(Dated: December 5, 2023)

In NiTe<sub>3</sub>O<sub>6</sub> with a chiral crystal structure, we report on a giant natural optical rotation of the lowest-energy magnon. This polarization rotation, as large as  $140^{\circ}$ /mm, corresponds to a path difference between right and left circular polarizations that is comparable to the sample thickness. Natural optical rotation, being a measure of structural chirality, is highly unusual for long-wavelength magnons. The collinear antiferromagnetic order of NiTe<sub>3</sub>O<sub>6</sub> makes this giant effect even more peculiar: Chirality of the crystal structure does not affect the magnetic ground state but is strongly manifested in the lowest excited state. We show that the dynamic magnetoelectric effect, turning this magnon to a magnetic- and electric-dipole active hybrid mode, generates the giant natural optical rotation. In finite magnetic fields, it also leads to a strong optical magnetochiral effect.

Chirality, as first termed by Kelvin, is a structural or geometrical property. A chiral object cannot be overlayed with its mirror image, it has only pure rotation symmetries and cannot possess an inversion center or mirror planes. A widely used tool for detecting chirality is natural optical activity, i.e., a rotation of linear polarization of light. It originates from the different velocities of right and left circularly polarized (rcp/lcp) photon polaritons in chiral media, i.e., circular birefringence. Via Kramers-Kronig relations, this is tied to circular dichroism, a difference in absorption for rcp and lcp light.

Chirality emerges in diverse material platforms. It is a key property of living matter that also governs its functionalities, as prominently manifested in the homochirality of life [1–3], with only left-handed amino acids existing in nature. In inorganic crystals, chirality is the source for a range of fascinating phenomena [4-13]. We restrict our discussion to the interplay with magnetism [14]. Chirality of the crystal structure can induce chirality of magnetic textures, leading to, e.g., spin helices and skyrmions [15, 16]. Such chiral spin textures may also emerge spontaneously in achiral crystals due to competing exchange interactions [17, 18]. Remarkably, chirality can arise from the superposition of achiral lattice symmetry and achiral magnetic order [8, 19]. This provides the possibility for magnetic control of chirality in materials hosting simple magnetic orders.

Recently, a plethora of non-reciprocal effects has been reported in chiral systems that are magnetic or exposed to a magnetic field [20, 21]. Magnetochiral dichroism refers to the difference in light absorption between counter-propagating beams with wavevector  $\mathbf{q}$  along and opposite to the magnetization or magnetic field and has been reported for magnon, phonon, and electronic excitations [7–10, 22–35]. Magnetochiral anisotropy has also been observed in dc electric and thermal transport [36], most recently in the mysterious kagome compound  $CsV_3Sb_5$  [12, 37]. Electromagnetic induction of a helix is another prominent example for functionalities governed by chirality [13].

The term chirality (handedness) has also been extended to dynamical processes such as quasiparticle excitations [38–44]. In the case of magnons, handedness refers to right and left circular polarizations. In a ferromagnet, magnons are typically right circular polarized, corresponding to clockwise precession of the magnetization [38, 39]. In contrast, in a collinear easy-axis antiferromagnet like Ni<sub>3</sub>TeO<sub>6</sub>, right- and left-handed magnons are degenerate in zero field such that a superposition of the two degenerate modes yields eigenstates that are not well characterized by handedness. The chiral crystal structure preserves this degeneracy. Concerning the optical response of the degenerate magnons to rcp and *lcp* light, we note that *the* typical source of natural optical rotation, the non-local effect of spatial dispersion [45], is relevant in the visible frequency range but can be neglected for magnons with energies in the GHz-THz regime where the wavelength of light is several orders of magnitude larger. However, as we show in the following, the  $\Gamma$ -point magnons still may cause giant natural optical rotation in a chiral crystal due to the dynamic magnetoelectric effect.

