a discrete dimensional complex Gaussian

$$Y_q = (z^q(\phi_1), \dots, z^q(\phi_M)),$$

as a discrete observation from the measurement device, then

$$J_{Y_q \mid \sigma^2}(\phi) = \exp(i \operatorname{Re}(\mathbb{E}(Y_q \mid \sigma^2)'\phi) - \frac{1}{2}\phi' \operatorname{Cov}(Y_q \mid \sigma^2)\phi).$$

Linearity implies that

$$\mathbb{E}(Y_q \,|\, \sigma^2) = 0$$

15

therefore,

$$\phi' \operatorname{Cov}(Y_q \mid \sigma^2) \phi = \sum_{i,j=1}^M \mathbb{E} \langle \phi_i, \overline{z^q} \rangle \langle \overline{\phi_j}, z^q \rangle)$$

Using complex polarization, namely by calculating

$$\mathbb{E}|\langle \left(\phi_i + \rho\phi_j\right), \overline{z^q} \rangle|^2 = \langle \left(\phi_i + \rho\phi_j\right), \overline{(A_q X(\sigma^2)A'_q + T)(\phi_i + \rho\phi_j)} \rangle,$$
for $\rho \in \{1, -1, i, -i\}$ we find that

$$\mathbb{E}(\langle \phi_i, \overline{z^q} \rangle \langle \overline{\phi_j}, z^q \rangle) = \langle \phi_i, \overline{\langle A_q X(\sigma^2) A'_q + T \rangle \phi_j} \rangle$$
$$= \sum_{k=1}^N \sigma_k^2 \langle \phi_i, A_q \iota \chi_k \rangle \overline{\langle \phi_j, A_q \iota \chi_k \rangle}$$
$$= \sum_{k=1}^N \sigma_k^2 \phi'_j \overline{A_q \iota \chi_k} (\overline{A_q \iota \chi_k})' \phi_i + T \phi'_j \phi_i$$
$$= \phi'_j (\sum_{k=1}^N \sigma_k^2 \overline{A_q \iota \chi_k} \chi'_k \iota' A'_q + T) \phi_i.$$

Interpreting this generalized covariance operator as an complex covariance operator of complex Gaussian vector, the density of $Y_q | \sigma^2$ is as a function of σ^2 seen to be proportional to an affine transform of the inverse Wishart distribution. The density function of inverse Wishart distribution $\mathcal{W}^{-1}(\Psi, \nu)$ is

$$|\sigma^2|^{-(\nu+p+1)/2} \exp(-\frac{1}{2} \operatorname{tr}(\Psi \sigma^{-2})),$$

where Ψ is positive definite $p \times p$ scale matrix and $\nu > p-1$ is the degrees of freedom. The Ψ is constructed from the observations (the actions of the measurement to the test functions). If we write this out explicitly we can get a representation for the posteriori distribution of the covariance of the signal. In the special case of Theorem 3.2, the $|\sigma|^2$ is constant and we can use a special smooth partition of unity that is obtained with a single χ_1 so that the all the others are periodic translates of this $\chi_j = \tau^j(\chi_1)$ with τ^j representing the j^{th} iterate of the single translate operation and which are rescaled to correspond to the discretization of the measured signal. Moreover, since translation commute with convolutions, we see that covariance operator for the disretization of the following quadratic form

(B.2)
$$\varphi \mapsto \int_{\mathbb{T}} |\sigma|^2 |\widehat{\epsilon}_j|^2(t)| \,\widehat{\varphi}(t)|^2 \mathrm{d}t.$$

where \mathbb{T} denotes the one-dimensional torus that is isomorphic with the half-open interval $[0, 2\pi)$ just as in the equation (2.7) in Definition 2.4.
