Bilayer materials may support interlayer excitons comprised of electrons in one layer and holes in the other. In experiments, a non-zero exciton density is typically sustained by a bias chemical potential, implemented either by optical pumping or by electrical contacts connected to the two layers. We show that if charge can tunnel between the layers, the chemical potential bias means that an exciton condensate is in the dynamical regime of ac Josephson effect. It has physical consequences such as tunneling currents and the ability to tune a condensate from bright (emitting coherent photons) to dark by experimental controlling knobs. If the system is placed in an optical cavity, coupling with cavity photons favors different dynamical states depending on the bias, realizing superradiant phases.

An exciton is a boson formed when an electron in a conduction band of an insulator becomes bound to a hole in its valence band. Interlayer excitons are formed of electrons and holes residing in different layers of a two dimensional (2D) ‘electron-hole bilayer’ system, which are of great current interest for their long life time and because their density, binding energy and other properties may be easily tuned by applied electric fields [1, 2]. The energy ω_{ex} of an exciton at zero momentum is the band gap G minus the exciton binding energy E_b . An exciton condensate may be formed in equilibrium at low temperatures if ω_{ex} becomes negative due to, e.g., a reduced band gap tuned by a gate voltage V_g in Fig. 1(a) [3–10]. Possible equilibrium condensates were studied in bilayers made of InAs/GaSb [11] and transition metal dichalcogenides (TMD) [12, 13], and also in the quantum hall regime of bilayers made of GaAs [14, 15], graphene [16–18] and TMD [19].

However, in most experimental systems to date, the exciton condensates are actually non-equilibrium ones maintained via injection of electrons and holes into the system by optical excitation [20–22], or electrical injection of carriers via conducting leads [23–27]. Carrier injection implies a chemical potential difference (μ in Fig. 1(a)) between the layers, which drives a time dependence of the phase of the excitonic order parameter, similar to optically pumped exciton polariton condensates [28–33]. If the electron and hole layers are electrically isolated from each other, the order parameter dynamics has no physical effects. However, we observe that if electrons can tunnel between layers, it results in an AC Josephson effect [34–37] that leads to important physical consequences. This includes coherent photon emission, a DC tunneling current, and remarkable tunability of phase transitions between bright and dark condensates. We further show that when placed in an optical cavity [38, 39], the coupling of the condensate with cavity photons selects different dynamical phases depending on the bias voltage, realizing the long sought super radiant states in non-equilibrium. We analyze this effect in the context of TMDBs, but the theory also apply to pumped TMD monolayers and other electron

FIG. 1. (a) Schematic of the biased TMDB. (b) The low energy electronic bands giving the interlayer excitons: conduction bands from the top layer and valence bands from the bottom layer. Both bands have two valleys K and K' with effective mass m . The arrows represent the spin eigenvalues. The dashed curves are schematic exciton energy levels, with the lowest one being the $1s$ exciton at frequency ω_{ex} . The gate bias λV_g exerts a vertical electric field that shrinks the original band gap G_0 to $G = G_0 - V_g$, where $\lambda > 1$ because of the thickness mismatch. The contact bias applies a chemical potential bias μ to inject the excitons [23].

hole bilayers such as GaAs structures, see supplemental information (SI) Sec. I.

The device and the excitonic Hamiltonian—Biased TMDB provide a favorable environment for high temperature excitonic condensates [1, 8, 9] and recently, exciting experiments have reported their signatures in these systems [24, 25]. The TMDB systems are composed of two layers of TMD stacked one on top of the other as shown in Fig. 1(a). The hexagonal monolayers are semiconductors with direct bandgaps of 1–2 eV at the K and K' points of the hexagonal Brillouin zone [2]. Near K and K' , spin-orbit coupling (SOC) splits the valence band by about 200 meV, and the conduction band by an amount that varies between 3–60 meV depending on the specific compound [40, 41]. Applying a gate voltage to TMDB shrinks the effective interlayer band gap by (say) lowering the energy of the top layer conduction band and raising the energy of the bottom layer valence band, making the interlayer excitons the lowest energy ones [8, 9]. For the low energy excitons, it is enough to consider only the lowest conduction band from the top layer and the highest valence

band from the bottom layer, as shown in Fig. 1(b).

We focus on the lowest energy s-excitons represented by the bosonic field Φ_{ij} , which is a 2×2 matrix with i, j taking the values of either K or K' , giving the four types of excitons: Φ_{11}, Φ_{22} means the two intravalley excitons and Φ_{12}, Φ_{21} means the two intervalley excitons (Fig. 2). It is convenient to represent it as $\Phi = \Phi_\mu \sigma_\mu / \sqrt{2} =$

$(\Phi_0 \sigma_0 + \Phi_1 \sigma_1 + \Phi_2 \sigma_2 + \Phi_3 \sigma_3) / \sqrt{2}$ where σ_μ are the usual Pauli matrices, grouping Φ into the valley singlet Φ_0 and the valley triplet Φ_1, Φ_2, Φ_3 . The effective Lagrangian is derived as $L = \int d^2 \mathbf{r} (\text{Tr}[-i\Phi^\dagger \partial_t \Phi] + H)$ where the Hamiltonian density $H = H_0 + H_J$ has two parts:

$$\begin{aligned} H_0 &= \text{Tr} \left[\Phi^\dagger \left(\omega_{\text{ex}} + \frac{p^2}{4m} \right) \Phi + c_4 (\Phi^\dagger \Phi)^2 \right] + \frac{1}{2} \int d\mathbf{r} d\mathbf{r}' \rho(\mathbf{r}) U(\mathbf{r} - \mathbf{r}') \rho(\mathbf{r}'), \\ H_J &= c_{\text{em}} (E_x \Phi_0 + iE_y \Phi_3 + c.c.) + c_J \left[\frac{1}{2} (\Phi_1^2 + \Phi_2^2 + c.c.) + \rho \right], \end{aligned} \quad (1)$$