Here, we report on the giant natural optical rotation of the lowest-energy magnon in the collinear antiferromagnet  $Ni_3 \text{TeO}_6$  with chiral crystal structure (R3). The stunning strength of the effect is well illustrated by the

FIG. 1. Giant natural optical rotation of Ni<sub>3</sub>TeO<sub>6</sub> at T = 3 K. a),c) Effective refractive index  $n_{\rm eff} = [L_{\rm opt}(\omega)/d] + 1$  measured with rcp and lcp light on samples with opposite helicity, L and R, where  $L_{\rm opt}$  denotes the measured optical path difference and d the sample thickness. Curves with the same color are related by symmetry, e.g.,  $n_{rcp}^{\rm R} = n_{lcp}^{\rm L}$ . b),d) Specific polarization rotation  $\alpha$  measured with linear polarization (orange) and as determined from  $\alpha_{\rm eff} = (\pi/\lambda\rho)(n_{\rm eff, rcp} - n_{\rm eff, lcp})$  measured with circular polarization (purple) on a sample with given helicity, cf. a). Solid black lines are based on Eq. (3) for  $\omega_0 = 12.42 \,{\rm cm}^{-1}$ ,  $|\omega_{xx}| = 0.0375 \,{\rm cm}^{-1}$ , and  $\gamma = 0.05 \,{\rm cm}^{-1}$ .

optical path difference between *rcp* and *lcp* light being similar to the sample thickness. We show that this magnon mode picks up the chirality of the lattice via the dynamic magnetoelectric effect, leading to the observed natural optical rotation. In the long-wavelength limit, applicable to our THz data, the light-matter interaction is restricted to uniform excitations of electric and magnetic dipole moments. Correspondingly, spatial dispersion can be neglected and the only way to generate sizable natural optical rotation is the interference between electric and magnetic dipole excitations, the so-called dynamic magnetoelectric effect. Despite the hybrid nature, the electromagnon in  $Ni_3TeO_6$  has an extraordinarily long lifetime in the nanosecond range, which implies an unusual mechanism of the magnetoelectric coupling. In finite magnetic field, where the collinear antiferromagnetic order is still preserved, this magnon also exhibits magneto-optical rotation and magnetochiral birefringence. In contrast to the former, the latter shares a common origin with the natural optical rotation, i.e., it is governed by the same magnetoelectric coefficient and is getting activated by the Zeeman splitting of the doubly-degenerate magnon resonance.

Natural optical activity in zero field – We study the terahertz response of insulating Ni<sub>3</sub>TeO<sub>6</sub> in transmission geometry for light propagation along the chiral c axis in the collinear antiferromagnetic phase at T = 3 K, well below the ordering temperature  $T_N = 52-55$  K [46–48]. In chiral Ni<sub>3</sub>TeO<sub>6</sub>, the eigenstates for light are right and left circular polarized (*rcp* and *lcp*), and we compare the response for circular polarization with the optical rotation for linear polarization. Figure 1 depicts results for both sample helicities, R and L, at 3K in zero magnetic field. The excitation with eigenfrequency  $\omega_0 = 12.42 \,\mathrm{cm}^{-1}$  (or 372.3 GHz, 1.540 meV) has been interpreted as an electromagnon since broad features were observed at similar frequencies in Raman results and time-domain terahertz data of ceramic samples [49]. Our data reveal the giant natural optical activity of this mode, underlining its chiral character. In Fig. 1, panels b) and d) show the specific rotation  $\alpha = \theta / \rho d$  for linear polarization (orange), where  $\theta$  denotes the measured polarization rotation,  $\rho = 6.4 \,\mathrm{g/cm^3}$  is the density [50], and d is the sample thickness. As expected, the sign of  $\alpha$  is inverted between the two sample helicities. With the actual thicknesses being  $d_{\rm R} = 0.78 \,\mathrm{mm}$  and  $d_{\rm L} = 1.05 \,\mathrm{mm}$ , strong absorption suppresses the amplitude below the noise level in a region of about  $\pm 0.1 \,\mathrm{cm}^{-1}$  around  $\omega_0$ , i.e., we are missing data at the very maximum of absorption. The measured  $\alpha$  is extraordinarily large, exceeding 1000° cm<sup>3</sup>/g dm at  $\omega_0 \pm 0.1 \,\mathrm{cm}^{-1}$ . The corresponding fit (see below) peaks at  $2.2 \cdot 10^3 \deg \text{ cm}^3/\text{g} \text{ dm}$ . For d = 1 mm, this corresponds to  $\theta \approx 140^{\circ}$ , indeed a giant rotation for a collinear antiferromagnet in zero magnetic field.

