(Dated: September 11, 2023)

We develop an efficient approach to evaluate range-separated exact exchange for grid or planewave based representations within the Generalized Kohn-Sham DFT (GKS-DFT) framework. The Coulomb kernel is fragmented in reciprocal space, and we employ a mixed deterministic-stochastic representation, retaining long wavelength (low-k) contributions deterministically and using a sparse ("fragmented") stochastic basis for the high-k part. Coupled with a projection of the Hamiltonian onto a subspace of valence and conduction states from a prior local-DFT calculation, this method allows for the calculation of long-range exchange of large molecular systems with hundreds and potentially thousands of coupled valence states delocalized over millions of grid points. We find that even a small number of valence and conduction states is sufficient for converging the HOMO and LUMO energies of the GKS-DFT. Excellent tuning of long-range separated hybrids (RSH) is easily obtained in the method for very large systems, as exemplified here for the chlorophyll hexamer of Photosystem II with 1,320 electrons.

I. INTRODUCTION

The introduction of hybrid exchange and long-range hybrid functionals into density functional theory (DFT) dramatically improved their accuracy.[1–7] These improvements, now thirty years old, enabled the rapid growth of DFT as a standard tool in the chemistry lab, with the establishment of many popular commercial and open-source software. Unfortunately, it is this key improvement in functional design, exact exchange, that limits the size of computation feasible for most researchers with a set budget of computing power and time. Traditional Hartree-Fock type exchange requires the generation of all 2-electron integrals in a given basis, scaling naively as $O(N_o^4)$ for N_o spatially occupied orbitals.

The most substantial advancement in improving the computational cost of exact exchange in ab-initio DFT has come in the form of the so-called "resolution of the identity" (RI) methods.[8] Now widely adopted, these methods reduce exact exchange to cubic in scaling. For the entire set of 2e-integrals, $\langle pq|rs \rangle$, one expands the identity in another auxiliary basis, β , reducing a 4-center integral tensor to a product of two 3-center integral tensors, $\langle pq|rs \rangle = \sum_{\beta} \langle pq|\beta \rangle \langle \beta|rs \rangle$. Such auxiliary basis sets are optimized with density fitting.[9, 10] With this intelligent design, one can cap the number of β to be comparable to the number of atomic orbitals needed for the calculation,[11] but without fundamental improvements, this auxiliary basis still scales with system size.

Other efforts involve the power of parallel computing, such as fragmented systems, localized auxiliary orbitals, and sparse matrix algorithms.[12, 13] In extended systems, the sparsity of overlap integrals allows for highly optimized localized auxiliary orbitals and near linear scaling.[14, 15] Multi-level fragmented approaches have also recently improved scaling, especially in spatially localized cases.[13] Modern graphical-processing units (GPUs) also contribute to unlocking larger and larger calculations with RI methods.[16, 17]

Separately, we introduced a stochastic formalism for Hartree-Fock or long-range exchange for grid based DFT codes.[18] In this formalism the exchange becomes a projection to a stochastic occupied orbital, which is a random linear combination of all occupied orbitals represented on a grid basis, times a random amplitude due to the Coulomb potential. A statistical average over multiple random vectors converges to the matrix elements of the exchange operator. In this case, each random orbital covers the entire eigenbasis of the molecule, and the number of such operators typically does not grow with system size, and occasionally shrinks due to self averaging.[18]

In this work we employ a different strategy whereby the individual molecular states are treated deterministically. However, the usual cost of making all the matrix elements of the Coulomb interaction is reduced by orders of magnitude (and its scaling made constant) by the fragmented-stochastic compression approach we developed in a different context, stochastic GW. [19] Basically, we have shown that data over a large grid can be efficiently represented by a stochastic basis made of many small "fragments". Beyond a small threshold, the error does not depend on the fragment size, only on the number of fragments, so a large number of short fragments can be used to represent efficiently data on a giant grid.

In this work, we combine the best of sparse stochastic basis compression with the resolution of the identity technique. In short, we split the Coulomb kernel for the exchange calculation to two sets (see also Ref. [20]). The first is the large interaction at few low-wavevectors (small k) which is treated deterministically. The remainder, the

^{*} dxn@ucla.edu

interaction at the very many (often millions) of high k's, is represented here cheaply and accurately by fragmented stochastic compression, i.e., by representing the interaction through a small number (few thousands here) of short stochastic vectors, and this number does not increase with system size.