see SI Sec. III. Note that we set the elementary charge e , the Planck constant $\hbar$ and the speed of light c to unity for notational simplicity, except when we discuss physical observables. Here $\omega_{\text{ex}} = G - E_b$ is the single exciton energy at zero center-of-mass momentum, $\rho = \text{Tr}[\Phi^\dagger \Phi] = \Phi_\mu^* \Phi_\mu$ is the local exciton density, and $U(\mathbf{r} - \mathbf{r}')$ is the kernel for dipole-dipole interaction between excitons [9]. For long wavelength behavior of the condensate, it is enough to approximate U by a local interaction with kernel $U_0 \equiv \int d^2 \mathbf{r} U(\mathbf{r}) = 4\pi d/\epsilon$ which is just the inverse of the capacitance C of the bilayer with the dielectric ϵ , such that the Hartree term becomes $U_0 \int d\mathbf{r} \rho^2/2$. The coefficient c_4 is the exchange interaction which is repulsive for adjacent bilayers such that the interlayer distance is small [9, 42, 43]. For an interlayer distance d much smaller than the excitonic Bohr radius $a_0 = 2\epsilon\hbar^2/me^2$, one has $c_4 \approx 8\pi/m$, larger than the dipole repulsion U_0 by a factor a_0/d .

The H_J part contains the Josephson terms due to the weak interlayer tunneling (hoping) that reduces the $U(1)$ symmetry [34, 44]. We focus on four $(H_M^M, H_X^M, R_M^X, R_M^M)$ of the six high symmetry interlayer stackings, where the conduction and valence bands in each valley have different eigenvalues under C_3 rotation around certain high symmetry centers [2, 45], forbidding a direct hoping at the K and K' points. Together with time reversal symmetry, the hoping matrix element is constrained to $t_k = v_t(k_x \pm ik_y)$ for the K/K' valley where $v_t \sim 10^3 - 10^4$ m/s is a velocity scale [45]. This chiral tunneling leads to the second order Josephson term [34] with the Josephson energy $c_J = mv_t^2 f_J(E_b, G, \omega)$ in Eq. (1), and the coupling coefficient $c_{\text{em}} = \sqrt{mv_t^2/E_b f_{\text{em}}(E_b, G, \omega)}$ to the in-plane electric field $\mathbf{E} = -\partial_t \mathbf{A}$, where f_J and f_{em} are dimensionless functions, see SI Sec. III. The coupling term to EM field reflects the circular optical selection rules for the bright excitons.

Without the leads, the classical equation of motion would be $\partial_{\Phi^\dagger} L = 0$, or in other words, $i\partial_t \Phi = \partial_{\Phi^\dagger} H$. The leads are modeled as a bath imposing the chemical potential μ for the interlayer excitons. In the simplest case, its only effect is to

add a dissipative term to the equation of motion:

$$i\partial_t \Phi = \partial_{\Phi^\dagger} H - i\Gamma \partial_{\Phi^\dagger} F, \quad F = H - \mu\rho \quad (2)$$

which acts to drag Φ to the value that minimizes the free energy F , see Ref. [46] for a detailed derivation with a bath. Here Γ is the dimensionless tunneling rate of excitons between the bilayer system and the leads. We assume the interlayer charge tunneling is the bottleneck of particle flow, such that the exciton tunneling between the system and the leads is effectively uniform all over the 2D device.

Supplemented by the free Lagrangian [47] of the electromagnetic (EM) field $\mathbf{A}$, Eqs. (1)(2) describes the device of interest.

Without interlayer tunnelling ($H_J = 0$), Eq. (1) has a $U(2) \times U(2)$ symmetry of valley rotations ($\Phi \rightarrow U_1^\dagger \Phi U_2$ where U_1, U_2 are 2×2 unitary matrices) [9], same as the excitons made of spin 1/2 electrons and holes. The steady state is an ‘equilibrium state’ which simply minimizes the free energy F [48]. For $\mu > \omega_{\text{ex}}$ and well below the Berezinskii-Kosterlitz-Thouless (BKT) temperature [49, 50], an exciton condensate occurs and the bosonic field develops a classical value Φ : the order parameter. Note that the repulsive exchange interaction

$$\text{Tr}[(\Phi^\dagger \Phi)^2] = \frac{1}{2} \rho^2 + \frac{1}{2} \sum_{l=1,2,3} \left(\Phi_0^* \Phi_l + c.c. + i\epsilon_{ljk} \Phi_j^* \Phi_k \right)^2 \quad (3)$$

favors the states with equally distributed exciton numbers between the two valleys. Therefore, the typical lowest energy condensate satisfies $|\Phi_{KK}| = |\Phi_{K'K'}|$ and $|\Phi_{KK'}| = |\Phi_{K'K}|$ such that the most generic ground state order parameter can be written as

$$\Phi_\mu = e^{i\theta} (ia_0, a_1, a_2, a_3), \quad a_\mu a^\mu = \rho_0 = \frac{\mu - \omega_{\text{ex}}}{2g} \quad (4)$$

where a_μ are real numbers and we defined $g = (c_4 + U_0)/2$. Therefore, the ground state manifold is four dimensional with the topology of $S_1 \times S_3$ where S_N means the N dimensional sphere. Choosing one point on this manifold corresponds to spontaneously breaking the continuous symmetries associated with this manifold and implies four gapless

FIG. 2. (a) Illustrations of the bright (intravalley) condensate with the dashed ovals denoting the electron-hole pairing. (b) The free energy plotted on the complex plane of the order parameter $|\Phi|e^{i\theta}$ for the bright condensate, with lower energy appearing bluer. The dashed line is the orbit of the dynamical order parameter without interlayer tunneling ($\nu_t = 0$). The solid line is that with tunneling ($\nu_t \neq 0$). (c,d) Same as (a,b) but for the dark (intervalley) condensate.