We focus on the frequency range close to the resonance, where circular birefringence is accompanied by circular dichroism. Consequently, linearly polarized light does not only experience a rotation of the polarization plane but becomes elliptically polarized or even circularly polarized. In the latter limit, the polarization rotation is an ill-defined quantity. Therefore, we confirm our result using circular polarization. The rotation of linear polarization  $\theta = (\pi d/\lambda)(n_{rcp} - n_{lcp})$  is caused by circular birefringence, i.e., a difference of the real parts of the refractive indices, where  $\lambda$  denotes the vacuum wavelength. Using circular polarization, our measured THz phase data probe  $n_{rcp}$  and  $n_{lcp}$  individually. Panels a) and c) of Fig. 1 plot the effective refractive index  $n_{\rm eff}(\omega)$  derived from the measured optical path difference  $L_{\text{opt}}(\omega) = [n_{\text{eff}}(\omega) - 1] d$  induced by the sample in comparison to vacuum. Neglecting multiple reflections within the sample,  $n_{\rm eff}(\omega)$  equals  $n(\omega)$  for a given circular polarization. For frequencies not too close to the absorption feature, such multiple reflections cause the small Fabry-Pérot interference fringes in  $n_{\rm eff}$  with a period of  $\Delta \omega = (2nd)^{-1} \approx 1.6 \text{ cm}^{-1} (2.1 \text{ cm}^{-1})$  in the L (R) sample. Panels b) and d) compare the specific polarization rotation  $\alpha$  measured with linear (orange) and circular polarization (purple), the latter determined via  $\alpha_{\rm eff} = (\pi/\lambda\rho)(n_{\rm eff,rcp} - n_{\rm eff,lcp})$  for a given sample helicity from the data plotted in a) and c). Note that the interference fringes nearly drop out by taking the difference. The two results for linear and circular polarization agree very well with each other, both for the L and the R domain.

Now we address the quantitative analysis. In Ni<sub>3</sub>TeO<sub>6</sub>, any sizable chiral response in the terahertz range has to arise from the dynamical magnetoelectric coupling tensor  $\hat{\chi}^{me}$ , as stated above. For light propagation along the trigonal *c* axis, we hence may consider both the dielectric

FIG. 2. Sketch of behavior in magnetic field. For simplicity, we depict simple peaks, and their intensity difference denotes dichroism, which via Kramers-Kronig relations is equivalent to birefringence. a) In zero field, different peak intensities  $I_{rcp}$  and  $I_{lcp}$  at  $\omega_0$  (black, white) depict natural circular dichroism. Finite magnetic field (anti-)parallel to the chiral axis yields a Zeeman splitting, which directly results in magnetochiral dichroism (MChD) and magnetocircular dichroism (MCD) sketched in b) and c), cf. Eqs. (4) and (5). The four colors reflect quadrochroism equivalent to MChD, cf. Fig. 3. b),c) MCD and MChD (thick solid lines) measure the sum and difference of the peaks at  $\omega_0 - \omega_Z$  compared to the sum and difference at  $\omega_0 + \omega_Z$ . Both MCD and MChD vanish in zero field for  $\omega_Z = 0$ . d) Applying time reversal (TR) and/or spatial inversion (Inv.) yields a family of four equivalent settings with identical responses, shown here for the blue feature in a).

function  $\varepsilon(\omega)$  and the permeability  $\mu(\omega)$  as scalar quantities, see Sect. I.C. Solving Maxwell's equations for the point group 31' of the collinear antiferromagnetic phase and  $\mathbf{q} \parallel c$ , we find the complex refractive index

$$N_{rcp/lcp}(\omega) = \sqrt{\varepsilon \,\mu + \left(\chi_{xy}^{me}\right)^2} \mp i \,\chi_{xx}^{me} \tag{1}$$

with  $N = n + i \kappa$ . This expression quantifies how the chiral character, detected by the natural optical rotation  $\alpha \propto \Re(N_{rcp} - N_{lcp})$ , arises based on the magnetoelectric tensor, i.e., for a finite imaginary part of the diagonal component  $\chi_{xx}^{me}$  that connects  $B_x(\omega)$  and  $E_x(\omega)$ . Considering a single mode and assuming a Lorentzian shape, time-reversal symmetry implies

