ABSTRACT

It is well known that supermassive black holes (SMBHs) and their host galaxies co-evolve. AGN feedback plays an important role on this symbiosis. To study the effect of the AGN feedback on the host galaxy, a popular method is to study the star-formation rate (SFR) as a function of the X-ray luminosity (L_X). However, hydrodynamical simulations suggest that the cumulative impact of AGN feedback on a galaxy is encapsulated in the mass of the SMBH, M_{BH} , rather than the L_X . In this study, we compare the SFR of AGN and non-AGN galaxies as a function of L_X , M_{BH} , Eddington ratio (n_{Edd}) and specific black hole accretion rate (λ_{SBHAR}) . For that purpose, we use 122 X-ray AGN in the XMM-XXL field and 3371 galaxies from the VIPERS survey and calculate the SFR_{norm} parameter, defined as the ratio of the SFR of AGN to the SFR of non-AGN galaxies with similar stellar mass, M, and redshift. Our datasets span a redshift range of $0.5 \le z \le 1.2$. The results show that the correlation between SFR_{norm} and M_{BH} is stronger compared to that between SFR_{norm} and L_X . A weaker correlation is found between SFR_{norm} and λ_{sBHAR} . No correlation is detected between SFR_{norm} and n_{Edd} . These results corroborate the idea that the M_{BH} is a more robust tracer of the cumulative impact of the AGN feedback compared to the instantaneous accretion rate (L_X) and, thus, a better predictive parameter of the changes of the SFR

ABST

It is well known that supermassive black holes (SMBHs) and their on this symbiosis. To study the effect of the AGN feedback on the (SFR) as a function of the X-ray luminosity (L_X). However, hydroof feedback on a galaxy is encapsulated in the mass of the SMBH, AGN and non-AGN galaxies as a function of L_X, M_{BH}, Eddingto that purpose, we use 122 X-ray AGN in the XMM-XXL field and parameter, defined as the ratio of the SFR of AGN to the SFR our datasets span a redshift range of 0.5 ≤ z ≤ 1.2. The results compared to that between SFR_{norm} and L_X. A weaker correlation between SFR_{norm} and n_{Edd}. These results corroborate the idea that AGN feedback compared to the instantaneous accretion rate (L_X) of the host galaxy.

1. Introduction

The supermassive black holes (SMBHs) that live in the centre of galaxies become active when material that is in the vicinity of the SMBH is accreted onto them. Many evidence have been presented the last two decades that show that there is a co-evolution between the SMBH and its host galaxy. For instance, both the activity of the black hole and the star-formation (SF) of galaxies are fed by the same material (i.e., cold gas) and both phenomena peak at about the same cosmic time (z ~ 2; e.g., Boyle et al. 2000; Sobral et al. 2013). Moreover, tight correlations have been found in the local universe, between the mass of the SMBH, M_{BH}, and various properties of the host galaxy, such as the stellar velocity dispersion the bulge luminosity and the bulge mass (e.g., Magorrian et al. 1998; Ferrarese & Merritt 2000; Tremaine et al. 2002; Häring & Rix 2004). These correlations also seem to exist at higher redshifts (z ~ 2; e.g., Jahnke et al. 2009; Merloni et al. 2010; Sun et al. 2015; Suh et al. 2020; Setoguchi et al. 2021; Mountrichas 2023).

Various mechanisms have been suggested that drive the gas from kiloparsec to sub-parsec scales (for a review see Alexander & Hickox 2012). AGN feedback in the form of jets, radiation, or winds is also included in most simulations to exp

der & Hickox 2012). AGN feedback in the form of jets, radiation, or winds is also included in most simulations to explain many galaxy properties, such as to maintain the hot intracluster medium (e.g., Dunn & Fabian 2006), to explain th shape of the galaxy stellar mass function (e.g., Bower et al. 2012) and the galaxy morphology (e.g., Dubois et al. 2016).

A popular method to study the symbiosis between the AGN and its host galaxy is to examine the correlation between the star-formation rate (SFR) and the power of AGN, using as a proxy for the latter the X-ray luminosity (L_X) . Most previous studies have found a positive correlation between the SFR and L_X (e.g., Lanzuisi et al. 2017; Masoura et al. 2018; Brown et al. 2019), although, no correlation has also been reported Stanley et al. (2015). However, more information can be gained when we compare the SFR of AGN with the SFR of non-AGN galaxies with similar redshifts and stellar masses, M*, as a function of L_X (e.g. Santini et al. 2012; Shimizu et al. 2015, 2017; Florez et al. 2020). In this case, most studies measure what is often call normalized SFR, SFR_{norm}, which is the ratio of AGN to the ratio of SF main-sequence (MS) galaxies with similar redshift and M_{*} (Rosario et al. 2013; Mullaney et al. 2015; Bernhard et al. 2019). A strong positive correlation has been found between SFR_{norm} and L_X at redshifts up to $z \sim 5$ (Masoura et al. 2021; Koutoulidis et al. 2022; Pouliasis et al. 2022). However, after minimizing systematics effects that may be introduced in the comparison of the SFR of AGN and non-AGN systems (e.g., due to the different methods that the SFR of the two populations have been calculated, the different photometric selection criteria that have been applied; for more details see Mountrichas et al. 2021c), a weaker correlation or even absence of correlation is detected between SFR_{norm} and L_X , depending on the M_* range (see Fig. 5 in Mountrichas et al. 2022a).

The different trends observed in the SFR_{norm} - L_X relation in different M_{*} regimes, also highlight the importance of M_{*} in this kind of investigations. There are observational works that have found that the black hole accretion rate (BHAR $\propto L_X$) is mainly linked to M_{*} rather than SFR (Yang et al. 2017). Moreover, SFR_{norm} appears to be stronger correlated with M_{*} than with L_X (Mountrichas et al. 2022a). Theoretical studies that used hydrodynamical simulations have also found that that the cumulative impact of AGN feedback on the host galaxy is encapsulated in the mass of the supermassive black hole, M_{RH} , and not in L_X , both in the local universe (Piotrowska et al. 2022) and at

high redshifts (Bluck et al. 2023). The fact that the SFR shows a strong link both with M_* and M_{BH} could be due to the underlying M_* - M_{BH} relation that has been found to hold up to at least redshift of 2 (e.g., Merloni et al. 2010; Sun et al. 2015; Setoguchi et al. 2021; Mountrichas 2023).