Goldstone modes. The solution of Eq. (2) says the overall phase constantly winds in time:

$$\theta = \theta(0) - \mu t \equiv \theta_0(t) \quad (5)$$

meaning the state may be represented as an one dimensional orbit in the order parameter space, as shown by the dashed curves in Fig. 2(b)(d). However, this dynamics doesn't have any observable effects.

Effect of interlayer tunneling—We now turn to the central topic of this paper: a nonzero electronic interlayer tunneling ν_t results in H_J in Eq. (1) and renders the dynamical condensate a truly non-equilibrium steady state. From the symmetry point of view, H_J breaks the conservation of exciton number and reduces the valley rotation symmetry to $O(2) \times O(2)$ rotations around σ_3 only. Two basic candidates of dynamical ‘ground states’ are the bright (intravalley, Fig. 2(a)(b)) and dark (intervalley, Fig. 2(b)(d)) condensates which have different properties.

The bright condensate (Fig. 2(a)(b)) corresponds to nonzero Φ_0 or Φ_3 or their linear combination. From H_J , this state has an in-plane electrical polarization $(P_x, P_y) = 2c_{em}(-\text{Re}[\Phi_0], \text{Im}[\Phi_3])$, which is dynamical since it is locked with the winding order parameter phase $\theta(t)$. For example, if only $\Phi_3 = \sqrt{\rho}e^{i\theta(t)}$ is nonzero, the polarization oscillates along the y -direction and emits coherent EM wave that propagates vertically away from the 2D device with the electric field $E_y = \frac{2\pi}{c}\partial_t P_y$ and radiation power

$$P_r = \frac{c}{4\pi}E_y^2 = 2\alpha\frac{mv_t^2 E_b}{G^2}\mu^2\rho \equiv \gamma_r\mu\rho, \quad (6)$$

as the name ‘bright’ suggests. Here γ_r is the radiative decay rate of intravalley excitons, E_b is the binding energy of the 1s exciton, $\alpha = e^2/(\hbar c) \approx 1/137$ is the fine structure

constant and we have temporarily restored e and $\hbar$. The radiation power also implies a tunneling charge current: $I_{\text{bright}} = P_r/\mu = \gamma_r\rho$. We have neglected dielectric screening ϵ since it does not affect such long wavelength physics for typical thin devices. Note that the polarization of emitted photons depends continuously on the ratio between Φ_0 and Φ_3 , which is spontaneously chosen by the non-equilibrium symmetry-broken state.

The dark condensate (Fig. 2(c)(d)), corresponding to nonzero Φ_1 or Φ_2 or their linear combination, does not emit photons, as its name suggests. Nevertheless, it experiences a second order Josephson effect [34]. Taking Φ_1 as an example, the free energy landscape plotted on the complex order parameter plane is no longer invariant in the phase direction, but is distorted by the weak Josephson term $c_J\rho\cos(2\theta)$ in H_J of Eq. (1), as shown by Fig. 2(d). Consequently, the system is in the AC Josephson effect regime with an interlayer charge current $J = c_J\rho\sin(2\theta)$ oscillating at the frequency 2μ , and a measurable DC current which we will discuss later.

The non-equilibrium phase diagram—The remaining question is which dynamical state the system prefers. In this paper, we address this question at the mean field level, meaning we neglect spatial fluctuations, and construct an effective static potential which the dynamical state should minimize. Without loss of generality, we pick Φ_3 for the bright condensate and Φ_1 for the dark one, and write the order parameter as somewhere between them:

$$(\Phi_1, \Phi_3) = (\sqrt{\eta}, \sqrt{1-\eta}e^{i\theta_a})\sqrt{\rho}e^{i\theta}. \quad (7)$$

Here $\eta \in [0, 1]$ controls which state the system lies in: $\eta = 0$ means the bright condensate and $\eta = 1$ means the dark one. Eq. (2) could be rewritten for the new variables ρ , θ , θ_a and η :

$$\begin{aligned} \dot{\theta} &= -\partial_\rho H, & \dot{\rho} &= \partial_\theta H - 4\Gamma\rho\partial_\rho F, \\ \rho\dot{\theta}_a &= \partial_\eta H, & \partial_t[(1-\eta)\rho] &= \partial_{\theta_a} H. \end{aligned} \quad (8)$$

For simplicity, we kept only the amplitude (ρ) direction of the damping term $\Gamma\partial_{\Phi^\dagger}F$, which does not change the qualitative conclusion. In the limit of $H_J = 0$, the solution is simply an orbit $S_0 = (\theta_0(t), \rho_0, 0, \eta_0)$ with $\theta_0(t)$ defined in Eq. (5), a constant exciton density $\rho = \rho_0$ defined in Eq. (4), $\theta_a = 0$, and a spontaneously chosen η_0 .

