Keywords: two-dimensional magnets, magnetic skyrmions, first-principle calculation

**Abstract:** 

The realization of magnetic skyrmions in two-dimensional (2D) magnets holds great

promise for both fundamental research and device applications. Despite recent progress,

two-dimensional skyrmions hosts are still limited, due to the fact that most 2D magnets

are centrosymmetric and thus lack Dzyaloshinskii-Moriya interaction (DMI). We show

here, using a general analysis based on symmetry, that Bloch-type skyrmions can, in

fact, be stabilized in 2D magnets, due to the interplay between in-plane component  $(d_x)$ 

of second nearest-neighbor DMI and magnetic anisotropy. Its validity is demonstrated

in Cr<sub>2</sub>Ge<sub>2</sub>Te<sub>6</sub> monolayer, which is also verified by recent experiments. Our work gives

a clear direction for experimental studies of 2D magnetic materials to stabilize

skyrmions and should greatly enrich the research on magnetic skyrmions in 2D lattices.

### Introduction

Magnetic skyrmions are a special class of vortex- or antivortex-like noncollinear spin textures [1-3]. Such spin textures showcase a variety of intriguing features (e.g., compact size, topological stability, and low-threshold driven currents), enabling the design of high-performance information processing and storage devices [4]. In principle, magnetic skyrmions provide a promising pathway to perpetuating the Moore's law [5]. Since its first realization in cubic B20 MnSi, the quest for magnetic skyrmions has received renewed interest. To date, magnetic skyrmions were experimentally discovered or theoretically proposed in a variety of materials, including bulk magnets and synthetic multilayer films composed of magnetic and heavy-metal layers [6-18]. In most cases, magnetic skyrmions are induced by chiral interactions between atomic spins, known as Dzyaloshinskii-Moriya interaction (DMI) [19, 20], existing in non-centrosymmetric magnetic compounds or in thin films in which inversion symmetry is broken by the presence of an interface [21].

In the past few years, magnetism in low dimensions has received renewed interest, marked by the observation of long-range magnetic order in 2D van der Waals materials, including but not limited to CrI<sub>3</sub>, CrGeTe<sub>3</sub>, and Fe<sub>3</sub>GeTe<sub>2</sub> [22-24]. This offers a promising alternative avenue for exploring exotic topological spin phenomena. Of particular interest, the Bloch-type magnetic skyrmions/bubbles have been very recently observed in van der Waals Cr<sub>2</sub>Ge<sub>2</sub>Te<sub>6</sub> [25-29]. However, the occurrence of skyrmions in this system goes against expectations due to that fact that its crystal structure is centrosymmetric with a honeycomb lattice, thereby precluding the manifestation of DMI. The intrinsic origin of topological spin textures in centrosymmetric van der Waals magnets like Cr<sub>2</sub>Ge<sub>2</sub>Te<sub>6</sub> remains elusive [26, 30]. Apart from Cr<sub>2</sub>Ge<sub>2</sub>Te<sub>6</sub>, there are many 2D magnetic materials that share the similar structure, while most of them exhibit collinear magnetic structure. Therefore, exploring alternative mechanisms to realize skyrmions in a new category of centrosymmetric materials will significantly enrich the diversity of magnetic skyrmion materials.

In the present work, we unveil that skyrmions can be spontaneously stabilized in centrosymmetric 2D magnets with a honeycomb lattice. Based the symmetry analysis, we demonstrate that centrosymmetric 2D magnets with a honeycomb lattice exhibit

finite second NN DMI due to the broken *local* inversion symmetry, which is primarily responsible for the formation of skyrmions. By using first-principles calculations and Monte Carlo simulations, we reproduce the spin spiral and skyrmions phases experimentally observed in  $Cr_2Ge_2Te_6$ . This unusual skyrmionics physics is revealed by introducing the dimensionless parameter  $\kappa$ , which can serve as a measurement whether the ground state is a non-collinear magnetic structure or not. Furthermore, we present the anisotropy-field phase diagram. Furthermore, we present the anisotropy-field phase diagram, demonstrating that not only out-of-plane anisotropy but also inplane anisotropy favors the formation of skyrmionic states.

### Results and discussion

Figure 1. Structure of monolayer Cr<sub>2</sub>Ge<sub>2</sub>Te<sub>6</sub>. (a, b, c) are the crystallographic directions and a is along x direction and c along z direction of Cartesian coordinates.