In this work, we compare the SFR of X-ray detected AGN with that of non-AGN galaxies as a function of different black hole properties. For that purpose, we use X-ray AGN detected in the XMM-XXL field, for which there are available M_{BH} measurements, and (non-AGN) galaxies from the VIPERS survey that (partially) overlaps with XMM-XXL. We use these two samples to calculate the SFR_{norm} parameter and examine the correlation of SFR_{norm} with the L_X, M_{BH} , Eddington ratio (n_{Edd}) and specific black hole accretion rate (λ_{sBHAR}). Finally, we discuss our results and describe our main conclusions. Throughout this work, we assume a flat Λ CDM cosmology with $H_0 = 70.4 \, \mathrm{Km \, s^{-1} \, Mpc^{-1}}$ and $\Omega_M = 0.272$ (Komatsu et al. 2011).

2. Data

The main goal of this study is to examine how the SFR of X-ray AGN compares with the SFR of non-AGN systems as a function of various black hole properties. For that purpose, we compile an X-ray dataset that comprises of AGN detected in the XMM-XXL field and a control sample of (non-AGN) galaxies which consists of sources observed by the VIPERS survey. The sky area that the two surveys cover (partially) overlaps. Below, we provide a brief description of these two surveys. The (final) AGN and non-AGN samples used in our analysis are described in Sect. 4.

2.1. The XMM-XXL dataset

The X-ray dataset used in this work, consists of X-ray AGN observed in the northern field of the *XMM-Newton-XXL* survey (XMM-XXL; Pierre et al. 2016). XMM-XXL is a medium-depth X-ray survey that covers a total area of 50 deg² split into two fields nearly equal in size, the XMM-XXL North (XXL-N) and the XXM-XXL South (XXL-S). The XXL-N dataset consists of 8445 X-ray sources. Of these X-ray sources, 5294 have SDSS counterparts and 2512 have reliable spectroscopy (Menzel et al. 2016; Liu et al. 2016). Mid-IR and near-IR was obtained following the likelihood ratio method (Sutherland & Saunders 1992) as implemented in (Georgakakis et al. 2011). For more details on the reduction of the XMM observations and the IR identifications of the X-ray sources, readers can refer to Georgakakis et al. (2017).

2.2. The VIPERS catalogue

The galaxy control sample used in our analysis comes from the public data release 2 (PDR-2; Scodeggio 2016) of the VIPERS survey (Guzzo et al. 2014; Garilli et al. 2014), that partially overlaps with the XMM-XXL field. The observations have been carried out using the VIMOS (VIsible MultiObject Spectrograph, Le Fèvre et al. 2003) on the ESO Very Large Telescope (VLT). The survey covers an area of $\approx 23.5 \, \text{deg}^2$, split over two regions within the CFHTLS-Wide (Canada-France- Hawaii Telescope Legacy Survey) W1 and W4 fields. Follow-up spectroscopic targets were selected to the magnitude limit i' = 22.5 from the T0006 data release of the CFHTLS catalogues. An optical colour-colour pre-selection, i.e., f(r-i)>0.5(u-g) or (r-i)>0.71, excludes galaxies at z<0.5, yielding a > 98% completeness for z>0.5 and up to $z\sim1.2$ (for more details see Guzzo et al.

2014). PDR-2 consists of 86,775 galaxies with available spectra. Each spectrum is assigned a quality flag that quantifies the redshift reliability. In all VIPERS papers, redshifts with flags in the range between 2 and 9 are considered as reliable and are those used in the science analysis (Garilli et al. 2014; Scodeggio 2016). The above criteria yield 45,180 galaxies within the redshift range spanned by the VIPERS survey (0.5<z<1.2). This is the same galaxy sample used in Mountrichas et al. (2019) (see their Sect. 2.1).

To add near-IR and mid-IR photometry, we cross-match the VIPERS catalogue with sources in the VISTA Hemisphere Survey (VHS, McMahon et al. 2013) and the AllWISE catalogue from the WISE survey (Wright et al. 2010). The process is described in detail in Sect. 2.5 in Pouliasis et al. (2020). Specifically, the xmatch tool from the astromatch package was used. xmatch utilizes different statistical methods for cross-matching of astronomical catalogues. This tool matches a set of catalogues and gives the Bayesian probabilities of the associations or non-association (Pineau et al. 2017). We only kept sources with a high probability of association (> 68%). When one source was associated with several counterparts, we selected the association with the highest probability. 14,128 galaxies from the VIPERS catalogue have counterparts in the near- and mid-IR.

3. Galaxy and supermassive black hole properties

In the following part of this work, we describe how we obtain measurements for the properties of the sources used in our analysis. Specifically, we present how we measure the SFR and M_* of AGN and non-AGN galaxies, how we calculate the bolometric luminosity (L_{bol}), n_{Edd} and λ_{sBHAR}) of AGN and how the available M_{BH} were estimated.

3.1. Calculation of SFR and M_{*}

For the calculation of the SFR and M_* of AGN host galaxies and non-AGN systems, we apply spectral energy distribution (SED) fitting, using the CIGALE algorithm (Boquien et al. 2019; Yang et al. 2020, 2022). CIGALE allows the inclusion of the X-ray flux in the fitting process and has the ability to account for the extinction of the UV and optical emission in the poles of AGN (Yang et al. 2020; Mountrichas et al. 2021b,a; Buat et al. 2021).