A weak H_J distorts the orbit, which could be written perturbatively in ν_t :

$$(\theta, \rho, \theta_a, \eta) = S_0 + S_1 + O(c_J^2). \quad (9)$$

where $S_1 = (\theta^{(1)}, \rho^{(1)}, \theta_a^{(1)}, \eta^{(1)})$ is the $O(c_J)$ correction to the orbit. In the dark condensate ($\eta = 1$), all the variables oscillate around the perfect circle S_0 with frequency 2μ , as shown schematically by the solid curve in Fig. 2(d). In the bright condensate ($\eta = 0$), the photon radiation tends to reduce the exciton density and drags the orbit smaller, as shown by the solid curve in Fig. 2(b). Note that the actual bright orbit also oscillates due to the linear polarization of the coherent emission, which for simplicity is not shown.

FIG. 3. (a) The phase diagram of the non-equilibrium steady states on the $\mu - V_g$ plane of the device (Fig. 1) well below the BKT temperature. The colored area is the exciton condensate phase, with the light blue/red region being the dark/bright dynamical condensate, and the dark blue region being the dark static condensate. The color scale in red is the coherent photon radiation power P_r of a $1 \mu\text{m}^2$ device, also meaning a tunneling current P_r/μ . When computing P_r , we have assumed $f_{\text{em}}(E_b, G, \omega) = f_{\text{em}}(E_b, G_0, \omega_{\text{ex}})$ since this function does not change dramatically across the phase diagram of interest. The other parameters are $\omega_{\text{ex}0} = 1.23 \text{ eV}$, $G_0 = 1.50 \text{ eV}$, $\gamma = 0.10 \text{ eV}$ and the typical ones as in table I of the SI. (b) Same as (a) but for the device in an optical cavity shown by the top inset, where the red wavy curve represents a cavity photon mode driven by the condensate. The cavity thickness is $2h = 0.8 \mu\text{m}$, the dielectric is $\epsilon = 10$, and the radiative damping rate of cavity modes is $\gamma_p = 30 \text{ meV}$. The red region now means the ‘superradiant’ bright condensate.

This fast oscillation exerts a slow force [51, 52] on the slow component of η , the Pondermotive force [51], which could be computed by time averaging the total force for η :

$$\begin{aligned} F_p &= \langle -\partial_\eta L \rangle_t \\ &= -\langle c_j \rho \cos 2\theta - \rho \dot{\theta}_a + c_4 \rho^2 (1 - 2\eta) \sin^2 \theta_a \rangle_t \\ &= c_j^2 \rho_0 \left[\frac{2\mu - 4g\rho_0\eta + (1-\eta)\frac{\gamma^2}{2\mu}}{4\mu^2 + \gamma^2} + c_4 \rho_0 \frac{2\eta - 1}{8\mu^2} \right] \end{aligned} \quad (10)$$

where the damping rate is $\gamma = 8g\rho_0\Gamma$. Note that we have neglected the c_{em} term in H_j , whose effect is suppressed by a factor of $\alpha^2\mu^2/\gamma^2$. The Pondermotive force corresponds to an effective potential for η , coined the Pondermotive potential [51]: $V_p = -\int d\eta F_p$.

Naturally, dissipation effects from the environment would relax η to minimize V_p (this effect is not contained in Eq. (2)), giving the non-equilibrium phase diagram in Fig. 3(a). The red region means in general a linear combination between the bright condensate and the dark one ($0 \leq \eta < 1$), with η given by $F_p(\eta) = 0$. The power of coherent radiation computed from Eq. (6) is also shown by the red color scale, which implies a DC tunneling current. The dark condensate (blue region, $\eta = 1$) occupies the most experimentally accessible part of the phase diagram. It does not radiate but still has a DC tunneling current

$$I_{\text{dark}} = \langle c_j \rho \sin(2\theta) \rangle_t = \Gamma \frac{c_j^2}{\mu} \rho_0 \frac{\mu^2 + \omega_{\text{ex}}^2 + \frac{1}{16}\gamma^2}{\mu^2 + \frac{1}{16}\gamma^2} \quad (11)$$

which is at the order of $0.1 \mu\text{A}/\mu\text{m}^2$ for typical parameters of TMDB, see SI Sec. VII. Therefore, one may tune the dynamical condensate across different phases by the gate and bias

voltages, with the photon radiation and tunneling currents as their signatures.

Dynamical condensate in a cavity—Since the bright condensate radiates, placing the device in a Fabry-Pérot cavity would result in interesting interplay between the condensate and cavity photons [1, 53], forming exciton-polariton condensates [30, 38].

In a cavity of thickness $2h$ formed with walls made of perfect metal and filled with dielectric spacers of dielectric constant ϵ , the cavity photon modes at zero in-plane momentum are polarized in-plane, have frequencies $\omega_n = (n+1)\omega_0$ with indices $n = 0, 1, 2, \dots$ and $\omega_0 = \pi/(2\sqrt{\epsilon}h)$ being the fundamental mode frequency. For simplicity, we assume that the TMDB is placed in the middle of the cavity. The oscillating in-plane polarization P would linearly drive the discrete photon modes of the cavity. The latter feed back by an oscillating electric field $E = \frac{2\pi}{\sqrt{\epsilon}c} \mu P \tan \frac{\pi\mu}{2\omega_0}$ on the TMDB plane that could be obtained by solving the Maxwell’s equations. This electric field couples to the order parameter through the c_{em} term in Eq. (1), and would therefore contribute an effective potential V_{Pcavity} for the bright condensate relative to the dark one, in the same spirit as that behind the formation of cold atomic super-radiant states [54]. Rigorously speaking, this effective potential is the Pondermotive potential [51] obtained by integrating out the cavity photon modes in the Keldysh path integral, which in the current case is proved to be simply one half of the coupling energy: $V_{\text{Pcavity}} = -\langle PE \rangle_t/2$, giving

$$V_{\text{Pcavity}} = -\frac{4\alpha}{\sqrt{\epsilon}} \frac{\mu E_b}{G^2} m v_t^2 \rho_0 \text{Re} \left[\tan \frac{\mu + i\gamma_p}{2\omega_0/\pi} \right] \quad (12)$$

where we have added the damping rate γ_p of the cavity

photons.