$$\chi_{ij}^{me}(\omega) = \frac{i\,\omega\,\omega_{ij}}{\omega_0^2 - \omega^2 - i\gamma\omega} \tag{2}$$

where  $\omega_{xx}$  and  $\omega_{xy}$  govern the strength of the magnetoelectric response and  $\gamma$  denotes the damping. Note that this expression for  $\chi_{ij}^{me}$  guarantees that the *static* linear magnetoelectric response vanishes, as required. For the real-valued difference  $n_{rcp} - n_{lcp}$  we find

$$\Re(N_{rcp} - N_{lcp}) = \frac{2\,\omega\,\omega_{xx}\,(\omega_0^2 - \omega^2)}{(\omega_0^2 - \omega^2)^2 + (\gamma\omega)^2}\,.$$
 (3)

FIG. 3. Zeeman splitting of the electromagnon in  $Ni_3 TeO_6$  for |B| = 1 T. All data sets are measured at 13.5 K with *lcp* light and the same direction of **q**, parallel to the *c* axis. The combination of natural circular birefringence and Zeeman splitting yields magnetochiral birefringence equivalent to quadrochroism. The four different responses in our data arise based on the direction of **B**, where  $\pm 1 T$  denotes  $\pm \mathbf{B} \parallel \mathbf{q}$ , and the two different sample helicities, L and R (left and right panels). The four responses can be classified by the eigenfrequency  $\omega_0 \pm \omega_Z$  and the oscillator strength in the refractive index. The color code follows Fig. 2a).

A fit of  $\alpha$  measured at 3 K yields  $\omega_0 = 12.42 \,\mathrm{cm}^{-1}$  and  $\omega_{xx}=-0.039\,\mathrm{cm}^{-1}~(0.036\,\mathrm{cm}^{-1})$  for the L (R) sample, see Figs. 1b), d). These results for  $\omega_0$  and  $\omega_{xx}$  are not affected by the uncertainty of  $\gamma$ , for which we estimate  $\gamma = 0.05 \,\mathrm{cm}^{-1}$  (or 1.5 GHz, 6  $\mu \mathrm{eV}$ ) with  $\gamma/\omega_0 \approx 0.004$ . We cannot exclude a still slightly smaller value since we are missing data at the absorption maximum in the range  $\omega_0 \pm 0.1 \,\mathrm{cm}^{-1}$ . This yields a rough estimate of the lifetime in the nanosecond range, a stunning result. The line widths of electromagnons in other compounds are much broader, with typical values of  $\gamma/\omega_0 \gtrsim 0.1$  in, e.g.,  $LiMPO_4$  (M = Fe, Co, Ni) or  $TbFe_3(BO_3)_4$  [51–54]. Still larger values have been observed in, e.g., RMnO<sub>3</sub>, also in inelastic neutron scattering [55–57], see [58] for a review. A large width agrees with the intuition for a hybrid mode that contains both magnetic and electric-dipole-active contributions, offering different decay channels. Comparably small values of  $\gamma \approx 1 \,\mathrm{cm}^{-1}$  and  $\gamma/\omega_0 \approx 0.02$ -0.03 were reported for Co<sub>2</sub>Mo<sub>3</sub>O<sub>8</sub> and Fe<sub>2</sub>Mo<sub>3</sub>O<sub>8</sub> [59, 60]. For electromagnons, our result  $\gamma/\omega_0 \approx 0.004$  is outstanding. The small line width observed in Ni<sub>3</sub>TeO<sub>6</sub> rather is comparable to results for pure magnon modes studied in collinear antiferromagnets with the neutron resonance spin echo technique [61]. In fact, the line width is only an order of magnitude larger than that of magnons in the reference low-loss spin-wave material vttrium iron garnet as observed in optical transmission experiments [62].