The second ingredient present to the deterministic/fragmented-stochastic approach is to represent the hybrid-DFT Hamiltonian in the basis of molecular orbital states (MOs) near the Fermi energy (near-gap) from local-DFT. Specifically, we first perform a local- (or semi-local) functional DFT calculation, by any efficient basis-set or plane-wave method. We then divide the resulting local-DFT MOs to core, valence and conduction, as well as high virtual orbitals which are ignored.

The core orbitals of this preliminary calculation are assumed to be a good representation of the core orbitals in the eventual hybrid calculation. We therefore assume that the valence and conduction orbitals of the hybrid case can be expanded from the valence and conduction MOs of the local-DFT calculation. This restriction to top valence and bottom conduction orbitals is of course routinely done in beyond-DFT methods, such as RPA, TD-DFT and the Bethe-Salpeter Equation.

With the introduction of sparse stochastic compression to the plane wave auxiliary basis, the scaling of the resulting approach is very gentle with system size, so that in practice the hybrid exchange correction costs less than the underlying local-DFT calculation. Further, the approach is easily parallelizable. We label it as near-gap Hybrid DFT (ngH-DFT).

In the sections below, we develop the ngH-DFT formalism, benchmark its convergence for naphthalene and fullerene, and then show the method's power by solving for a hexamer dye complex, a large system of biological significance. The proper inclusion of exact exchange here in such a large biomolecule is promising for future use of general post-DFT methods in giant systems.

II. METHODOLOGY

A. Hybrid DFT in the Valence-Conduction Subspace

We begin with the Kohn-Sham (KS) orbitals $\{\phi_s\}$ and associated eigenvalues $\{\varepsilon_s\}$ of a ground-state DFT calculation approximately satisfying $h_0\phi_s \approx \varepsilon_s\phi_s$. It is not necessary that the starting calculation be fully converged, and it can originate from LDA, PBE, or whichever DFT flavor of choice, but for simplicity it will be denoted here as LDA-DFT.

The molecular orbitals from the LDA-DFT calculation, denoted by ϕ , are then divided into four set of states: $N_{\rm core}$ core, $N_v (= N_o - N_{\rm core})$ valence, N_c conduction, and the remainder are high conduction states which are neglected. We then assume that the core states from the LDA calculation are unchanged in the GKS-DFT, i.e.,

$$\psi_f = \phi_f, \, f \in \text{core} \tag{1}$$

where ψ refers to a GKS molecular orbital. Therefore, the $M \equiv N_v + N_c$ GKS near-gap (i.e., valence+conduction) states are assumed to be described by the valence-conduction LDA states, i.e.,

$$\psi_s(r) = \sum_p \phi_p(r) C_{ps},\tag{2}$$

where s, p, q are indices over the M near-gap states.

The converged LDA-DFT Hamiltonian is expressed as (using atomic units throughout)

$$h_0 = -\frac{1}{2}\nabla^2 + v_{eN}^{NL} + v^0[n_0](r), \qquad (3)$$

with the respective terms being the kinetic energy, nonlocal component of electron-nucleus interaction, and the local KS potential. The latter is a functional of the LDA density, $n_0(r)$, and contains the local electron-nucleus interaction, Hartree potential, and local exchange-correlation (XC) potential, taken here to be PW-LDA [21]):

$$v^{0}[n_{0}](r) = v_{eN}^{local}(r) + \int \frac{n_{0}(r')}{|r-r'|} dr' + v_{XC}^{0}[n_{0}](r).$$
(4)

The electron-nucleus interaction is handled with Troullier-Martins norm-conserving pseudopotentials.[22] Additionally, the Martyna-Tuckerman approach is used to avoid the effect of periodic images in our simulations.[23]

We now turn to the GKS Hamiltonian. Here we employ a long-range hybrid, though the same formulation applies also to any other form, such as short-range or Becke-type fractional exchange. Note that to avoid a cluttering of indices we write here only the closed-shell GKS formalism, but the GKS Hamiltonian would generally be spin selective (unlike the LDA-DFT). In fact, the tuning procedure we use to yield the correct γ requires a spin-selective Hamiltonian, as discussed later.