For consistency with our previous studies (Mountrichas et al. 2021c, 2022b,a; Mountrichas & Shankar 2023), we use the same templates and parametric grid in the SED fitting process as those used in these previous works. In brief, the galaxy component is modelled using a delayed SFH model with a function form SFR $\propto t \times \exp(-t/\tau)$. A star formation burst is included (Małek et al. 2018; Buat et al. 2019) as a constant ongoing period of star formation of 50 Myr. Stellar emission is modelled using the single stellar population templates of Bruzual & Charlot (2003) and is attenuated following the Charlot & Fall (2000) attenuation law. To model the nebular emission, CIGALE adopts the nebular templates based on Villa-Velez et al. (2021). The emission of the dust heated by stars is modelled based on Dale et al. (2014), without any AGN contribution. The AGN emission is included using the SKIRTOR models of Stalevski et al. (2012, 2016). The parameter space used in the SED fitting process is shown in Tables 1 in Mountrichas et al. (2021b, 2022b,a).

CIGALE has the ability to model the X-ray emission of galaxies. In the SED fitting process, the intrinsic L_X in the $2-10\,\text{keV}$ band are used. The calculation of the intrinsic L_X

¹ https://github.com/ruizca/astromatch

is described in detail in Sect. 3.1 in Mountrichas et al. (2021b). In brief, we use the number of photons in the soft (0.5 – 2 keV) and the hard (2 – 8 keV) bands that are provided in the Liu et al. (2016) catalogue. Then, a Bayesian approach (BEHR; Park et al. 2006) is applied to calculate the hardness ratio, $HR = \frac{H-S}{H+S}$, of each source, where H and S are the counts in the soft and hard bands, respectively. These hardness ratio measurements are then inserted in the Portable, Interactive, Multi-Mission Simulator tool (PIMMS; Mukai 1993) to estimate the hydrogen column density, N_H , of each source. A power law with slope $\Gamma = 1.8$ for the X-ray spectra is assumed. The value of the galactic N_H is $N_H = 10^{20.25} \, \mathrm{cm}^{-1}$.

The reliability of the SFR measurements, both in the case of AGN and non-AGN systems, has been examined in detail in our previous works and, in particular, in Sect. 3.2.2 in Mountrichas et al. (2022b). Finally, we note that the AGN module is used when we fit the SEDs of non-AGN systems. This allows us to uncover AGN that remain undetected by X-rays (e.g., Pouliasis et al. 2020) and exclude them from our galaxy control sample (see Sect. 4).

3.2. Calculation of SFR_{norm}

The goal of this study is to compare the SFR of AGN host galaxies with the SFR of non-AGN systems, as a function of various black hole properties. For the comparison of the SFR of AGN and non-AGN galaxies, we use the SFR_{norm} parameter. SFR_{norm} is measured following the process of our previous studies (e.g., Mountrichas et al. 2021c, 2022b,a). Specifically, the SFR of each X-ray AGN is divided by the SFR of galaxies in the control sample that are within ± 0.2 dex in M_* and $\pm 0.075 \times (1+z)$ in redshift. Furthermore, each source is weighted based on the uncertainty of the SFR and M_{*} measurements made by CIGALE. Then, the median values of these ratios are used as the SFR_{norm} of each Xray AGN. We note that our measurements are not sensitive to the choice of the box size around the AGN. Selecting smaller boxes, though, has an effect on the errors of the calculations (Mountrichas et al. 2021c). The calculation of SFR_{norm} requires both datasets to be mass complete in the redshift range of interest. This requirement is met in the stellar mass range we perform our analysis (see Sect. 4).

3.3. Black hole mass measurements

Out of the 2512 AGN in the XXL-N catalogue that have reliable spectroscopy from SDSS-III/BOSS (Sect 2). 1786 have been classified as broad line AGN (BLAGN1), by Menzel et al. (2016). A source was classified as BLAGN1 using the full width at half-maximum (FWHM) threshold of 1000 Km s⁻¹. Liu et al. (2016) performed spectral fits to the BOSS spectroscopy of these 1786 BLAGN1 to estimate single-epoch virial M_{BH} from continuum luminosities and broad line widths (e.g., Shen et al. 2013). The details of the spectral fitting procedure are given in Sect. 3.3 of Liu et al. (2016) and in Shen et al. (2013). In brief, they first measured the continuum luminosities and broad line FWHMs. Then, they used several single-epoch virial mass estimators to calculate M_{BH} . Specifically, they applied the following fiducial mass recipes, depending on the redshift of the source: $H\beta$ at z < 0.9, Mg II at 0.9 < z < 2.2 and C IV at z > 2.2.

Previous studies have shown that single-epoch M_{BH} estimates that use different emission lines, when adopting the fiducial single-epoch mass formula, are generally consistent with each other with negligible systematic offsets and scatter (e.g.,

Shen et al. 2008, 2011; Shen & Liu 2012; Shen et al. 2013). Liu et al. (2016) confirmed these previous findings. Finally, their M_{BH} measurements have, on average, errors of ~ 0.5 dex, whereas sources with higher SNR have uncertainties of the measured M_{BH} that are less than 0.15 dex.

3.4. Bolometric luminosity of the AGN, Eddington ratio and specific black hole accretion rate calculations

There are two measurements available for the L_{bol} of the AGN in our sample. The catalogue of Liu et al. (2016) includes L_{bol} calculations. These have been derived by integrating the radiation directly produced by the accretion process, that is the thermal emission from the accretion disc and the hard X-ray radiation produced by inverse-Compton scattering of the soft disc photons by a hot corona (for more details see their Sect. 4.2). CIGALE also provides L_{bol} measurements. Mountrichas (2023) compared the two L_{bol} estimates and found that their distributions have a mean difference of 0.08 dex with a standard deviation of 0.42 dex. Following Mountrichas (2023), we choose to use the L_{bol} calculations of CIGALE. However, we note that using the L_{bol} measurements from the Liu et al. (2016) catalogue does not affect our results and conclusions.

