ter the long-standing aging issue was overcome [6] by coating the MCPs with an ultra-thin layer of alumina and/or magnesia by applying an ALD (atomic layer deposition) technique [7] to the MCP pores the performance of recent devices was additionally optimized in other important parameters like, e.g., the collection efficiency and the QE and gain homogeneity across the active surface. This and other advantageous properties in terms of radiation hardness, an excellent time resolution, a low

monitoring the integrated anode charge (IAC) and measuring the spectral and spatial QE distribution in regular time intervals. In 10 years of PANDA operation time a MCP-PMT has to withstand $\geq 5 \,\mathrm{C}\,\mathrm{cm}^{-2}$ IAC without suffering any photocathode damage.

Figure 1 shows the current status of the lifetime performance for various MCP-PMTs from different vendors. When comparing non-ALD tubes to tubes with ALD coating a tremendous

Figure 1: QE (400 nm) versus IAC; lifetime data for various ALD-coated MCP-PMTs from different vendors compared to non-ALD PMTs (upper right).

increase of collected IAC without QE loss is visible (compare also to Refs. [10, 11, 12, 13]). The by far best-performing MCP-PMT is Photonis 9001393, which has collected almost 35 C cm^{-2} IAC which would correspond to nearly 70 years of PANDA operation time. Both latest Photonis tubes 9002192 & 9002193 surpassed the requirement without any QE decrease as well. Also seen in fig. 1 the Photek A1200107 and A3191220 tubes show a continous QE decrease from the beginning of illumination.

Figure 2: QE scans of Photek A3191220 measured at a wavelength of 372 nm in 0.5 mm steps: (a) in February 2020 directly after the receipt of the tube, and (b) in March 2022 two years later.

In fig. 2 two QE surface scans of Photek A3191220 are exemplarily shown for different dates and collected IACs. Even though the left half of the sensor was covered and only the right side illuminated, the QE started dropping from the inital bad spot in the bottom left corner. A similar behavior was observed for the Photek A1200107 with the left half having been illuminated and the Photek A1200116 even without illumination at all [14]. These results and the fact that all three MCP-PMTs have spots with low QE in some corners are strong indicators for vacuum microleaks. The problem seems to be solved meanwhile as the later produced Photek A2200606 does neither have evolving QE damages nor shows any QE loss up to 2.4 C cm⁻².

Figure 3: QE (a) and gain (b) surface scans of two of the most recent Photonis MCP-PMTs measured at a wavelength of 372 nm in 0.5 mm step sizes.

In fig. 3 surface scans of two of the most recent Photonis MCP-PMTs are presented. Fig. 3a shows the QE spatial distribution of the Photonis 9002222 while in fig. 3b the spatial distribution of the gain (corrected for QE) is presented. For an easier comparison of the quantitative values in terms of uniformity the mean QE and gain, respectively, are calculated for each anode pixel to determine a maximum to minimum ratio. Figures 4 and 5 show the QE and gain uniformity plotted versus the active area for the latest Photek and Photonis MCP-PMTs.

Figure 4: Max/min ratio of the QE uniformity across the active area.

For the PANDA Barrel DIRC a QE max/min ratio over the

Figure 5: Max/min ratio of the gain uniformity across the active area.

whole active area of less than 1.5 is required, which is met by all MCP-PMTs shown in fig. 4 except for the Photek A3191220. It exceeds this limit due to the initial QE damage seen in fig. 2a. For the gain uniformity a max/min ratio of less than 3 is required. This is fulfilled for at least 90 % of the active area for all sensors shown in fig. 5 apart from Photek A1200107 which exceeds the required max/min ratio already after 55 % active area.

2.2. MCP-PMT characteristics inside magnetic fields

Another important aspect of MCP-PMTs is their performance inside magnetic fields. Therefore several test measurements were performed using a dipole magnet with a field strength up to 2.1 T. In fig. 6 the results of gain measurements with three different MCP-PMTs are shown where a central pixel was illuminated with single photon intensity for different field strengths and tilting angles.

Figure 6: Gain versus magnetic field strength for different tilting angles between PMT-axis and field direction.