The starting point is the long-range part of the Coulomb interaction, defined as $u^{\gamma}(|r - r'|) = \operatorname{erf}(\gamma|r - r'|)/|r - r'|$, so for the exchange the Coulomb kernel in position space is split as [7]

$$\frac{1}{|r-r'|} = \frac{\operatorname{erfc}(\gamma |r-r'|)}{|r-r'|} + u^{\gamma}(|r-r'|).$$
(5)

The first term dominates at short-distances and is treated locally, while the second, long-range term, is accounted for explicitly.

Range-separated hybrid functionals excel in charge transfer and excitonic effects due to the correct -1/|r - r'| asymptotic behavior of the exchange term. The

use of exact exchange helps alleviate the non-physical long-range self-repulsion in the LDA potential. The range-separation parameter γ is best obtained by enforcing piece-wise linearity of the energy with electron number.[24]

The GKS Hamiltonian is then

$$h = -\frac{1}{2}\nabla^2 + v_{eN}^{NL} + v^{\gamma}(r) + X_{val}^{\gamma} + X_{core}^{\gamma}, \qquad (6)$$

where γ refers to one or more parameters of the hybrid exchange. The γ -dependent Kohn-Sham potential is:

$$v^{\gamma}(r) = v_{eN}^{local}(r) + \int \frac{n(r')}{|r-r'|} dr' + v_{XC}^{\mathrm{SR},\gamma}[n], \quad (7)$$

where SR denotes short-range and n(r) is the overall density, made from a sum of core and valence densities:

$$n(r) = n^{core}(r) + n^{val}(r), \qquad (8)$$

where $n^{core}(r) = 2 \sum_{f \in \text{core}} |\phi_f(r)|^2$. The valence density is

$$n^{val}(r) = 2\sum_{i} f_{i} |\psi_{i}(r)|^{2} = 2\sum_{pq} \phi_{p}(r) P_{pq} \phi_{q}(r), \quad (9)$$

where the density matrix is $P_{pq} = \sum_{i} C_{pi} f_i C_{qi}$. Here, the sum runs over all occupied (or partially occupied) valence GKS MOs, and f_i is the occupation, which can be fractional:

$$f_i(\varepsilon_i;\mu) = \frac{1}{1 + e^{(\varepsilon_i - \mu)/k_B T}}.$$
(10)

The action of the valence (short-hand *val*) component of the γ -dependent exact exchange operator on a general function η is

$$(X_{val}^{\gamma}\eta)(r) = -\sum_{i} f_{i}\psi_{i}^{*}(r) \int u^{\gamma}(|r-r'|)\eta(r')\psi_{i}(r')dr'.$$
(11)

The contribution of the core states to the exchange part of the Hamiltonian will be done perturbatively as discussed later. The LDA \rightarrow GKS rotation matrix, Eq. (2), is initially $C_{ps} = \delta_{ps}$ and is then iterated in the SCF procedure.

The Hamiltonian matrix elements in the valenceconduction basis are

$$h_{pq} = \langle \phi_p | h_0 + \delta v + X_{val}^{\gamma} | \phi_q \rangle, \qquad (12)$$

where $\delta v \equiv v^{\gamma}(r) - v^{0}(r)$ is the difference between the current GKS and initial estimate KS potentials.

Formally, the matrix elements of the valence exactexchange are written as a 4-index integral tensor by starting with:

$$\langle \phi_q | X_{val}^{\gamma} | \phi_p \rangle = -\sum_i f_i \langle \phi_q \psi_i | u^{\gamma} (|r - r'|) | \psi_i \phi_p \rangle, \quad (13)$$

and inserting the expanded wavefunction gives

$$\langle \phi_q | X_{val}^{\gamma} | \phi_p \rangle = -\sum_{st} \langle \phi_q \phi_s | u^{\gamma} | \phi_t \phi_p \rangle P_{st}, \qquad (14)$$

where real-valued orbitals are used with the chemists' convention of $\langle rr | r'r' \rangle$.

B. Deterministic/Fragmented-Stochastic Representation of the Coulomb Kernel

Our starting point is the exchange kernel in Eq. (14) which requires a generic convolution form, written schematically as $w(r) = \int u^{\gamma}(r-r')y(r')dr'$. This form is diagonal in reciprocal space and for finite grids it reads:

$$w(k) = \frac{1}{V} \sum_{k} u^{\gamma}(k) y(k).$$
(15)

In the Martyna-Tuckerman approach V is the overall volume including full padding in each direction (i.e., V is $2^3 = 8$ times the wavefunctions volume). Further, $u^{\gamma}(k)$ is not necessarily positive due to the Martyna-Tuckerman construct.