The n_{Edd} is defined as the ratio of the bolometric luminosity, L_{bol} , and the Eddington luminosity, L_{Edd} . L_{Edd} is the maximum luminosity that can emitted by the AGN and is determined by the balance between the radiation pressure and the gravitational force exerted by the black hole ($L_{Edd}=1.26\times10^{38}\,M_{BH}/M_{\odot}\,{\rm erg\,s^{-1}}$). In our analysis, we use n_{Edd} measurements derived using the L_{bol} calculations from CIGALE, as opposed to those available in the Liu et al. (2016) catalogue. Nevertheless, this choice does not affect our results.

The λ_{sBHAR} is the rate of the accretion onto the SMBH relative to the M_* of the host galaxy. It is often used as a proxy of the Eddington ratio, in particular when black hole measurements are not available. For the calculation of λ_{sBHAR} the following expression is used:

$$\lambda_{sBHAR} = \frac{k_{bol} L_{X,2-10 \, keV}}{1.26 \times 10^{38} \, erg \, s^{-1} \times 0.002 \frac{M_*}{M_{\odot}}},$$
(1)

where k_{bol} is a bolometric correction factor, that converts the 2 – 10 keV X-ray luminosity to AGN bolometric luminosity. For our sample, L_{bol} measurements are already available, as described earlier in this section, and thus a bolometric correction is not required. Nevertheless, we choose to use equation 1 for the calculation of λ_{sBHAR} , as it is the most common method to calculate λ_{sBHAR} and it also will facilitate a direct comparison with the SFR_{norm} – λ_{sBHAR} measurements of our previous studies (Mountrichas et al. 2021c, 2022b). For the same reasons, instead of the M_{BH} measurements that are available for our sources, we choose to use the redshift-independent scaling relation between M_{BH} and bulge mass, M_{bulge} , of Marconi & Hunt (2003) with the assumption that the M_{bulge} can be approximated by the M_* . Specifically, we use $M_{BH}=0.002\,M_{bulge}$. Finally, for k_{bol} , we adopt the value of $k_{bol}=25$. This value is used in many studies (e.g., Elvis et al. 1994; Georgakakis et al. 2017; Aird et al. 2018; Mountrichas et al. 2021c, 2022b). Lower values have also be used (e.g., $k_{bol} = 22.4$ in Yang et al. 2017), as well as luminosity dependent bolometric corrections (e.g., Hopkins et al. 2007; Lusso et al. 2012). In Sect. 5.3.3, we examine how good these approximations are and what is their effect on the calculation of λ_{sBHAR} .

4. Final samples

In this section, we describe the criteria we apply to compile the final dataset of X-ray sources, drawn from the XMM-XXL catalogue (Sect. 2.1) and the final control sample of non-AGN galaxies, drawn from the VIPERS survey (Sect. 2.2).

4.1. The final X-ray dataset

We need to use only sources (X-ray and non-AGN galaxies) that have the most reliable M_{*} and SFR measurements. For that purpose, for the X-ray sources, we use the final sample presented in Mountrichas (2023). A detailed description of the photometric and reliability criteria that have been applied is provided in Sect. 2.4 of that study. In brief, we require our sources to have measurements in the following photometric bands: u, g, r, i, z, J, H, K, W1, W2 and W4, where W1, W2 and W4 are the WISE photometric bands at 3.4, 4.6 and $22 \mu m$. To exclude sources with bad SED fits and unreliable host galaxy measurements, a reduced χ^2 threshold of $\chi_r^2 < 5$ has been imposed (e.g. Masoura et al. 2018; Buat et al. 2021). We also exclude systems for which CIGALE could not constrain the parameters of interest (SFR, M_{*}). Towards this end, the two values that CIGALE provides for each estimated galaxy property are used. One value corresponds to the best model and the other value (bayes) is the likelihoodweighted mean value. A large difference between the two calculations suggests a complex likelihood distribution and important uncertainties. We therefore only include in our analysis sources with $\frac{1}{5} \leq \frac{SFR_{best}}{SFR_{bayes}} \leq 5$ and $\frac{1}{5} \leq \frac{M_{*,best}}{M_{*,bayes}} \leq 5$, where SFR_{best} and $M_{*,best}$ are the best-fit values of SFR and M_{*} , respectively and SFR_{bayes} and M_{*,bayes} are the Bayesian values estimated by CIGALE. 687 broad-line, X-ray AGN with spectroscopic redshifts meet the above requirements and also have available M_{BH} measurements in the catalogue of Liu et al. (2016).

We then restrict the redshift range of the X-ray dataset to match that of the galaxy control sample (i.e., the VIPERS survey, $0.5 \le z \le 1.2$). 240 AGN meet this requirement. In Mountrichas et al. (2021c, 2022b,a), we found that the SFR_{norm} -L_X relation depends on the M_{\ast} range probed by the sources. Specifically a flat SFR_{norm}-L_X relation was found for the least and most massive systems (log $[M_*(M_{\odot})]$ < 10.5 and log $[M_*(M_{\odot})]$ > 11.5), with SFR_{norm} ~ 1 . Albeit, for intermediate stellar masses (10.5 < $log[M_*(M_{\odot})] < 11.5)$ SFR_{norm} was found to be ≤ 1 at low-tomoderate L_X (log [$L_{X,2-10keV}(erg s^{-1})$] < 44) whereas at higher L_X , SFR_{norm} > 1 (e.g., see Fig. 5 in Mountrichas et al. 2022a). Therefore, in this study, we restrict the analysis to those sources with $10.5 < \log [M_*(M_{\odot})] < 11.5$. Within this M_* range both of our datasets are also mass complete (Davidzon et al. 2013; Mountrichas & Shankar 2023), as it required for the calculation of SFR_{norm} .