The gain behavior of Photek A12000116, Photonis 9002192 and 943P541 (3x100 anode pixels) is shown in fig. 6 (6a, 6b, and 6c, respectively). All tubes show different slopes of the gain behavior. The tubes with 8x8 anode pixels show a gain loss factor of \sim 3 from 0 to 1 T while the Photonis MCP-PMT with 3x100 anode pixels loses only a factor of 2 in gain due to a different internal geometry. For higher magnetic fields up to 2 T the Photonis MCP-PMTs show a significantly higher gain loss than the Photek tube. The main reason for the big difference in gain loss is the MCP pore diameter, 6 µm for the Photek MCP-PMT and 10 µm for the Photonis devices.

Another investigated effect is the change of the charge cloud width with increasing magnetic field strength. In fig. 7 all events are plotted where only one of the 64 anodes detected a charge signal (= 1 hit). At 0.02 T the pixels in fig. 7a are clearly separated since at this field the charge cloud at the anode is still quite wide and it is likely that the charge is spread across two or more pixels simultaneously. This produces two (or more) detected hits. At 1.0 T, seen in fig. 7b, the gap between the pixels shrinks drastically because the charge cloud width and thus the probability of hitting two or more pixels at the same time is decreased. This shows that at a high magnetic field the spatial resolution of the PMT is improved.

(a) Spatial distribution of one hit events at (b) Spatial distribution of one hit events at 0.02 T field strength. 1.0 T field strength.

Figure 7: Spatial charge distribution for one hit events at a low and a high magnetic field strength. Only the inner 9 anode pixels of the MCP-PMT Photonis 9002192 were scanned. The upper left hole corresponds to a dead electronics channel.

2.3. Collection efficiency (CE) and time resolution

The CE describes the fraction of how many photoelectrons created at the PC lead to a measurable signal at the anode.

The number of signals at the anode $N_{pe, Anode}$ can be extracted from a fit [15] to the charge distribution spectrum measured at a low laser frequency f_{low} (~10 kHz) in standard operation mode. The number of photoelectrons $N_{pe, PC}$ created at the PC can only be measured indirectly. For this the sensor is illuminated at high frequencies f_{high} in the order of tens of MHz and operated in the QE setup mode (200 V between PC and MCP-in) where the current $I_{PC,f_{high}}$ at the MCP-in is measured. In both setups the laser beam was split to additionally measure the laser intensity with a calibrated photodiode because the number of photons per pulse changes with frequency ($I_{diode, f_{high}}, I_{diode, f_{low}}$). The CE can then be calculated with the following formula:

$$CE = \frac{N_{pe, Anode, f_{low}} \cdot e \cdot f_{high}}{I_{PC, f_{high}}} \cdot \frac{I_{diode, f_{high}} \cdot f_{low}}{I_{diode, f_{low}} \cdot f_{high}}$$

In table 1 the results of the CE for various MCP-PMTs from different production years and vendors are compared. Old sensors of Photonis like the 9001394 have a CE of ~65 %. A comparable Hamamatsu MCP-PMT like the YH0250 has a similar CE. For older MCP-PMTs (JS0022) from Hamamatsu which had a PC protection film in front of the first MCP a significantly reduced CE was measured. Later Photonis has built the Hi-CE MCP-PMT 9002108 with an increased CE of up to 95 %. The newest MCP-PMTs of Photonis and Photek reach similar values.

Table 1: Collection efficiency measured for different types of MCP-PMTs.

The increased CE was reached by capturing more electrons recoiling from the MCP-in and guiding them to the MCP pores for amplification. This however deteriorates the time resolution. In fig. 8a the result of the time resolution measurement in standard operation setup (~200 V PC-MCP voltage) is shown. One obtains a transit time spread σ_{TTS} of 42 ps and σ_{RMS} of 290 ps in the time window of -0.5 to 2 ns. By applying a higher voltage between PC and MCP-in (~700 V) the well separated recoil peak, seen in fig. 8a, is now shifted into the main peak, shown in fig. 8b. This leads to a significantly improved σ_{RMS} of 109 ps.

2.4. Rate capability

Due to the high interaction rates of up to 20 MHz protonantiproton annihilations in the PANDA experiment the MCP-PMTs have to be able to detect photons at high rates without gain loss. To obtain the results of the rate capability a reference diode as well as the whole MCP-PMT were illuminated homogeneously (by using a diffusor) and the current of the diode and that of all anode pixels shorted were measured. While the photon rate is increased the PMT anode current and that of the reference diode are compared. Once the shorted anode current increases at a lower rate than the diode current this is an indication of a gain saturation. The gain drop is caused by a too slow recharging of the MCP pores due to the high MCP resistance.