Since $u^{\gamma}(k)$ is large at low k, its action is evaluated deterministically below an assigned cutoff, $k_{\rm cut}$. (The results are correct upon convergence for any $k_{\rm cut}$, as this parameter only affects the speed of convergence). Specifically, for a given $k_{\rm cut}$ we divide k-space into 3 subspaces; "low" – values of k below $k_{\rm cut}$.; "high⁺" – values above $k_{\rm cut}$ where $u^{\gamma}(k)$ is positive; and "high⁻" – values above $k_{\rm cut}$ where $u^{\gamma}(k)$ is negative. The number of points in each space is denoted, respectively, as $N_{k_{\rm low}}$, $N_{k_{\rm high}^+}$, and $N_{k_{\rm high}^-}$. Formally we write then the identity operator in the reciprocal space as

$$I = \sum_{k_{\text{low}}} |k_{\text{low}}\rangle \langle k_{\text{low}}|$$

+
$$\sum_{k_{\text{high}^+}} |k_{\text{high}^+}\rangle \langle k_{\text{high}^+}| + \sum_{k_{\text{high}^-}} |k_{\text{high}^-}\rangle \langle k_{\text{high}^-}|.$$
(16)

The Coulomb long-range operator is then

$$u^{\gamma} = \sum_{k_{\text{low}}} |k_{\text{low}}\rangle u^{\gamma}(k_{\text{low}})\langle k_{\text{low}}|$$

$$+ \sum_{k_{\text{high}^{+}}} \sqrt{u^{\gamma}(k_{\text{high}^{+}})} |k_{\text{high}^{+}}\rangle \langle k_{\text{high}^{+}}| \sqrt{u^{\gamma}(k_{\text{high}^{+}})}$$

$$- \sum_{k_{\text{high}^{-}}} \sqrt{|u^{\gamma}(k_{\text{high}^{-}})|} |k_{\text{high}^{-}}\rangle \langle k_{\text{high}^{-}}| \sqrt{|u^{\gamma}(k_{\text{high}^{-}})|}.$$
(17)

Next we introduce stochastic fragmented bases [19] for the positive and negative high-k components. We detail the discussion for the high⁺ space, and it follows analogously for the high⁻ space.

A set of N_{α^+} short vectors is chosen, where each is randomly positive and negative in a "strip", also labeled as "fragment":

$$\alpha^{+}(k_{\text{high}^{+}}) = \pm \sqrt{\frac{N_{k^{+}}}{L}} A_{\alpha^{+}}(k_{\text{high}^{+}}).$$
(18)

Here $A_{\alpha^+}(k)$ is a projection to a randomly placed fragment α^+ of length L, i.e., is 1 within the fragment and 0 outside, so $\alpha^+(k_{\text{high}^+})$ is randomly positive or negative in the fragment and vanishes outside. The strip length, L, is the same for each fragment. The fragments thus randomly and uniformly sample the entire $\{|k_{\text{high}^+}\rangle\}$ space.

The constant factor in Eq. (18) ensures that with sufficient sampling the α^+ vectors form an orthonormal set, as explained below. A technical point is that fragments that start near the edge of the k_{high^+} space, i.e., that their starting point is larger than $N_{k_{\text{high}^+}} - L$, need to wrap around; alternately one can zero pad the space of $N_{k_{\text{high}^+}}$ points by L points on both sides, and then the constant square root factor in Eq. (18) needs to be slightly modified.

The strip length L and the number of stochastic vectors N_{α^+} are chosen such that each k point in the high⁺ space is sufficiently "covered", i.e., will be adequately visited by the stochastic basis α^+ . Specifically, we choose a coverage parameter, *cov*, that samples how often, on average, each point is sampled. The number of chosen stochastic vectors is then

$$N_{\alpha^+} = \frac{cov \cdot N_{k_{\text{high}^+}}}{L}.$$
 (19)

In the limit that this coverage parameter is large the stochastic fragments form an orthonormal basis, i.e.,

$$\left\{\alpha^{+}(k_{\rm high^{+}})\alpha^{+}(k_{\rm high^{+}}')\right\} = \delta_{k_{\rm high^{+}}}k_{\rm high^{+}}' \qquad (20)$$

where the large curly brackets denote a stochastic sampling with formally $cov \rightarrow \infty$. In practice it is enough to use $cov \simeq 5$.