Following previous studies that examined the impact of the AGN feedback on their host galaxies, by calculating SFR_{norm} using only star-forming systems (e.g., Mullaney et al. 2015; Masoura et al. 2018; Mountrichas et al. 2021c), we exclude from our sources quiescent (Q) systems. To identify Q galaxies, we use the distribution of the specific SFR (sSFR = $\frac{SFR}{M_*}$) measurements of the galaxy control sample (i.e., similarly to Mountrichas et al. 2021c, 2022b,a). Mountrichas & Shankar (2023), applied this methodology on sources in the XMM-XXL field to classify galaxies as Q. From their subset of Q sources, 19 are among our 178 AGN. Their exclusion results in 159 X-ray systems. We note that the inclusion of the 19 AGN hosted by Q

Table 1: p-values from the correlation analysis we apply for the four SMBH properties used in our analysis.

relation	Pearson	Spearman	Kendall
M_{BH} -L _X	2.1×10^{-11}	3.4×10^{-11}	6.5×10^{-11}
n_{Edd} - L_X	0.40	0.59	0.51
λ_{sBHAR} - \mathbf{L}_X	2.9×10^{-15}	2.0×10^{-14}	2.6×10^{-13}
n_{Edd} - M_{BH}	4.7×10^{-15}	6.5×10^{-14}	1.1×10^{-12}
λ_{sBHAR} - M_{BH}	6.6×10^{-6}	6.7×10^{-6}	5.2×10^{-6}
λ_{sBHAR} -n $_{Edd}$	6.1×10^{-7}	1.4×10^{-5}	1.3×10^{-5}

systems in our analysis, does not affect our overall results and conclusions.

Since the galaxy control sample used in this study is smaller compared to those used in our previous works (see next section), we apply a final criterion to ensure that the SFR_{norm} calculations of each AGN that is included in our analysis is robust. That is, we only use AGN that their SFR_{norm} has been calculated by matching the X-ray sources with at least 300 sources in the galaxy control sample. Increasing this threshold reduces significantly the size of the X-ray dataset, while at lower values the scatter of our measurements is higher. 122 X-ray AGN fulfil all the aforementioned criteria. Their L_X and M_{BH} as a function of redshift are presented in Figure 1.

4.2. The final galaxy control sample

For the galaxy control sample, we apply the same photometric selection criteria and reliability requirements that we applied for the X-ray AGN sample. In addition, we exclude sources that are included in the X-ray catalogue and we identify and reject non-X-ray AGN systems. Specifically, we use the CIGALE measurements and exclude sources with $frac_{AGN} > 0.2$, consistently with our previous studies (Mountrichas et al. 2021c, 2022b,a). frac_{AGN} is the fraction of the total IR emission coming from the AGN. This excludes $\sim 60\%$ of the sources in the galaxy reference catalogue. This fraction is in line with our previous studies. A detailed analysis of the frac_{AGN} criterion is provided in Sect. 3.3 in Mountrichas et al. (2022a). There are 3622 galaxies that fulfil all the aforementioned requirements. Finally, we exclude quiescent galaxies following the process described in the previous section. There are 3371 galaxies that remain and these are the sources in our control sample that we include in the analysis.

5. Results and Discussion

We compare the SFR of AGN and non-AGN galaxies as a function of various black hole properties. Specifically, we study SFR_{norm} as a function of L_X, M_{BH}, n_{Edd} and λ_{sBHAR} . Fig. 2, presents the four SMBH properties for the final X-ray dataset. We also apply three correlation statistics, one parametric (Pearson) and two non-parametric statistics (Spearman and Kendall), to quantify the correlations among them. The p-values are presented in Table 1. All parameters are strongly correlated with each other with the exception of the n_{edd} –L_X.

5.1. SFR_{norm} as a function of X-ray luminosity

First, we examine SFR_{norm} as a function of L_X . The results are shown in the left, top panel of Fig. 3. The small, blue circles present the measurements for individual AGN, while the large,

Fig. 1: L_X (left panel) and M_{BH} (right panel) as a function of redshift, for the 122 X-ray AGN used in our analysis.

red circles show the binned results. For the latter, the measurements are grouped in bins of L_X of size 0.5 dex. The errors presented are 1σ errors, calculated via bootstrap resampling (e.g., Loh 2008). We find that the SFR of AGN is lower or at most equal to that of non-AGN galaxies (SFR_{norm} \leq 1) at low and moderate L_X (log [$L_{X,2-10\text{keV}}$ (ergs⁻¹)] \leq 44) and increases at higher L_X , in agreement with previous studies (Mountrichas et al. 2021c, 2022b,a).

The p-values from the three correlation statistics we use to calculate the correlation between SFR_{norm} and L_X , are presented in Table 2. The results indicate a strong correlation between the two parameters, independent of the statistical method applied.

5.2. SFR_{norm} as a function of black hole mass

In a recent study, Piotrowska et al. (2022), analyzed three cosmological hydrodynamical simulations (Eagle, Illustris and IllustrisTNG), by utilizing Random Forest classification. They searched for the most effective parameter to separate star-forming and quenched galaxies, in the local universe. They considered stellar mass, dark matter halo mass, black hole accretion rate and black hole mass in their investigation. Their analysis showed that black hole mass was the most predictive parameter of galaxy quenching. Bluck et al. (2023), extended these results from the local universe to cosmic noon. These findings suggest that the cumulative impact of AGN feedback on a galaxy is encapsulated in the mass of the supermassive black hole and not in the X-ray luminosity, which is a proxy of the current accretion rate.

Hence, here we examine the SFR_{norm} as a function of black hole mass. Our goal is to examine if SFR_{norm} and M_{BH} are correlated and compare their correlation with that between SFR_{norm} and L_X. The top, right panel of Fig. 3 presents the SFR_{norm} as a function of M_{BH}. The results show that SFR_{norm} increases with M_{BH} on the full range of black hole masses spanned by our dataset. Specifically, in galaxies that host AGN with low M_{BH} (log [M_{BH} (M_{\odot})] < 8) their SFR is lower or equal to the SFR of non-AGN systems. AGN with more massive black holes (log [M_{BH} (M_{\odot})] > 8.5) live in galaxies that their SFR is enhanced compared to non-AGN. The correlation analysis (Table 2) suggests a strong correlation between SFR_{norm} and M_{BH}.