Since V_{pcavity} is at the order of v_t^2 , it dominates over the $O(v_t^4)$ potential from Eq. (10) due to Josephson oscillations. Furthermore, V_{pcavity} is negative and resonantly enhanced whenever the dynamical frequency μ is a little below the frequency ω_n of an even index cavity mode whose anti-node is on the TMDB, strongly favoring the bright condensate. This is because this cavity mode is driven almost resonantly and in phase with the polarization of the condensate. As a result, the phase diagram of this device is modified by the cavity to that in Fig. 3(b).

The driving of cavity modes leads to the dissipation power $P_{\text{cavity}} = \langle E\dot{P} \rangle = \frac{1}{2\sqrt{\epsilon}} P_r \text{Im} \left[\tan \frac{\mu + i\gamma_p}{2\omega_0/\pi} \right]$ with P_r from Eq. (6), which in turn means a tunneling current $I = P_{\text{cavity}}/\mu$. If the damping of cavity photons comes only from leakage out of the cavity, all the power is converted to coherent photon radiation as plotted by the red color scale in Fig. 3(b). Furthermore, when a resonance is met at $\mu \approx \omega_n$, the power of radiation peaks at $P_r \omega_0 / (\sqrt{\epsilon} \gamma_p)$, enhanced by a photon quality factor compared to a bright condensate without cavity. This realizes a long sought super-radiant state [55] in a solid state system, which is forbidden in equilibrium [56–58]. Therefore, this device may work as a laser [59–64] that converts DC current into coherent photons at the energy of the bias voltage, with the allowed ‘shining’ frequencies tunable by the thickness of the device.

Discussion—The dynamical condensates may be viewed as continuous time crystals: they spontaneously break the time translational symmetry by picking a θ , which is observable by the phase of the coherent emission or the oscillating current [65–69]. This dynamics also periodically modulate the dispersion of the Goldstone modes and lead to parametric generation of quantum entangled phasons [70], see SI Sec. IX.

The bright condensate may be favored by other mechanisms not explicitly considered here, e.g., a nonzero first order Josephson tunneling, a coupling to lattice distortion,

or by driving the system with coherent light. We note that a nonzero local electron-hole exchange interaction [71] that favors the dark condensate (see SI Sec. I), the indirect band gaps in some compounds [72], and bi-excitons effects in monolayer TMDs [73, 74] may also change the phase diagrams in Fig. 3.

It is a meaningful future direction to investigate the fluctuation effects of the dynamical condensate using, e.g., numerical methods [37]. In the case of $H_j = 0$ so that the ground state manifold is $S_1 \times S_3$, previous study of spinor BEC [75] indicates that the thermal phase transition is of the BKT type [49, 50] controlled by the vortices of the overall phase θ . In the low temperature phase, the θ field has quasi long range (algebraic) order while the S_3 degrees of freedom are disordered. With nonzero H_j , the symmetry is further reduced and quasi long range order probably still exists. It is also interesting to generalize the current study to TMDBs with first order Josephson tunneling (SI Sec. XI), to those with periodic Moire patterns [76–78], and to double layers in the quantum hall regime [16–18].

I. THE DEVICES

Although we used the electrically biased TMD bilayer as an example in the figures of the main text, our theory applies to the optically pumped case equally well, where the bath becomes the free electrons and holes pumped by light [20, 21, 29, 32, 55]. It also applies to other materials such as graphene in the quantum hall regime [16–18] and GaAs [14, 15]. In Fig. S1, we show five types of devices that the theory and the qualitative conclusions apply to.

II. THE ELECTRONIC HAMILTONIAN

Since we are interested in the lowest energy exciton condensates, we keep the four relevant electronic bands: a highest valence band and a lowest conduction band at each valley, represented by the four component electron annihilation operator

FIG. S1. The five types of devices that the theory (Eqs. (1)(2)) and the qualitative conclusions apply to. (a) The device that the main text focused on. The excitons are sustained by a chemical potential μ provided by the electrical contacts [25, 79]. The top and bottom gates may play two roles: providing a z-direction electric field that tunes the interlayer band gap, and forming an optical cavity. (b) In this device, the chemical potential μ for the excitons is provided by the two tunneling gates [23] made of, e.g., graphene. The yellow metallic gates play the role of optical cavity. (c) Same as (b) but for monolayer excitons. (d) The reservoir for the excitons is the optically pumped free electrons and holes, which effectively exerts a chemical potential μ . The top and bottom gates play two roles: tuning the gap and forming the cavity. (e) The excitons are intralayer excitons in a monolayer [38]. The optically pumped free electrons and holes provide the reservoir which exerts a chemical potential μ for the excitons.