We then define N_{α^+} states, $|\xi^+\rangle$, with components

$$\langle k_{\text{high}^+} | \xi^+ \rangle = \sqrt{u^{\gamma} \left(k_{\text{high}^+} \right)} \, \alpha^+ (k_{\text{high}^+}), \qquad (21)$$

We repeat the whole procedure for the high⁻ space, and end up with N_{α^-} states for the negative high-k portion of the exchange kernel

$$\langle k_{\text{high}^-} | \xi^- \rangle = \sqrt{\left| u^{\gamma} \left(k_{\text{high}^-} \right) \right|} \, \alpha^-(k_{\text{high}^-}). \tag{22}$$

We now define a combined set of states, of size $N_{\xi} = N_{k_{\text{low}}} + N_{\alpha^+} + N_{\alpha^-}$, that is glued together via direct summation

$$|\xi\rangle = \{\sqrt{|u^{\gamma}(k_{\text{low}})|}|k_{\text{low}}\rangle\} \oplus \{|\xi^{+}\rangle\} \oplus \{|\xi^{-}\rangle\}.$$
 (23)

FIG. 1. (Top) Convergence of the fundamental gaps of fullerene and (Bottom) hexamer with the number of valence states, N_v , and the number of conduction states, N_c , chosen either $N_c=2N_v$ (blue diamonds) or fixed at $N_c=480$ (black x). The red-line is the reference value of the fullerene gap including all occupied states, $N_v = N_o = 120$ and $N_c = 480$.

We similarly define a sign vector of length N_{ξ}

$$g_{\xi} = \{ sign(u^{\gamma}(k_{low})) \} \oplus \{1\} \oplus \{-1\},$$
 (24)

i.e., in addition to the sign of the interaction for the low-k components, g is composed of N_{α^+} values of 1 and N_{α^-} values of -1.

With these definitions, we now reach the stochastic fragmented basis representation of the exchange operator

$$u^{\gamma} = \sum_{\xi} |\xi\rangle g_{\xi} \langle \xi|.$$
 (25)

This is the central equation of the deterministic/stochastic-fragment representation of the Coulomb interaction. As mentioned, it is used here only for the exchange component and not for the direct Coulomb interaction.

Inserting this form of u^{γ} in the matrix element of Eq. (14)

$$\langle \phi_q | X_{val}^{\gamma} | \phi_p \rangle = -\sum_{st\xi i} \langle \phi_q \phi_s | \xi \rangle g_{\xi} \langle \xi | \phi_t \phi_p \rangle C_{si} f_i C_{ti}, \quad (26)$$

and defining

$$u_{\xi pi} \equiv \sum_{t} C_{ti} \langle \xi | \phi_t \phi_p \rangle, \qquad (27)$$

5

TABLE I. Fundamental gaps for naphthalene, fullerene, and a 476 atom hexamer dye complex. Also shown are the total number of occupied states, the maximum numbers valence and conduction states, and the range-separation parameter for each system. All energies are in eV. The atomic basis-set calculation uses the NWChem package. Both ngH-DFT and the atomic basis-set RSH-DFT use the BNL XC functional.

| | | | | | | Atomic | Atomic | |
|-------------|-------|--------------|--------------|------------------------|------------|-----------|---------|-----------|
| | | | | Optimal γ | Plane-wave | Basis-Set | | Basis-Set |
| System | N_o | N_v^{\max} | N_c^{\max} | (Bohr^{-1}) | LDA-DFT | LDA-DFT | ngH-DFT | RSH-DFT |
| Naphthalene | 24 | 24 | 104 | 0.285 | 3.34 | 3.34 | 8.63 | 8.54 |
| Fullerene | 120 | 120 | 480 | 0.189 | 1.63 | 1.64 | 5.42 | 5.40 |
| Hexamer | 660 | 200 | 400 | 0.120 | 1.23 | | 3.81 | |

yields the final expression for the exact exchange matrix elements:

$$\langle \phi_q | X_{val}^{\gamma} | \phi_p \rangle = -\sum_{i\xi} u_{\xi qi}^* f_i g_{\xi} u_{\xi pi}.$$
(28)

Note that for a spin-resolved calculation, the only difference is that, in addition to the amplitudes C_{ti} and the exchange correlation potential δv , the transformed exchange vectors $u_{\xi p}$ and the X_{val}^{γ} matrix would also gain a spin index.