We also split our datasets into two redshift bins, using a threshold at z=0.9 and repeat the correlation analysis. The choice of the redshift cut is twofold. Primarily, it aligns with

the median redshift of the AGN sample. Furthermore, this redshift value corresponds to the redshift at which different spectral lines have been used for the calculation of M_{BH} (see Sect. 3.3). The results are presented in Tables 3 and 4. The same trends are observed with those using sources in the full redshift interval, that is a strong correlation is found between SFR_{norm} and M_{BH} in both redshift ranges. However, this correlation appears less strong in the lowest redshift interval compared to that found in the highest redshift bin. This could imply that the correlation between the two properties is, mainly, driven by massive M_{BH} $(M_{BH} > \sim 10^{8.5} M_{\odot})$ that are poorly detected at z < 0.9 in the dataset used in our analysis (Fig. 1). This interpretation is also supported by the strong correlation between L_X and M_{BH} (Fig. 2) combined with the results from previous studies that have shown that the SFR_{norm}-L_X relation is nearly flat at L_X < 10^{44} erg/s and shows a positive correlation only at higher L_X (Mountrichas et al. 2021c, 2022b,a).

A comparison of the p-values with those in the previous section, shows that the correlation between SFR_{norm} and M_{BH} is similar to that between SFR_{norm} and L_X. Subsequently, we explore whether this observation holds when considering the associated uncertainties of L_X and M_{BH}. For that purpose, we utilize the linmix module (Kelly 2007) that performs linear regression between two parameters, by repeatedly perturbing the datapoints within their uncertainties. The p-values obtained are 3.2×10^{-5} and 7.6×10^{-4} for the SFR_{norm}-L_X and SFR_{norm}-M_{BH}, respectively. These findings suggest, that despite accounting for uncertainties in L_X and M_{BH} measurements, there exists a robust correlation between these two properties and SFR_{norm} and that the two correlations are indeed similar.

As shown in Fig. 2 and Table 1, L_X and M_{BH} are strongly correlated. To investigate further the correlation among SFR_{norm}, L_X and M_{BH} , we perform a partial-correlation analysis (PCOR). PCOR measures the correlation between two variables while controlling for the effects of a third (e.g. Lanzuisi et al. 2017; Yang et al. 2017; Mountrichas et al. 2022b). We use one parametric statistic (Pearson) and one non-parametric statistic (Spearman). Table 5 lists the results of the p-values. Regardless of the parametric statistic of choice, p-values for the SFR_{norm}- M_{BH} relation are smaller compared to the corresponding p-values for the SFR_{norm}- L_X relation. This implies that the correlation between SFR_{norm} and M_{BH} is more robust compared to that with L_X , even when factoring in the existing correlation between M_{BH} and L_X .

Fig. 2: Correlations among the four SMBH properties used in our study. Specifically, we present the correlations among the M_{BH} , the L_X , the specific black hole accretion rate $(\lambda_{sBHAR} \propto \frac{L_X}{M_*})$ and the Eddington ratio $(n_{Edd} \propto \frac{L_{bol}}{M_{BH}})$. The p-values from the correlation analysis are shown in Table 1.

This deduction remains valid even when we partition the dataset into two redshift bins, specifically at z = 0.9.

Mountrichas et al. (2022b) applied PCOR analysis on sources in the COSMOS field and found that SFR_{norm} is correlated stronger with M_* than with L_X . Yang et al. (2017) used galaxies in the CANDELS/GOODS-South field and examined the correlation between the black hole accretion rate (BHAR; which is measured directly from the L_X), SFR and M_* . They found that the BHAR is linked mainly to M_* rather than SFR. There is also a well known correlation between the M_* and the M_{BH} (e.g., Merloni et al. 2010; Sun et al. 2015; Suh et al. 2020; Setoguchi et al. 2021; Poitevineau et al. 2023). Recently, Mountrichas (2023) reported such a correlation between M_{BH} and M_* using AGN in the XMM-XXL field, that is the same X-

ray dataset used in this work. We apply a PCOR analysis, this time among SFR_{norm}, M_{BH} and M_* . The results presented in Table 6 (top two lines) suggest that SFR_{norm} is linked more to M_{BH} than M_* . However, we note that, for the reasons mentioned in Sect. 4, our datasets have been restricted to a relatively narrow M_* range (10.5 < log [$M_*(M_\odot)$] < 11.5). Therefore, although the M_{BH} parameter spans ~ 2.5 orders of magnitude, M_* spans only an order of magnitude in our samples.

To increase the M_* range that our sources probe, we lift the M_* requirement. There are 209 AGN and 4454 galaxies within $10 < \log \left[M_*(M_\odot) \right] < 12$. Using these two subsets we calculate the SFR_{norm} for the 240 AGN and, then, we apply a PCOR analysis among SFR_{norm}, M_{BH} and M_* . The results are presented in the two bottom lines of Table 6. The p-

Fig. 3: SFR_{norm} as a function of SMBH properties. The SFR_{norm} parameter as a function of L_X (top, left panel), M_{BH} (top, right panel), Eddington ratio (bottom, left panel) and λ_{sBHAR} (bottom, right panel) are presented.

values of the non-parametric statistic (Spearman) are similar, however, the p-value using the parametric statistic (Pearson) are lower for the SFR_{norm}-M_{BH}, suggesting that the correlation between SFR_{norm}-M_{BH} is stronger than the correlation between SFR_{norm}-M_{*}. We note that these results should be taken with caution since our samples are not mass complete in the full M_{*} range that is considered in this exercise and specifically within $10.0 < \log \left[M_*(M_\odot) \right] < 10.5$.