$\psi(r) = (\psi_{K,c}, \psi_{K',c}, \psi_{K,v}, \psi_{K',v})^T$. Here $\psi_{K,c/v}$ is the annihilation operator of conduction/valence band electrons at the K valley and $\psi_{K',c/v}$ is that at the K' valley. There is no spin index since the spins are locked with the valley by the spin orbit interaction, see Fig. 1b of the main text. The four band Hamiltonian reads

$$\begin{aligned}
 H &= \psi^\dagger \begin{pmatrix} \xi_1(p) & \hat{t}_p \\ \hat{t}_p^\dagger & -\xi_2(p) \end{pmatrix} \psi + V_{ee} + V_{hh} + V_{eh} + V_{ex}, \\
 V_{ee/hh} &= \int dr dr' \frac{1}{|r-r'|} \rho_{e/h}(r) \rho_{e/h}(r'), \quad V_{eh} = - \int dr dr' \frac{1}{\sqrt{|r-r'|^2 + d^2}} \rho_e(r) \rho_h(r'), \\
 V_{ex} &= V_{ex0} \int dr \sum_\tau \psi_{\tau,c}^\dagger(r) \psi_{\tau,v}(r) \psi_{\tau,v}^\dagger(r) \psi_{\tau,c}(r), \\
 \rho_e(r) &= \sum_\tau \psi_{\tau,c}^\dagger(r) \psi_{\tau,c}(r), \quad \rho_h(r) = \sum_\tau \psi_{\tau,v}(r) \psi_{\tau,v}^\dagger(r)
 \end{aligned} \tag{S1}$$

where p should be understood as a spatial derivative $-i\nabla$ acting on the field operators. The electromagnetic (EM) field represented by the vector potential A enters via the minimal coupling $p \rightarrow p - A$. We use quadratic approximation to the band dispersion $\xi_1(k) = \xi_2(k) = k^2/(2m) + G_0/2 - V_g/2 = k^2/(2m) + G/2 = \varepsilon_k + G/2$ with effective mass m . $\hat{t}_p$ is the interlayer hopping. V_{ee} , V_{hh} and V_{eh} are the Coulomb interaction between the carriers and ρ_e , ρ_h are the density operators of the electrons and holes. The summation of τ is over K, K' . The effective mass has been chosen to be the same for electron and holes for notational simplicity which does not affect the conclusions.

We now discuss the electron-hole exchange interactions [71, 80, 81]. In the case of interlayer excitons, since this exchange requires nonzero overlap between the atomic orbitals of the electron and the hole that reside in different layers, it is much weaker than that of the intralayer excitons. The first exchange interaction is the weak long range Coulomb interaction between interband transition dipoles (this is not to be confused with the direct dipole-dipole interaction between the permanent dipoles). It is implicitly included by the minimal coupling to the EM field in $\hat{t}_{p-A}$. Together with the Lagrangian of the EM field in vacuum, this coupling leads to the electron-hole ‘exchange’ interaction that splits longitudinal and transverse bright excitons (also called exciton polaritons) at nonzero center of mass momentum q [80]. However, the splitting is zero at zero q for two dimensions, and is therefore inconsequential for our discussion of the mean field condensate. The second electron-hole exchange interaction is the local exchange between overlapping atomic orbitals. In the local limit, this interaction does not distinguish the K and K' valleys, and therefore does not break the degeneracy between all four types of the lowest energy excitons. Away from the local limit, the exchange is represented as the V_{ex} term in Eq. (S1). Since the C_3 eigenvalues of conduction and valence electrons at the K valley differ by $e^{i2\pi/3}$, while those at the K' valley differ by $e^{-i2\pi/3}$, the C_3 rotational symmetry constrains the two electron-hole pairs of the exchange term to be in the same valley. This means that this exchange does not have valley rotational symmetry like that for spins. It raises the energy of the bright excitons Φ_0, Φ_3 by the same amount, although Φ_0 is a valley singlet and Φ_3 belongs to the valley triplet. Since the exchange interaction V_{ex} is weak and unknown, we don’t include it in the main text.

The interlayer tunneling matrix element $\hat{t}_p$ has contributions from both direct hopping and higher order processes involving remote bands, but its magnitude is small and its form is controlled by symmetry depending on the way in which the two components of the bilayer are stacked. In four of the six high symmetry interlayer stackings (H_M^M , H_X^M , R_M^X , R_M^M), the conduction and valence bands in each valley have different eigenvalues under C_3 rotation around certain high symmetry centers, which forbids a direct tunneling at the K and K' points [2]. Together with time reversal ($\hat{T}: (\psi_{K,c}, \psi_{K',c}, \psi_{K,v}, \psi_{K',v}) \rightarrow (\psi_{K',c}, \psi_{K,c}, -\psi_{K',v}, -\psi_{K,v})$) symmetry, the leading terms of the tunneling matrix element is

constrained to be [45]

$$\hat{t}_k = v_t \begin{pmatrix} k_x + ik_y & 0 \\ 0 & k_x - ik_y \end{pmatrix} \quad (S2)$$

where k is the crystal momentum measured from the K/K' point, and $v_t \sim 10^3 - 10^4$ m/s for bilayers with no interlayer spacers [45]. This form of $\hat{t}_k$ leads to a second order Josephson effect [34] which we will focus on for most of this paper. The other two stacking types (R_X^M and H_X^X) will lead to a $\hat{t}_k$ that is non-vanishing as $k \rightarrow 0$, producing a first order Josephson effect whose consequences are discussed in Sec. XI.