Let us first consider the crystal structure of monolayer  $Cr_2Ge_2Te_6$ , as illustrated in Figure 1. The crystal adopts the space group  $P\overline{3}1m$ . Obviously, monolayer  $Cr_2Ge_2Te_6$  presents overall inversion symmetry, and thus the DMI between the first nearest neighbors (NN) will cancel out upon space inversion, in accordance with Moriya's first rule [20]. However, it is noteworthy that local inversion symmetry is inherently broken for the second nearest neighbors. Let's take  $Cr_1-Cr_2$  pair as an example. As indicated in Figure 1, there is a two-fold rotation axis  $C_{2y}$  perpendicular to the line connecting the second NN. According to Moriya's fourth rule [20], the DM vector is perpendicular to

this axis. Consequently, the DM vector associated with  $Cr_1$ - $Cr_2$  pair possesses a z component  $(d_z)$  and a planar component  $(d_x)$  aligned along  $Cr_1$ - $Cr_2$  bond. Considering the three-fold rotational symmetry around [001] and the translational symmetry, the inplane component of the DM vector between  $Cr_1$  and  $Cr_i$  (i = 2-7) points towards (or away from)  $Cr_1$ . While the out-of-plane component alternates in sign every 60 degrees, specifically, the orientation of  $d_z$  component remains consistent for  $Cr_1$ - $Cr_2$ ,  $Cr_1$ - $Cr_4$ , and  $Cr_1$ - $Cr_6$  pairs, which is opposite to that of the  $Cr_1$ - $Cr_3$ ,  $Cr_1$ - $Cr_5$ , and  $Cr_1$ - $Cr_7$  pairs.

Based on the symmetry analysis presented above, we demonstrate that a finite second NN DMI is allowed to exist in centrosymmetric 2D magnetic materials with a honeycomb lattice owing to the broken local inversion symmetry. Usually, the ratio of first NN DMI  $(d_1)$  to the  $J_1$  is regarded as an important parameter to assess the feasibility of forming topological spin textures. The typical range for  $|d_1/J_1|$  falls within 0.1–0.2 [31]. However, for monolayer Cr<sub>2</sub>Ge<sub>2</sub>Te<sub>6</sub> and other 2D magnetic materials with similar structure, the  $d_1$  is inhibited by inversion symmetry. To deeply understand this unusual skyrmionics physics in centrosymmetric 2D magnetic materials with a honeycomb lattice, we thus introduce the dimensionless parameter  $\kappa = (\frac{4}{\pi})^2 \frac{AK}{D^2}$ , that can help us identify magnetic ground state [32, 33]. Here A is the exchange stiffness that includes both Heisenberg exchange interaction  $J_1$  and  $J_2$ , K is the total magnetic anisotropy, and D is the DMI parameter in micromagnetic format, respectively. It has been demonstrated that, when  $0 \le \kappa \le 1$ , the magnetic ground state of the system exhibits spin spiral. Under a moderate magnetic field, spin spiral might transform into skyrmions. Whereas for  $\kappa > 1$ , the system tends to exhibit a collinear magnetic structure, i.e., a FM state.

The material parameter A is related to the parameters of the atomistic model by:

$$A = \frac{1}{2V} \sum_{i} J_{0j} (R_{0j}^{x})^{2} = \frac{a^{2}}{2V} (\frac{1}{2} J_{1} + 3J_{2})$$
 (1)

Here  $J_{0j}$  is the NN and second NN Heisenberg exchange interactions,  $R_{0j}^x$  is the x component of Cr pair vector, respectively. V is the volume of the magnetic part of the unit cell, e.g. the  $Cr_2Ge_2Te_6$  monolayer. And a is the distance between two second NN

Cr atoms. As indicated by our symmetry analysis, the orientation of  $d_z$  for adjacent second NNs is opposite for centrosymmetric 2D magnetic materials with a honeycomb lattice, thus only the  $d_x$  is left to contribute to the material parameter D. Hence, D can be expressed as follow:

$$D = \frac{1}{V} \sum_{i} d_{0j}^{x} R_{0j}^{x} = \frac{a}{V} (3d_{2}^{x})$$
 (2)

Finally, we can rewrite  $\kappa$  with the parameters of atomistic model as:

$$\kappa = \left(\frac{4}{\pi}\right)^2 \frac{(J_1 + 6J_2)K}{(6d_2^x)^2} \tag{3}$$

We now examine the SIA- $d_x$  phase diagram at 0 K without external magnetic field. To this end, we adopt the following spin Hamiltonian in parallel tempering Monte Carlo (PTMC) simulations:

$$H = -\frac{1}{2} \sum_{\langle i,j \rangle} J_{ij} \mathbf{S}_i \cdot \mathbf{S}_j - \frac{1}{2} \sum_{\langle i,j \rangle} \mathbf{d}_{ij}^x \cdot (\mathbf{S}_i \times \mathbf{S}_j) - \sum_i K(S_i^z)^2 - B \sum_i S_i^z$$
(4)