C. Algorithm cost

In addition to the underlying local-DFT, the algorithm cost is mostly due to preparing the $\langle \phi_q \phi_s | \xi \rangle$ and then calculating in each SCF iteration the exact exchange matrix elements. The steps are:

- First one Fourier transforms, i.e., prepares $\langle \phi_q \phi_s | k \rangle$ from $\phi_q(r)\phi_s(r)$, which costs $\mathcal{O}(M^2N\log N)$ operations, where N is the number of total number of grid and k points.
- Next one dot-products $\langle \phi_q \phi_s | k \rangle$ with the $N_{\alpha} (\equiv N_{\alpha^+} + N_{\alpha^-})$ fragmented stochastic orbitals of length *L* each, to yield $\langle \phi_q \phi_s | \xi^{\pm} \rangle$, at a cost of $\mathcal{O}(M^2 N_{\alpha} L)$ operations. For simplicity we choose here $N_{\alpha} = N_{k_{\text{low}}} = N_{\xi}/2$. Therefore, the dot product cost is $\mathcal{O}(M^2 \cdot cov \cdot N_{\xi})$.
- Finally, in each of the N_{scf} iterations one prepares the matrix elements via Eqs. (27) and (28), at a cost of $M^2 N_v N_{\xi}$ operations each.

The overall cost is therefore:

$$\mathcal{O}\Big(M^2\big(N(\cos v + \log N) + N_{scf}N_vN_{\xi}\big)\Big).$$
(29)

Since N_{ξ} does not grow with system size, as demonstrated below, the scaling is formally cubic with system size. However, in practice the scaling is gentler, since a very low number of near-gap (i.e., valence+conduction) states, M, is sufficient for large systems.

D. Core States Correction to the Exchange

In the previous sections, the core state contributions to the exact exchange were neglected. We will account for it by a perturbative correction to the KS eigenvalues $\varepsilon_s \rightarrow \varepsilon_s + \Delta_s$, where

$$\Delta_s = \langle \psi_s | X_{core}^{\gamma} | \psi_s \rangle, \tag{30}$$

is evaluated as

$$\Delta_s = -\sum_{f \in \text{core}} \langle \psi_s \phi_f | u^\gamma | \phi_c \psi_f \rangle.$$
(31)

Since in this work we are only interested in the HOMO and LUMO energies, we calculate the correction for these two states only, labelled as Δ_{occ} , Δ_{unocc} . The corecorrections stabilize the frontier orbital eigenvalues and bandgap even when the number of active valence and conduction orbitals included in the GKS-Hamiltonian is dramatically reduced. Computationally these core corrections are very cheap as they are only added in the last iteration, and they are calculated as explicit convolution integrals.

III. RESULTS

We test the ngH-DFT method with three molecular systems of increasing size: naphthalene $(N_o=24)$, fullerene $(N_o=120)$, and a hexamer dye complex $(N_o=660)$. An initial PW-LDA DFT calculation is performed for all systems. The large dye system's nuclear coordinates, optimized at the PBE/def2-TZVP-MM level, were taken from [25, 26]. All simulations use a generous box size that extends 6 Bohr beyond the extent of the molecule in each direction, with real-space grids (before the Martyna-Tuckerman expansion) of $N_g=50, 688$, 216,000, and 2,273,280 points respectively, and uniform grid spacings dx=dy=dz=0.5 Bohr. The RSH-DFT studies use the Baer-Neuhauser-Livshits (BNL) XC functional.

To balance the cost between the deterministic low-kand sparse stochastic high-k components of the exchange, we set, as mentioned, the size of the sparse basis, N_{α} , equal to the number of deterministic k-vectors, $N_{k_{low}}$.

FIG. 2. (Top) Convergence of γ , and (Bottom) the core corrections as a function of N_v for the hexamer system.

The $k_{\rm cut}$ parameter, separating the deterministic and fragmented-stochastic term, is adjusted so that for most of our simulations (except for a few reported in Table IV) a constant $N_{k_{\rm low}} \simeq N_{\alpha} = 5000$ is used, so the auxiliary basis size is $N_{\xi} \simeq 10,000$. The associated $k_{\rm cut}$ values (in atomic units) are, respectively, 1.8, 1.1 and 0.5.