Overall, we conclude that SFR_{norm} is mostly linked to M_{BH} rather than L_X. Our results also suggest that the SFR_{norm}-M_{*} correlation is due to the underlying M_*-M_{BH} . The picture that emerges corroborates the idea that the M_{BH} is a more robust tracer of AGN feedback compared to the instantaneous activity of the SMBH - represented by L_X - and as such M_{BH} is a better predictive parameter of the changes of the SFR of the host galaxy, as theoretical studies have also suggested (Piotrowska et al. 2022; Bluck et al. 2023). Our results are also in line with the aforementioned studies regarding the negative AGN feedback they report, at least up to $M_{BH} \sim 10^{8.5}~M_{\odot}$ (i.e., SFR_{norm} < 1). The increase of SFR_{norm} we detect in our results, suggest that this negative feedback may become less impactful on the SFR of the host galaxy, as we transition to systems with more massive SMBHs. These studies have additionally shown that the fraction of quenched galaxies increases with M_{BH} . To investigate this claim, we would need to examine the fraction of quiescent systems as a function of M_{BH} , in our dataset. However, the small

5.3. SFR_{norm} as a function of Eddington ratio and specific black hole accretion rate

In this section, we investigate the correlation between SFR_{norm} and two other SMBH properties, that represent the instantaneous AGN activity. Specifically, we study the relation between $SFR_{norm}-n_{Edd}$ and $SFR_{norm}-\lambda_{sBHAR}$. We also examine whether λ_{sBHAR} is a good proxy of the n_{Edd} .

5.3.1. SFR_{norm} as a function of Eddington ratio

The Eddington ratio provides another important property of the SMBH. Setoguchi et al. (2021) used 85 moderately luminous ($\log L_{bol} \sim 44.5 - 46.5 \, \mathrm{erg \, s^{-1}}$) in the Subaru/XMM-Newton Deep Field (SXDF) and found a strong correlation between the SFR of AGN and n_{Edd} (correlation coefficient: r=0.62). Recently, Georgantopoulos et al. (2023) studied the stellar populations of obscured and unobscured AGN at 0.6 < z < 1.0. Based on their analysis, the stellar age of both AGN types increases at lower Eddington ratio values (see the bottom left panel of their Fig. 4 and the top, right panel of their Fig. 11).

The bottom, left panel of Fig. 3, presents our calculations for SFR_{norm} as a function of the Eddington ratio. SFR_{norm} remains roughly constant regardless of the value of n_{Edd} . This is confirmed by the results of the correlation analysis, shown in Table 2 (see also Tables 3 and 4 for different redshift intervals). This nearly flat SFR_{norm}- n_{Edd} relation can be explained by the correlations among the M_{BH} , L_X and n_{Edd} , presented in Fig. 2. There is a strong anti-correlation between n_{Edd} and M_{BH} , but a positive correlation between n_{Edd} and L_X , while a strong positive correlation is detected between M_{BH} and L_X . We note, that, when we examine the relation between the SFR of AGN and n_{Edd} , we find a (strong) correlation (r = 0.54), similar to that found by Setoguchi et al. (2021).

5.3.2. SFR_{norm} as a function of specific black hole accretion rate

The specific black hole accretion rate is often used as a proxy of the Eddington ratio. Previous studies found an increase of the SFR_{norm} with λ_{sBHAR} (Figures 10 and 11 in Mountrichas et al. 2021c, 2022b, respectively). Pouliasis et al. (2022), used X-ray AGN in the COSMOS, XMM-XXL and eFEDS, at z > 3.5 and found that AGN that lie inside or above the main-sequence (i.e.,

Table 6: p-values of partial correlation analysis, among SFR_{norm}, M_* and M_{BH} .

	Pearson	Spearman
SFR _{norm} -M _*	0.515	0.0068
SFR_{norm} - M_{BH}	1.6×10^{-8}	2.5×10^{-9}
SFR_{norm} - M_* (ext)	0.027	2×10^{-6}
SFR_{norm} - M_{BH} (ext)	1.1×10^{-5}	5×10^{-6}

Notes. The top two lines present the results using sources within $10.5 < \log{[M_*(M_\odot)]} < 11.5$. The bottom two lines present the results within $10 < \log{[M_*(M_\odot)]} < 12$

Fig. 4: Comparison of the L_{bol} calculations of CIGALE with the L_{bol} measurements using the formula derived in Lusso et al. (2012). The two measurements are in very good agreement with a mean difference of 0.04 dex. and a dispersion of 0.34.

SFR_{norm} \geq 1) have higher λ_{sBHAR} compared to X-ray sources that lie below the MS.

Our results, presented in the bottom, right panel of Fig. 3 agree with these previous findings. Specifically, we observe an increase of SFR_{norm} with λ_{sBHAR} . Application of correlation analysis shows that there is a strong correlation between the two parameters, albeit not as strong as the correlation found between SFR_{norm}-L_X and SFR_{norm}-M_{BH} (Tables 2, 3 and 4).

Mountrichas et al. (2022b) examined the correlation between SFR_{norm} and λ_{sBHAR} using X-ray sources in the COSMOS field and compared their results with those using AGN in the Boötes, presented in Mountrichas et al. (2021c) (see Fig. 11 and Table 5 in Mountrichas et al. 2022b). Although both datasets present a nearly, linear increase of the SFR_{norm} with L_X , the amplitude of SFR_{norm} differs for the same λ_{sBHAR} values, for the two datasets. They attributed this difference to the different properties of the AGN from the two samples included in λ_{sBHAR} bins of the same value. Specifically, COSMOS sources are less luminous and less massive than their Boötes counterparts in λ_{sBHAR} bins of similar values. Therefore, if a dataset probes AGN within a large range of L_X and M_{*}, this could increase the scatter of SFR_{norm} for the same λ_{sBHAR} values and thus weaken the correlation between SFR_{norm} and λ_{sBHAR} , rendering λ_{sBHAR} not a good parameter to study the impact of AGN feedback on the SFR of the host galaxy.