The very small linewidth  $\gamma$  also drives the very large specific polarization rotation  $\alpha$ . The fit using Eq. (3) allows us to determine the maximum value at about  $\omega_0 \pm \gamma/2$ , where  $\alpha$  reaches 2200° cm<sup>3</sup>/g dm at 3 K. This corresponds to a maximum difference  $|n_{rcp} - n_{lcp}|_{max} \approx \omega_{xx}/\gamma \approx 3/4$  such that the relative optical path delay  $\delta L_{opt} = (n_{rcp} - n_{lcp}) d$  between the two polarizations nearly equals the sample thickness, again highlighting the giant strength of the effect. Also in the visible frequency range, a large value of  $\alpha_{\rm VIS}=1355^\circ\,{\rm cm}^3/{\rm g}\,{\rm dm}$  has been reported [63]. We emphasize that the corresponding value of  $n_{rcp}-n_{lcp}\propto\alpha\,\lambda$  is orders of magnitude smaller in the visible than in the terahertz range.

In passing we mention that  $n_{rcp}$  may turn negative, as discussed for chiral metamaterials [64]. In the present case, this would be achieved for  $\gamma \leq 0.012 \text{ cm}^{-1}$  or for an increase of  $\omega_{xx}$  by a factor 5. Another noteworthy aspect is the asymptotic behavior of  $\theta$ . For large  $\omega \gg \omega_0$ , the difference  $|n_{rcp} - n_{lcp}|$  extrapolates to  $2\omega_{xx}/\omega$ . This yields the counterintuitive result of a constant high-frequency extrapolation  $\theta(\omega = \infty) = 2\pi d \omega_{xx}$  with d in units of cm and  $\omega_{xx}$  in cm<sup>-1</sup>. For d = 1 mm, our model predicts  $|\theta(\infty)| \approx 1.4^{\circ}$ . In fact, this has to be compensated by other excitations such that the total high-frequency limit of the rotation  $\theta$  vanishes [65].

Nonreciprocal directional birefringence in finite magnetic field – In the collinear antiferromagnetic phase at 3K in zero magnetic field, considering a given sample helicity, there are two degenerate electromagnons at  $\omega_0 = 12.42 \,\mathrm{cm}^{-1}$ . Due to  $\chi_{xx}^{me}$ , they show opposite helicities such that one contributes to  $n_{rcp}$ , the other one to  $n_{lcp}$ , together causing the giant natural optical activity. Application of an external magnetic field **B** along the chiral axis breaks time-reversal symmetry and induces a Zeeman splitting between these two modes, as shown in Fig. 3 for  $B = \pm 1 \text{ T}$  at 13.5 K and sketched in Fig. 2a). The Zeeman splitting of the eigenfrequencies  $\omega_0 \pm \omega_Z$  with  $\omega_Z = g \,\mu_B |B| / (\hbar 2\pi c)$  in units of cm<sup>-1</sup> reveals the q factor  $q \approx 2.2$ . A value of 2.26 has been found in an ESR study on a polycrystalline sample [66]. Furthermore, the Zeeman splitting causes magnetocircular birefringence (MCB), i.e., Faraday rotation, see Fig. 2c),

$$n_{\rm MCB} = \left(n_{rcp}^{+q} + n_{lcp}^{-q}\right) - \left(n_{rcp}^{-q} + n_{lcp}^{+q}\right) \tag{4}$$

where +q and -q refer to **q** parallel and antiparallel to **B**. The result shown in Fig. 4 and the sketch in Fig. 2c) illustrate that MCB measures the difference between the responses at  $\omega_0 - \omega_Z$  and  $\omega_0 + \omega_Z$ . Note that MCB changes upon time reversal but is unaffected upon spatial inversion, i.e., it appears in magnetic field also in the absence of natural circular birefringence. In contrast, magnetochiral birefringence (MChB, cf. Figs. 2b) and 4)

$$n_{\rm MChB} = \left(n_{rcp}^{+q} - n_{lcp}^{-q}\right) - \left(n_{rcp}^{-q} - n_{lcp}^{+q}\right)$$
(5)

$$= \left(n_{rcp}^{+q} - n_{rcp}^{-q}\right) + \left(n_{lcp}^{+q} - n_{lcp}^{-q}\right) \tag{6}$$

is inverted upon either time reversal or spatial inversion. It arises in our data due to the Zeeman splitting of chiral modes showing circular birefringence, as emphasized by Eq. (5) and sketched in Fig. 2b). Note that for such electromagnon excitations, natural optical birefringence and circular dichroism are two sides of the same coin in terms of Kramers-Kronig relations connecting real and