here  $S_i$  is the unit vector of spin at site *i*. The isotropic Heisenberg exchange coupling, denoted by  $J_{ij}$ , spans over all first and second nearest-neighbor (NN) magnetic ions. Second term  $\mathbf{d}_{ij}^{\times}$  represents the vector that characterizes the x component of DMI for the second NN magnetic ions. The third term is the single ion anisotropy K. In the last term, B indicates the strength of the external magnetic field along Z axis, which is same as indicting in Figure 1. The PTMC simulations are performed over a  $60 \times 60 \times 1$  supercell. The phase diagram is obtained by fixing  $J_1 = 10$  meV and  $J_2 = 0$  meV as a function of the  $d_x$  and single ion anisotropy (SIA). To obtain the ground state at 0 K, various periods of spin spirals are inputted as initial states for each set of magnetic parameters and fully relax them. The energy of the FM state (FM-x for easy-plane anisotropy, and FM-z for easy-axis anisotropy) is set as the zero reference. One can clearly see in Figure 2 that, within the  $|\kappa| < 1$  threshold, the spin spiral is indeed more energetically favorable compared to FM state for both easy-axis and easy-plane anisotropy. Even a small second NN  $d_x$ , when coupled with sufficiently low SIA, results in  $0 < |\kappa| < 1$ , maintaining a spin spiral ground state.

Figure 2.The  $d_x$ -SIA phase diagram at 0 K. The solid line denotes  $|\kappa| = 1$ . The energy difference between spin spiral and FM state is shown in the color bar.

To confirm the analysis provided above, by combining DFT calculations and the energy mapping method, we extract magnetic coefficients of monolayer  $Cr_2Ge_2Te_6$ , including Heisenberg exchange coupling J, DMI, and magnetocrystalline anisotropy (C-MAE). The first and second NN Heisenberg exchange coupling  $J_1$  and  $J_2$  is calculated to be 10.85 and -0.34 meV, respectively, which agree well with previous studies [34-36]. Due to the inversion symmetry, the first NN DMI is determined to be zero. In line with the aforementioned analysis, the second NN Cr pair does exhibit finite DMI. Specifically, for  $Cr_1$ - $Cr_2$  pair as depicted in Figure 1, the planar component  $d_x$  is calculated to be 0.27 meV, the perpendicular component  $d_z$  is -0.61 meV, while the other planar component  $d_y$  is zero. Magnetic anisotropy energy (MAE) is also a crucial factor that influences the formation of topological spin texture. The MAE is composed of magnetocrystalline anisotropy energy (C-MAE) and magnetic dipolar anisotropy energy (D-MAE). The calculated C-MAE is 0.065 meV per Cr atom (prefers an out-of-plane magnetization), and the D-MAE is -0.039 meV per Cr atom (favors an in-plane magnetization). Thus, the total magnetic anisotropy energy is out-of-plane for

monolayer Cr<sub>2</sub>Ge<sub>2</sub>Te<sub>6</sub>, which is also consistent with both theoretical and experimental works [37, 38].

After we obtained all the magnetic parameters, we now investigate the spin textures of monolayer Cr<sub>2</sub>Ge<sub>2</sub>Te<sub>6</sub> under different magnetic fields at 0 K. The spin Hamiltonian of Eq. (4) is used in PTMC simulations. For simplicity, both the C-MAE and D-MAE are included into the SIA. The PTMC simulations are also performed over a  $60 \times 60 \times 1$  supercell. The initial spin configurations are obtained through fully relaxing the paramagnetic (random) state. To ensure the converged spin structures to be the ground state at 0 K, the conjugate gradient (CG) method is subsequently applied to relax the spin configurations obtained through PTMC simulations. Remarkably, without applying magnetic field, Bloch-type labyrinth domains are observed in monolayer Cr<sub>2</sub>Ge<sub>2</sub>Te<sub>6</sub> at 0 K, as depicted in Figure 3(a, c). For monolayer Cr<sub>2</sub>Ge<sub>2</sub>Te<sub>6</sub>, the  $\kappa$  is determined to be 0.288, indicating a spin spiral ground state, which aligns closely with the results from PTMC simulations. Although there are many 2D magnetic materials that share the similar structure as Cr<sub>2</sub>Ge<sub>2</sub>Te<sub>6</sub>, most of them exhibit collinear magnetic structure. Our phase diagram can explain this very well. It is known that  $Cr_2Si_2Te_6$  is an FM insulator. Our calculated magnetic parameters lead to a  $\kappa$  value of 3.4, also suggesting FM ground state. Likewise, using the magnetic parameters available for monolayer  $CrI_3$  [39], its  $\kappa$  is determined to be 10.7, indicating again FM ground state.