Note that at these values, and for the tuned values of γ listed below (0.285, 0.189 and 0.12 Bohr⁻¹, respectively), the high-k interaction is very small, as $v_{\gamma}(k) \propto \exp(-k^2/4\gamma^2)/k^2$ (although it is numerically somewhat larger in the Martyna Tuckerman approach). For a preliminary study of the potential usefulness of the approach for other types of Hybrid functionals, where $v_{\gamma}(k)$ is not so tiny at high k, we also include later results at a lower $k_{\rm cut}$.

Before showing the promise of using only a fraction of near-gap states, we report in Table I the fundamental gaps obtained for naphthalene, fullerene and the hexamer, using a large number of valence and conduction states (including all N_o occupied states for the two smaller systems). For naphthalene and fullerene we benchmark vs. an all-electron calculation that uses the NWChem package,[27] with a Gaussian aug-cc-pvdz basis containing 302 atomic basis functions for naphthalene and 1380 for fullerene. The fundamental gaps agree well between ngH-DFT and NWCHEM, and we demonstrate below that this agreement is maintained even when we reduce significantly the size of the valence-conduction

TABLE II. Naphthalene frontier orbital eigenvalues, fundamental gap, and core corrections for different numbers of valence to conduction states. All energies are in eV. The first row includes all occupied states so it has no core correction.

| 20:20 | -8.23 | -2.77 | 5.46 | -0.42 | -0.29 |
| 10:10 | -8.25 | -2.83 | 5.42 | -1.12 | -0.63 |

near-gap space.

Both the ngH-DFT and RSH-DFT calculations use the same optimal range-separation parameter γ obtained by systematic tuning of the HOMO energies, i.e., ensuring that the HOMO energy does not change when the system is slightly ionized, and we use here $\varepsilon_{\text{HOMO}}^{\text{neutral}} = \varepsilon_{\text{HOMO}}^{+0.1}$. The ngH-DFT for the charged system is done via an open-shell calculation.

A side note is that to ensure rapid convergence with the valence basis size N_v , we find it important to do the initial LDA calculation with the right charge, as this ensures that the core eigenstates are correctly polarized. Thus, the charged system ngH-DFT requires a initial basis-set ϕ_s from an LDA SCF with fractional occupation $f_{\rm HOMO} = 1-0.1$ (though done in a non-spin-selective calculation) rather than relying on the ϕ_s from the neutral LDA.

In Table II, we provide the HOMO and LUMO eigenvalues and gap for naphthalene for a chosen number of valence and conduction states. The first row in the table includes all occupied and a large number of unoccupied states, while the following two use a reduced valence-conduction space. Reduction of this active space necessitates the core corrections of the HOMO and LUMO eigenvalues. The gap is not changed much when the valence-conduction basis-set size is made smaller.

As Table III shows, the convergence is even better for the next bigger system, fullerene. The number of included valence and conduction states can now be much smaller than N_o . This rapid convergence with N_v is also shown in Fig.1a. The figure further shows that the results converge rapidly with the conduction basis size, so that $N_c = 2N_v$ gives essentially the same result as using a very large value of N_c .

The convergence with N_v further improves for the biggest system, the hexamer, as shown in Fig. 1b. The gaps shown all agree within ± 0.02 eV even for very small

TABLE IV. Fundamental gap and its standard deviation, σ , for three test systems (in eV), for different numbers of deterministic low-k terms, $N_{k_{low}}$, and sizes of the sparse stochastic basis, N_{α} .

| System | N_v | N_c | $N_{k_{low}}$ | N_{α} | gap | σ |
|-------------|-------|-------|---------------|--------------|--------|--------|
| Naphthalene | 20 | 40 | 501 | 500 | 8.6329 | 0.0122 |
| | | | 501 | 5000 | 8.6373 | 0.0077 |
| | | | 4987 | 5000 | 8.6344 | 0.0004 |
| Fullerene | 40 | 80 | 515 | 500 | 5.4209 | 0.0066 |
| | | | 515 | 5000 | 5.4226 | 0.0051 |
| | | | 4945 | 5000 | 5.4228 | 0.0001 |
| Hexamer | 40 | 80 | 503 | 500 | 3.7914 | 0.0286 |
| | | | 503 | 5000 | 3.8018 | 0.0152 |
| | | | 4785 | 5000 | 3.8032 | 0.0002 |

 N_v and N_c . This implies that very large systems could be used with a small valence-conduction space.