FIG. 4. Magnetocircular birefringence (MCB) and magnetochiral birefringence (MChB) for |B| = 1 T at 13.5 K. The data (symbols) were derived from the results shown in Fig. 3 using Eqs. (4), (5), and (8). The Fabry-Pérot interference fringes nearly cancel out for frequencies below and above the two features, but they cause some deviation from the expected line shape in between the two peaks. Solid lines depict a fit based on Eq. (1) plus Zeeman splitting, neglecting the fringes.

imaginary parts of a linear response function. MChB is equivalent to non-reciprocal directional birefringence, i.e., different properties for counterpropagating electromagnetic waves as highlighted by Eq. (6).

Non-reciprocal directional dichroism is also called quadrochroism, referring to the four different values of  $N_{rcp/lcp}^{\pm q}$  for a given sample helicity. Concerning magnons, it typically occur in complex magnetic structures that are affected by the external magnetic field [8, 9, 25–30]. In contrast, we consider the intuitive case of a collinear antiferromagnet with chiral crystal structure, in which the existence of quadrochroism is straightforward. Starting from natural circular dichroism, the simple role of the magnetic field is to lift the degeneracy of the chiral magnons, hence quadrochroism appears based on the Zeeman effect. More explicitly, we consider circular polarization, sample helicity, and the orientations of **B** and q along the chiral axis. This yields 16 possible variants  $N_{rcp/lcp,L/R}^{\pm q,\pm B}$ . Applying time reversal and/or spatial inversion to the entire experimental setup yields four families, each hosting four members with equivalent properties. One example is given in Fig. 2d). Quadrochroism means that these four families exhibit different properties. The four quantities  $\Re(N_{rcp/lcp}^{\pm q})$  in Eq. (5) refer to a fixed orientation of  $\mathbf{B}$  and fixed sample helicity and represent the four different families.

For measurements in finite B, our setup is restricted to lcp light. Observation of the four different responses hence requires to study both domains, L and R. The data in Fig. 3 depict the four different cases  $n_{lcp,L/R}^{+q,\pm B}$  that are equivalent to  $n_{rcp/lcp,L}^{\pm q,+B}$  according to

$$n_{\rm MChB} = n_{rcp,L}^{+q,+B} - n_{lcp,L}^{-q,+B} - n_{rcp,L}^{-q,+B} + n_{lcp,L}^{+q,+B}$$
(7)  
=  $n_{lcp,R}^{+q,-B} - n_{lcp,L}^{+q,-B} - n_{lcp,R}^{+q,+B} + n_{lcp,L}^{+q,+B}$ , (8)

as schematically depicted in Fig. 2b). Similarly,  $n_{MCB}$  can also be determined from measurements on both L and R domains with *lcp* light. The corresponding spectra of  $n_{MChB}$  and  $n_{MCB}$  are plotted in Fig. 4.

Finite *B* breaks time-reversal symmetry and allows for additional terms in the tensors  $\hat{\varepsilon}$ ,  $\hat{\mu}$ , and  $\hat{\chi}^{me}$  such as an off-diagonal contribution to  $\hat{\varepsilon}$  reflecting the Faraday effect. We cannot separate the effects of all additional parameters and hence refrain from a quantitative microscopic analysis in finite field. For simplicity, we stick to Eq. (1) where we add the Zeeman splitting, resulting in the solid lines plotted in Fig. 4. For the parameters at 13.5 K we find  $\omega_0 = 12.35 \text{ cm}^{-1}$ ,  $\omega_Z = 1.05 \text{ cm}^{-1}$ ,  $|\omega_{xx}| = 0.035 \text{ cm}^{-1}$ , and  $\gamma = 0.09 \text{ cm}^{-1}$ . Compared to 3 K, the values of  $\omega_0$  and  $\omega_{xx}$  are only slightly reduced at 13.5 K, while the linewidth is enhanced by almost a factor of 2.

In conclusion, the dynamic magnetoelectric tensor is the source of the giant natural optical rotation in the collinear antiferromagnet  $Ni_3 TeO_6$  with chiral crystal structure. In a straightforward way, it also yields a strong magnetochiral effect in finite magnetic field. The mechanism strongly differs from the typical case based on spatial dispersion. It also differs from previous reports of natural optical activity of magnons in other compounds where a large effect arises in a large magnetic field [8, 67– 69].