Figure 3. (a) The energy difference  $\Delta E$  of E(relax) and E(FM-z) as a function of B at 0 K for monolayer  $\text{Cr}_2\text{Ge}_2\text{Te}_6$ . Here E(relax) is the energy obtained from CG method, E(FM-z) is the energy of FM state with magnetization lying along the z direction. The insets present the spin textures at different B. (b) The topological charge |Q| as a function of B at 0 K. The phases found are as follows: labyrinth domains (I), labyrinths and skyrmion mixed phase (II), discrete skyrmions/skyrmions lattice (III), and saturated ferromagnetic state (IV), respectively. (c) and (d) are local view of spin textures in the insets of (a).

More intriguing, Bloch-type skyrmion is observed on the background of labyrinth domains at 0.17 T, as shown in Figure 3(a). The sense of in-plane spin rotation for both labyrinth domain and skyrmions are exactly consistent with the experimental observations [25, 27]. When the magnetic field is larger than 0.2 T, the labyrinth domains are totally wiped out. Importantly, as illustrated in Figure 3 (b), this skyrmion state is preserved within the range of 0.2-0.55 T. Above 0.55 T, the monolayer  $Cr_2Ge_2Te_6$  is completely magnetized into the trivial ferromagnetic (FM) state. It should be noted that the skyrmions state is metastable within the field range of 0.31-0.55 T, which possesses a higher energy compared to the corresponding FM state. We note that Khela et al. [26] have also proposed that the second NN DMI plays a crucial role in the

formation of skyrmions in  $Cr_2Ge_2Te_6$ . However, in their atomistic spin dynamics simulations, three distinct types of topological spin texture are found: Bloch-type skyrmions and anti-skyrmions, and skyrmioniums. Importantly, the sense of in-plane spin rotation of the skyrmion identified in their simulations however contradicts the previous experimental results, which means the orientation of  $d_x$  component of second NN DMI used in their simulations is opposite to the direction derived from our DFT results.

Figure 4. The SIA-field phase diagram with ferromagnetic (FM), spin spiral (SS), and skyrmion/skyrmions crystal (SkX) phases for D = 0.3 and J = 10 meV. The SS\* and SkX\* denotes the metastable spin spiral and skyrmion/skyrmions crystal (SkX) phase, respectively. The dashed line H = 2A separates the out-of-plane FM from the tilted FM. For the FM,  $m^z$  is shown in the color bar. The phase boundary is constructed based on magnetization ( $m^z$ ), topological number, and energy difference between SS/SkX and the corresponding FM state, as a function of SIA and field. The red shot line indicates the boundary of  $|\kappa| = 1$ .

Finally, we establish anisotropy *versus* magnetic field phase diagram at 0K, as a function of dimensionless magnetic field  $HJ/D^2$  and anisotropy  $KJ/D^2$ , with fixed  $D(d_x)$ 

= 0.3 and J = 10 meV, respectively. To construct the phase diagram (K, H), we compare the energy of the states obtained by PTMC to that of the uniform (tilted) FM state, with the assistance of magnetization (m<sup>z</sup>) and topological number. The uniform FM state can either be the spin polarized FM state along the magnetic field direction ( $n_z = 1$ ) or the spin tilted FM state with  $n_z < 1$ . As shown in Figure 4, surprisingly, the easy-plane regime (K > 0) leads to an unexpectedly large stable SkX phase, compared to the easyaxis anisotropy (K < 0). This large region of the skyrmion/skyrmions crystal (SkX) within the phase diagram predominantly aligns around dashed line H = 2A in Figure 4, marking the boundary between the "tilted FM" and the easy-axis FM. As demonstrated in the previous study [40, 41], this is due to: (i) the rotated spins within the skyrmion configuration reduce the DMI contribution to the free energy as compared to the FM state for easy-plane anisotropy; (ii) the skyrmion presents a more optimal balance between an easy-plane anisotropy and a field along the z-axis compared to a spiral configuration. Note that our PTMC calculations fail to give clear results near the phase boundaries because the system gets trapped in metastable states. Hence, the phase diagram depicted in Fig. 4 should be regarded only as semi-quantitative.

# Summary

To summarize, we propose a mechanism that stabilize the skyrmions in centrosymmetric 2D magnets. Based the symmetry analysis, we ascertain that centrosymmetric 2D magnets with a honeycomb lattice do possess finite second NN DMI due to the broken local inversion symmetry. Our DFT and MC results well reproduce the spin spiral and skyrmions phases experimentally observed in  $Cr_2Ge_2Te_6$ , indicating the importance of the synergetic effect between the in-plane component ( $d_x$ ) of the second NN DMI and the magnetic anisotropy. This unusual skyrmionics physics is revealed by introducing the dimensionless parameter  $\kappa$ , serving as determinants for non-collinear magnetic ground states. Furthermore, we present the anisotropy-field phase diagram, demonstrating that an in-plane anisotropy favors the formation of skyrmion states. Our results should serve as a guide for material parameters of 2D centrosymmetric magnets such that a large skyrmion region can be probed

experimentally.