Figure 9: Results of the rate capability measurement.

The results of these measurements are presented in fig. 9 for different MCP-PMTs. For the PANDA Barrel DIRC a photon rate of a few 100 kHz cm⁻² is expected whereas it is $\sim 1 \text{ MHz cm}^{-2}$ for the Endcap Disc DIRC. The sensors shown in fig. 9 loose $\sim 10 \%$ or less gain at 1 MHz cm⁻² photon rate, so they are suitable for both DIRC detectors.

2.5. Results of measurements with the TRB/DiRICH system

The multihit capable TRB/DiRICH DAQ system [16] is used to perform surface scans of the MCP-PMTs [17]. By analysing the hit time and the time over threshold information for each hit of every anode channel and combining this with other measured quantities, e.g., the xy-position and the hit multiplicity one can deduce higher level internal PMT properties like afterpulse ratio, dark count rate, charge sharing and electronic crosstalk, and the time resolution.

To deduce the afterpulse ratio the following approach is applied: in the analysis the same threshold is used for all hits and the measured hit time distribution (ranging from -10 to $1 \mu s$) is shifted in such a way that the centroid of the laser induced main peak is at 100 ns. The integral of this main peak is determined between 99 ns and 104 ns. The afterpulse time window is defined from 104 to 604 ns. In addition, the number of dark count hits is calculated within a wide window before the main peak (e.g., between -1000 to 0 ns). Given that, the afterpulse ratio is simply defined as the ratio between the integral. Both values are corrected for the number of darkcount hits appropriately scaled to the integration time windows.

Figure 10: Afterpulse ratio and dark count rate of Photonis 9002223.

In fig. 10 the results of the afterpulse ratio (fig. 10a) and dark count rate per pixel (fig. 10b) are shown. A mean afterpulse ratio for the whole tube of 0.74 % and a mean dark count rate of 104 Hz per pixel corresponding to 247 Hz cm⁻² is received, which meet the requirements of the DIRC detectors.

2.6. Escalation

While performing test measurements with recent MCP-PMTs from Photonis an unexpected new behavior was observed. When the MCP-PMT is operated at high gains (\gtrsim 5×10^6) several not yet understood effects start to show up already at low (few kHz single photons) or even without photon illumination. This also indicates that the effect is not correlated to the rate capability of the tube. At high photon rates the effect may already be triggered at lower gains. The main observations when escalation starts are:

- massive count rate increase
- significant gain drop
- drop of the MCP resistance
- · significant production of white photons

(a) MCP and anode currents before and during escalation for the Photonis 9002222. The applied gain was $\sim 5 \times 10^6$ and there was no external photon illumination.

(b) Picture of the Photonis 9002193 (c) Picture of the same MCP-PMT built in measurement setup before as in fig. 11b, while operated in "esoperation. calation" mode without external illumination. 20 s exposure time of the photograph.

Figure 11: Some escalation effects seen in the recent MCP-PMTs with two ALD layers.

In fig. 11a the MCP and anode currents versus time are shown. A slight increase of the MCP voltage by 10 V causes a massive increase of the currents at the anode and across the MCPs. In order to investigate the increased count rate, a digital camera was placed opposite to the MCP-PMT. In Fig. 11b a reference picture of the tube before operation is displayed. Figure 11c shows the same MCP-PMT when operated in this "escalation" mode without ambient light and for a 20 s exposure time. One can clearly see that a massive number of photons is generated inside the sensor which explains the increased count rate. Further tests showed that these photons are created at or inside the MCP layers. At this point it is not yet clear if the observed escalation effect is of a similar origin as the signal induced noise reported in [18] and other references.

3. Conclusion and outlook

Over the last years several significant improvements of MCP-PMTs were made. Especially the lifetime was increased enormously by applying an ALD technique to the pores. Furthermore, with the newest MCP-PMTs reaching $\geq 90 \%$ CE, a big improvement in detective quantum efficiency was accomplished. A somewhat worrisome observation is the "escalation" effect currently seen only in MCP-PMTs with two ALD layers. The consequences of this effect is being further investigated. Nevertheless, the recent MCP-PMTs are suitable for operation in both PANDA DIRC detectors. For the Barrel DIRC 155 Photonis MCP-PMTs of the type XP85112-S-BA were ordered. Delivery of the series production tubes to Erlangen started in May 2022 and seven units are currently undergoing detailed quality assurance measurements.