Fig. 2 shows, for the hexamer, the convergence of the range-separation parameter as well as the core corrections. The extracted γ values are consistent, even with a valence-conduction space of only ten valence and ten conduction orbitals. This implies that optimal tuning of long-range separated hybrids of giant systems could be done rather cheaply.

The single-run stochastic error, i.e., the standard deviation of the energy, is shown in Table IV. It is estimated from the results of ten independent runs. As mentioned, for $N_{k_{\text{low}}} \simeq 5000$, k_{cut} is large for each of the three studied systems so that that the values of $v_{\gamma}(k)$ are very small for the stochastically-sampled high-k spaces. We therefore also include results with a smaller k_{cut} so $N_{k_{\text{low}}} \simeq 500$, for $N_{\alpha} = 500$ and $N_{\alpha} = 5000$ (i.e., $N_{\xi} \simeq 1000, 5500$). As shown, the statistical error is still quite small, about 0.01-0.03eV, and is lower than or similar to the low stochastic error associated with using a small value of N_v .

To conclude the results section, we show in Fig. 3, for the hexamer, the number of CPU-core hours needed in ngH-DFT vs. N_v , using standard AMD Rome processors. The ngH-DFT cost is very small, and even for the largest sample studied $N_v = 200$, $N_c = 400$ the required effort is less than for the underlying LDA-DFT stage.

IV. DISCUSSION

We developed and demonstrated here a new method, ngH-DFT, for incorporating exact exchange within a GKS-DFT framework. Long wavelength (low k) components of the exchange are evaluated deterministically, and high momenta are represented by a sparse stochastic basis. Using an underlying MO basis from a preliminary LDA calculation the frontier eigenvalues converge with a small number of included valence and conduction orbitals.

We reiterate that this method only has stochasticity in its handling the high momenta components of the exchange, which are not as physically important as the low

FIG. 3. CPU-core hours required for the ngH-DFT method for the large hexamer complex. Parabolic scaling with the number of valence states (for a given grid) is shown. The red line indicates the core hours required for the initial LDA DFT calculation.

components. Treating less relevant degrees of freedom stochastically works very well here when combined with the sparse compression technique.

Future work will expand the method in several directions:

First, the stochastic compression gave equal weight to all high-k components, and could be replaced by preferred sampling of points with relatively higher $u^{\gamma}(k)$ within the high[±] spaces, either explicitly or division to several sub-spaces.

Next, a relatively simple extension would be to construct random combinations of the core states that would be used to calculate the core-exchange. This would reduce the memory requirements since the full set of core states would not need to be stored.[18] Further, for the corrections of other states we could use a rigid scissor approximation [28], where the all occupied and unoccupied subspaces are shifted by the respective HOMO and LUMO orbital expectation values of X_{core}^{γ} ; or, better yet, sample a few more states to determine an energydependent core-state contribution, analogous to our GW matrix elements.[29, 30] Since it will be applied only to the core states the contribution would be small and therefore so will its underlying stochastic error.

The present near-gap approach method will be useful for many-body perturbation theory (MBPT). In MBPT methods, having access to exact exchange corrected eigenstates gives an improved starting point for methods such as one-shot G_0W_0 where the quality of the beginning canonical states is very important.[31, 32]

Our formalism will also apply to time-dependent Hybrid-DFT, where, like in GKS-DFT SCF, the $\langle \phi_q \phi_s | \xi \rangle$ vectors would be evaluated once while the exchange matrix, Eqs. (27), (26) will be updated repeatedly, here once per time step. It will be useful both for real-time TDDFT

and for frequency resolved TDDFT and BSE.[33, 34] We also expect applications within basis set based DFT codes, where the wavefunction is eventually represented on a complete grid. Additionally, we anticipate that this method will have applications in auxiliary field quantum Monte-Carlo methods (AFQMC), where the bulk of the computational effort also lies in evaluating exchange energy on many Slater determinants.[35–37]

Finally, the underlying LDA-DFT approach could be efficiently done with stochastic DFT, [38, 39] so very large systems could be used, with tens of thousands of electrons or more. Eigenstates are not produced automatically in stochastic DFT, so the set of $N_v + N_c$ near-gap eigenstates, required for ngH-DFT, would be then extracted by filter-diagonalization.[40]