The stunning strength of  $140^{\circ}$ /mm rotation for linear polarization is based on the very narrow line width of 1.5 GHz. This value is much smaller than typically reported for electromagnons in other compounds. The experimental determination of such a narrow line width hinges on the fact that the frequency resolution of our continuous-wave THz spectrometer is by far superior to the values that are typically achieved with the commonly used time-domain setups. The combination of excellent frequency resolution, broadband use of circular polarization, and phase-sensitive detection sets a benchmark for optical spectroscopy of (electro-) magnons.

#### I. MATERIALS AND METHODS

# A. Samples

The compound Ni<sub>3</sub>TeO<sub>6</sub> crystallizes in a trigonal corundum-related structure with space group R3 [50, 63, 70]. It is chiral and polar even at room temperature, a rare combination. Chirality arises due to ordered distortions of the NiO<sub>6</sub> octahedra, while the polarization is due to a displacement of Ni and Te ions from the center of the surrounding oxygen octahedra [63]. The compound exhibits two enantiomers which correspond to growth twins or domains that can be transformed into each other by inversion. Growth and characterization of the L sample has been described in Refs. [47, 63]. It shows both enantiomers, and we covered the R pieces using a polarization microscope. The single-crystalline R sample of Ni<sub>3</sub>TeO<sub>6</sub> has been grown using the chemical transport reaction method. As initial material for the crystal growth, we used polycrystalline Ni<sub>3</sub>TeO<sub>6</sub> prepared by solid state reactions from binary NiO and TeO<sub>2</sub>. Anhydrous TeCl<sub>4</sub> was utilized as a transport agent. The growth was performed in a two-zone furnace in a temperature gradient from 740 to 680°C.

With the nominal valence  $Ni^{2+}$ , this Mott-insulating material hosts spin S = 1 on three inequivalent Ni sites. Collinear antiferromagnetic order (AFM-I) with the propagation vector (0, 0, 1/2) sets in at  $T_N = 52-55$  K [46– 48]. The ordered moments form ferromagnetic planes that are stacked antiferromagnetically along the c axis [47, 48]. At 5 K, a spin-flop transition to the AFM-II phase has been reported for B = 8.83 T applied along the c axis [46, 47, 71]. Usually, the combination of antiferromagnetic order and electric polarization is discussed in terms of multiferroicity. Strictly speaking, however,  $Ni_3TeO_6$  does not belong to the class of multiferroics since the structure is polar already in the paramagnetic state. The electric polarization is not induced by magnetic order but it is strongly enhanced in the magnetically ordered state due to magnetoelectric coupling [47].

Concerning the symmetry in the AFM-I phase, we may stick to the ordinary magnetic space groups due to the collinear character of magnetic order. Starting from R3, only  $R_R3$  (No. 1242 or 146.3.1242) describes antiferromagnetic order, it hence is the correct magnetic space group for the AFM-I phase. The corresponding point group is 31'. It contains time reversal 1' since the combination of 1' and  $\frac{1}{2}\mathbf{c}$  translation remains a symmetry operation of the space group in the antiferromagnetic state.