III. THE EFFECTIVE ACTION FOR THE EXCITONS

In this section, we show how to derive the effective action for the excitons from the Hubbard-Stratnovich transformation with the suitable basis (wave functions) for the excitons. For notational simplicity, we temporarily neglect the interlayer tunneling $\hat{t}$, the electron-electron, hole-hole repulsion V_{ee}, V_{hh} and the electron-hole exchange V_{ex} , and add them back latter. The only remaining interaction is the electron hole attraction V_{eh} , which can be decomposed generally with the Hubbard-Stratnovich field Δ :

$$L_e = \sum_k \psi_k^\dagger \begin{pmatrix} -i\partial_t + \xi(k) & 0 \\ 0 & -i\partial_t - \xi(k) \end{pmatrix} \psi_k + \sum_{k,q} \left(\psi_{k+q/2}^\dagger \hat{\Delta}_{k,q} \psi_{k-q/2} + c.c. \right) + \sum_{k_1, k_2, q} \text{Tr}[\hat{\Delta}_{k_1, q}^\dagger V_{k_1, k_2}^{-1} \hat{\Delta}_{k_2, q}] \quad (S3)$$

where q has the meaning of center of mass momentum of excitons, V_{k_1, k_2}^{-1} is the k_1, k_2 component of the inverse of the electron hole attraction V_{eh} . Note that the above formalism should be understood as a functional integral: $Z = \int D[\psi, \Delta] e^{i \int dt dr L_e}$. Integrating out the fermions and keeping the quadratic terms in Δ , one obtains the effective action:

$$S[\Delta] = \sum_{k_1, k_2, q} \text{Tr} \left[\hat{\Delta}_{k_1, q}^\dagger V_{k_1, k_2}^{-1} \hat{\Delta}_{k_2, q} + \sum_{\omega} \chi_{\Delta}(\omega, k, q) \hat{\Delta}_{k, q}^\dagger(\omega) \hat{\Delta}_{k, q}(\omega) \right], \quad \chi_{\Delta}(\omega, k, q) = \frac{1}{-\omega + \xi_{k-q/2} + \xi_{k+q/2}}. \quad (S4)$$

Taking the saddle point equation $\frac{\delta S}{\delta \Delta_{k, q}^\dagger} = 0$ and defining $\Delta_{k, q} = \sum_{k'} V_{k, k'} \varphi_{k'} \Phi_q$ where Φ_q means the excitonic field at momentum q and $\varphi_{k'}$ has the meaning of the wave function of the relative coordinate between the electron and the hole, one obtains the eigen mode equation

$$\sum_{k'} (2\xi_k \delta_{kk'} + \frac{q^2}{4m} + V_{k, k'}) \varphi_{k'} = \omega \varphi_k. \quad (S5)$$

It is the same as the Schrodinger equation for the two body bound state. Its eigen-modes φ_n with eigen-values $\omega_{\text{exn}} + q^2/(4m)$ correspond to the excitons labeled by 'n'. Therefore, the excitonic eigen modes correspond to the two body bound states, and the order parameter field can be expanded using the eigen modes as

$$\Delta_{k, q} = \sum_{n, k'} V_{k, k'} \varphi_{n, k'} \Phi_{n, q} = \sum_n (\omega_{\text{exn}} - 2\xi_k) \varphi_{n, k} \Phi_{n, q} \quad (S6)$$

where $\Phi_{n, q}$ is the canonical bosonic field of the n th exciton with center of mass momentum q , and ω_{exn} is its energy at zero q .

In the following, we focus on the lowest s -exciton and drop the index 'n', and add back the interlayer tunneling $\hat{t}$, the electron-electron and hole-hole repulsion V_{ee}, V_{hh} and the electron-hole exchange V_{ex} . The decomposed Lagrangian for coupled fermions and excitonic fields is simplified to

$$L_e = \psi^\dagger \begin{pmatrix} -i\partial_t + \xi(p) & \hat{t}_p + \hat{\Delta}_p \\ \hat{t}_p^\dagger + \hat{\Delta}_p^\dagger & -i\partial_t - \xi(p) \end{pmatrix} \psi + \sum_k (\omega_{\text{ex}} - 2\xi_k) |\varphi_k|^2 \text{Tr}[\Phi^\dagger \Phi] + V_{ee} + V_{hh} + V_{ex}, \quad (S7)$$

$$\hat{\Delta}_k = (\omega_{\text{ex}} - 2\xi_k) \varphi_k \Phi$$

where we have suppressed the center of mass momentum q for notational simplicity. The excitonic action is obtained by integrating out the Fermions:

$$S = \sum_q c_2(q) \text{Tr} [\Phi^\dagger(-q) \Phi(q)] + \sum_{\Sigma q_i=0} c_4(q_1, q_2, q_3, q_4) \text{Tr} [\Phi^\dagger(q_1) \Phi(q_2) \Phi^\dagger(q_3) \Phi(q_4)] + \frac{1}{2} \int dr dr' \rho(r) U(r-r') \rho(r') \\ + \sum_q c_j(q) \left[\Phi_{12}(-q) \Phi_{21}(q) + c.c. + \sum_{ij} \Phi_{ij}^*(-q) \Phi_{ij}(q) \right] + \sum_q c_{\text{em}}(q) [A_x(-q) \partial_t \Phi_0(q) + i A_y(-q) \partial_t \Phi_3(q) + c.c.] \\ + \delta_{\text{ex0}} (\Phi_0^* \Phi_0 + \Phi_3^* \Phi_3) \quad (S8)$$

FIG. S2. The diagrammatic representation of each term in Eq. (S8). Black solid lines are electron propagators. Blue dashed lines are order parameter fields. Black dashed lines are the interlayer tunneling $\hat{t}$. Wavy lines connecting two fermion lines are electron-electron or hole-hole interactions or electron-hole exchange interactions. Open wavy lines are EM vector potentials, meaning the current operator. The ‘Hartree’ diagrams are for the direct dipole interaction between excitons (last term in Eq. (S8)). Note that all of them are ‘one particle irreducible’ with respect to the exciton field (blue dashed line).

where q should be understood as (q, ω) .