5.3.3. Is λ_{sBHAR} a good proxy of the Eddington ratio?

As mentioned in the previous section, λ_{sBHAR} is often used as a proxy of n_{Edd} on the basis that there is a linear relation between the M_* and M_{BH} and that L_{bol} can be inferred by L_X . Prompted by the different relations found between SFR_{norm}- n_{Edd} and SFR_{norm} - λ_{sBHAR} , we investigate this further.

Lopez et al. (2023) used X-ray selected AGN in the mini-JPAS footprint and found, among others, that the Eddington ratio and λ_{sBHAR} have a difference of 0.6 dex. They attributed this difference to the scatter on the $M_{BH}-M_*$ relation of their sources. The median value of n_{Edd} of our sample, calculated using the L_{bol} measurements of CIGALE, is $n_{Edd} = -1.26$, ($n_{Edd} = -1.33$, using the values available in the Liu et al. 2016, catalogue). The median value of λ_{sBHAR} , estimated using eqn 1, is $\lambda_{sBHAR} = -1.08$. Thus, we find a median difference of ~ 0.25 between n_{Edd} and λ_{sBHAR} . Although this difference is lower than that reported by Lopez et al. (2023), below we examine the cause of it.

We re-calculate λ_{sBHAR} , using the L_{bol} measurements from CIGALE (see Sect. 3.4) instead of the product of k_{bol} L_X . In this case, the median value of λ_{sBHAR} is -1.25. This value is in excellent agreement with that of n_{Edd} (-1.26), using for the calculation of the latter the L_{bol} measurements from CIGALE. We also calculate λ_{sBHAR} keeping the same numerator as in eqn 1, but using the M_{BH} measurements available in our dataset instead of the $M_{BH}-M_*$ scaling relation. In this case, the median difference between the distributions of λ_{sBHAR} and n_{Edd} is ~ 0.08 . We note that for the sources used in our analysis, the scaling relation between M_{BH} and M_* is, $M_{BH} \approx 0.003 \, M_*$ (see also Sect. 3.3 in Mountrichas 2023), which is in good agreement with the $M_{BH} = 0.002 \, M_{bulge}$ used in eqn 1.

Therefore, the way the L_{bol} is calculated seems to play an equally important role with the $M_{BH}-M_*$ scaling relation on the comparison between n_{Edd} and λ_{sBHAR} , in our sample. The mean difference between the L_{bol} calculated by CIGALE and the product of $k_{bol} L_X$ is 0.24 dex with a dispersion of 0.35. CIGALE measurements suggest a mean $k_{bol} = 14.8$ (i.e., for the two L_{bol} measurements to have a mean difference of zero). Finally, we compare the L_{bol} measurements of CIGALE with those using a luminosity dependent k_{bol} . Specifically, we use the prescription of Lusso et al. (2012), using the values presented in their Table 2 for their spectroscopic, type-1 AGN. In this case, the two calculations are in very good agreement with a mean difference of 0.04 dex and a dispersion of 0.34. Fig. 4 presents the comparison between the L_{bol} measurements using the formula presented in Lusso et al. (2012) and CIGALE.

We conclude that caution has to be taken when λ_{sBHAR} is used as a proxy of n_{Edd} , since the calculation of L_{bol} and the scatter in the $M_{BH}-M_*$ scaling relation can cause (large) discrepancies between the estimated values of the two parameters.

6. Conclusions

We used 122 X-ray AGN in the XMM-XXL-N field and 3371 VIPERS galaxies, within redshift and stellar mass ranges of 0.5 \leq z \leq 1.2 and 10.5 < log $[M_*(M_\odot)]$ < 11.5, respectively. The X-ray sources probe luminosities within 43 < log $[L_{\rm X,2-10keV}(ergs^{-1})]$ < 45. Both populations meet strict photometric selection criteria and various selection requirements to ensure that only sources with robust (host) galaxy measurements are included in the analysis. The latter have been calculated via SED fitting, using the CIGALE code. Using these datasets, we calculated the SFR $_{norm}$ parameter, to compare the SFR of AGN

with the SFR of non-AGN galaxies, as a function of various black hole properties. Specifically, we examined the correlations of SFR_{norm} with the L_X, M_{BH}, n_{Edd} and λ_{sBHAR} . Our main results can be summarized as follows:

- AGN with low black hole masses ($\log{(M_{BH}/M_*)} < 8$) have lower or at most equal SFR compared to that of non-AGN galaxies, while AGN with more massive black holes ($\log{(M_{BH}/M_*)} > 8.5$) tend to live in galaxies with (mildly) enhanced SFR compared to non-AGN systems.
- SFR_{norm} strongly correlates with both L_X and M_{BH} . However, the correlation between SFR_{norm}- M_{BH} is stronger compared to the correlation between SFR_{norm}- L_X . Our results also suggest that M_{BH} drives the correlation between SFR_{norm}- M_* found in previous studies.
- We do not detect a significant correlation between SFR_{norm} and Eddington ratio.
- A correlation is found between SFR_{norm} and specific black hole accretion rate. However, this correlation is weaker compared to that between SFR_{norm}-L_X and SFR_{norm}-M_{BH} and its scatter may increase for samples that span a wide range of L_X and M_{*}.
- The estimation of the AGN bolometric luminosity and the scatter of the M_{BH}-M_{*} scaling relation, may cause discrepancies between the specific black hole accretion rate and the Eddington ratio measurements. Therefore, caution has to be taken when the former is used as a proxy for the latter.

The results suggest that there is a strong correlation between SFR_{norm} and AGN activity, when the latter is represented by L_X , λ_{sBHAR} and M_{BH} . A flat relation was only found between SFR_{norm} and n_{Edd} , that can be interpreted as the net result of the different correlations (i.e., positive and negative) among n_{edd} , M_{BH} and L_X (Fig. 2). Based on our analysis, M_{BH} is the most robust tracer of AGN feedback and the best predictive parameter of the changes of the SFR of the host galaxy.