### B. Continuous-wave terahertz measurements

The essential experimental aspects of our study are the usage of circularly polarized light with high frequency resolution and phase-sensitive detection. This is achieved with a continuous-wave spectrometer based on photomixing [72–75]. The beams of two tunable nearinfrared lasers (TOPTICA) are superimposed in a fiber array and illuminate photomixers – proprietary technology from the Max Planck Institute for Radio Astronomy. Using phase-sensitive homodyne detection and two fiber stretchers for phase modulation, we measure both amplitude and phase of the terahertz radiation. Comparing the results on the sample with those of a reference measurement on an empty aperture, the phase delay  $\varphi(\omega) = \varphi_{\rm sam}(\omega) - \varphi_{\rm ref}(\omega)$  corresponds to the optical path difference  $L_{\text{opt}}(\omega) = \varphi(\omega)\lambda/2\pi = (n_{\text{eff}}(\omega)-1) d$  induced by the sample in comparison to vacuum. The photomixers emit and detect left circularly polarized (lcp) light [76– 78]. In transmission geometry, data for right circular polarization (rcp) were collected using a linear polarizer in front of the sample and a stainless steel plate behind the sample, reflecting the light under  $45^{\circ}$  incidence to transform the transmitted *rcp* component to *lcp*. Alternatively, the polarization rotation was determined using a linear polarizer in front of the sample and a second one operating as analyzer behind the sample. The analyzer was rotated in steps of  $5^{\circ}$  in the vicinity of the magnon and in steps of  $10^{\circ}$  otherwise. The setup achieves a frequency resolution in the MHz range. In the vicinity of the electromagnon, data were collected with a typical step size of  $\Delta \omega = 50 \,\mathrm{MHz} \,(0.0017 \,\mathrm{cm}^{-1})$ , otherwise  $\Delta \omega = 500 \,\mathrm{MHz}$  was used. In zero magnetic field, data were measured at 3 K in an optical <sup>4</sup>He bath cryostat on an optical table with four lenses forming two Gaussian telescopes, focusing the beam onto the sample [72]. For measurements in magnetic field up to 8 T, we employ fiber-coupled photomixers that we have engineered for cryogenic operation, allowing us to operate the photomixers inside a windowless magneto-cryostat. Using face-to-face geometry with a distance of about 6 cm between the photomixers, the sample is located in the focus of the photomixers' Si lens that couples the terahertz radiation to free space. Inside the magnet, reference and sample can be exchanged using a piezo-rotator. Data in magnetic field were collected at 13.5 K where the setup is most stable, which is related to the heat carried into the magnet by the two laser beams.

The magnon eigenfrequency  $\omega_0 = 12.42 \text{ cm}^{-1}$  corresponds to a vacuum wavelength  $\lambda_{\text{vac}} \approx 0.8 \text{ mm}$ . This is comparable to the sample size. Therefore, we focus on the phase data which is less sensitive to possible diffraction effects for measurements on samples in a frequency range where the sample size is not much larger than the vacuum wavelength  $\lambda_{\text{vac}}$  [72]. Roughly speaking, diffraction reduces the detected amplitude but the photons that arrive at the detector still carry meaningful phase information. Similar to the phase data, the measurement of the rotation of linear polarization is not sensitive to a diffraction-induced suppression of the absolute value of the terahertz amplitude.

# C. Oscillator model

Assuming a Lorentzian shape of the excitation, timereversal symmetry implies

$$\varepsilon(\omega) = \varepsilon_{\infty} + \frac{\omega_p^2}{\omega_0^2 - \omega^2 - i\gamma\omega} \tag{9}$$

$$\mu(\omega) = 1 + \frac{\omega_m^2}{\omega_0^2 - \omega^2 - i\gamma\omega}$$
(10)

$$\chi_{ij}^{me}(\omega) = \frac{i\,\omega\,\omega_{ij}}{\omega_0^2 - \omega^2 - i\gamma\omega} \tag{11}$$

with 
$$\omega_p^2 \omega_m^2 / \omega_0^2 = \omega_{xx}^2 + \omega_{xy}^2$$
, (12)

where  $\omega_0$  denotes the eigenfrequency,  $\gamma$  is the linewidth, and  $\omega_{xx}$  and  $\omega_{xy}$  govern the strength of the magnetoelectric response in analogy to the plasma frequency  $\omega_p$  and the equivalent parameter  $\omega_m$  for the magnetic dipole response, while  $\varepsilon_{\infty}$  summarizes the contributions from higher energies. With the typical choice  $\mu_{\infty} = 1$ , such high-energy contributions are neglected in  $\mu(\omega)$ .

# ACKNOWLEDGMENTS

We gratefully acknowledge fruitful discussions with P. Becker and L. Bohatý as well as funding from the Deutsche Forschungsgemeinschaft (DFG, German Research Foundation) via Project numbers 277146847 (CRC 1238, project B02) and 492547816 (TRR 360). SWC was supported by the W. M. Keck foundation grant to the Keck Center for Quantum Magnetism at Rutgers University. DS acknowledges the support of the Janos Bolyai Research Scholarship (BO-00580/22/11) and that of the the New National Excellence Program (ÚNKP-23-5-BME-414). VT acknowledges support via the project ANCD 20.80009.5007.19 (Moldova).