We now compute the coefficient of each term of the excitonic action Eq. (S8), diagrammatically represented in Fig. S2. In the simplest case, we neglect the screening from higher energy excitations which changes the interaction kernel to the Keldysh potential [82], and assume that the interlayer distance is much smaller than the exciton size, such that the electron and hole attracts via the two dimensional Coulomb potential, $V_q = 2\pi e^2 / (\epsilon q)$, where ϵ is a constant dielectric screening. The s-exciton wave function satisfying the bound state condition Eq. (S5) has the analytical form

$$\varphi_k = \sqrt{8\pi} \frac{q_0^2}{(q_0^2 + k^2)^{3/2}} \quad (S9)$$

in two dimensions where $q_0 = 2/a_0$, $a_0 = 2\epsilon\hbar^2 / me^2$ is the exciton Bohr radius, and $E_b = me^4 / (\hbar^2 \epsilon^2) = \hbar^2 q_0^2 / m$ is the binding energy [83]. In the following integrals, there are apparent divergence as $G \rightarrow 0$. This is not physical because when G is too small or when it is negative, the system crossovers to the BCS regime even for moderate μ , such that the power expansion of the action in Φ fails. We do not address this regime explicitly.

The c_2 term is the second term of Eq. (S8) plus the bubble diagram in Fig. S2(a):

$$\begin{aligned} c_2(\omega, q) &= \sum_k (\omega_{\text{ex}} - 2\xi_k) |\varphi_k|^2 - \sum_k (\omega_{\text{ex}} - 2\xi_k)^2 |\varphi_k|^2 \frac{1}{\omega - \xi_{k+q/2} - \xi_{k-q/2}} \\ &= \left(\omega - \left(\omega_{\text{ex}} + \frac{q^2}{4m} \right) \right) \sum_k |\varphi_k|^2 \frac{\omega_{\text{ex}} - 2\xi_k}{\omega - \frac{q^2}{4m} - 2\xi_k} \xrightarrow{\omega \approx \omega_{\text{ex}} + \frac{q^2}{4m}} \omega - \left(\omega_{\text{ex}} + \frac{q^2}{4m} \right) \end{aligned} \quad (\text{S10})$$

which gives the first term in Eq. (1) of the main text.

The c_4 term contains the positive ‘interlayer’ exchange (first diagram in Fig. S2 (b)) and negative intralayer exchanges (second and third diagrams) [9, 42, 43]. Note that regardless of the terminology, these exchanges don’t require any overlap between the atomic orbitals between the two layers. Here we compute the interlayer exchange at the zero momentum limit only:

$$\begin{aligned} c_4 &= \sum_k |\varphi_k|^4 (\omega_{\text{ex}} - 2\xi_k)^4 \frac{2}{(-\omega + 2\xi_k)^3} = (2\pi)^4 \frac{8E_b^4}{\pi^2 m^2} \sum_k \frac{1}{(E_b + 2\varepsilon_k)^2} \frac{1}{(\omega_{\text{ex}} - \omega + E_b + 2\varepsilon_k)^3} \\ &\xrightarrow{\omega \approx \omega_{\text{ex}}} \frac{16\pi^2 v}{m^2} = \frac{8\pi}{m} = \frac{4}{v} \end{aligned} \quad (\text{S11})$$

where $v = m/2\pi$ is the electronic density of states of the conduction/valence band. With the intralayer exchanges included, the c_4 term can be estimated from dimensional analysis. It can only be a function of m , e , $\hbar$ and the interlayer distance d , which means $c_4 \sim \frac{1}{m} f(\frac{d}{a_0})$ from dimensional analysis where $a_0 = \hbar^2/(me^2)$. In the limit of small interlayer distances, d drops out such that $c_4 \sim \frac{1}{m}$ which does not even depend on e . As shown in Refs. [9, 43], as d/a_0 increases, $f(\frac{d}{a_0})$ crossovers from ~ 1 to negative values. Therefore, for adjacent bilayers such that the interlayer distance is small, the positive interlayer exchange is generally larger in magnitude than the intralayer exchange, rendering the net exchange interaction a repulsive one [9].

The Hartree diagrams (Fig. S2(c)) simply give the long range dipole-dipole interaction $U(r) \approx \frac{d^2}{r^3}$ between the excitons due to their permanent interlayer dipoles.

The c_J term is the second order Josephson term represented by Fig. S2(d) where the first diagram gives $c_J v_t^2 \rho$ and the second diagram gives $c_J v_t^2 (\Phi_{12} \Phi_{21} + c.c.)$ since the intravalley terms vanish due to the chiral momentum dependence of t_k . The coefficient is

$$\begin{aligned} c_J(\omega) &= v_t^2 \sum_k |\varphi_k|^2 k^2 \frac{(\omega_{\text{ex}} - 2\xi_k)^2}{\xi_k (4\xi_k^2 - \omega^2)} = 4\pi^2 v_t^2 \sum_k \frac{4}{\pi} E_b^2 \left\{ \begin{aligned} &\frac{2\varepsilon_k}{(E_b + 2\varepsilon_k)^2 (G + 2\varepsilon_k) (2G - E_b + 2\varepsilon_k)}, & \omega = \omega_{\text{ex}} \\ &\frac{2\varepsilon_k}{(E_b + 2\varepsilon_k) (G + 2\varepsilon_k)^3}, & \omega = 0 \end{aligned} \right. \\ &= 4\pi^2 \frac{2}{\pi} v_t^2 v E_b^2 \left\{ \begin{aligned} &\frac{2(G - E_b) + E_b \ln \frac{E_b}{2G - E_b} + 2G \ln \frac{E_b (2G - E_b)}{G^2}}{4(E_b - G)^3}, & \omega = \omega_{\text{ex}} \\ &\frac{E_b^2 - G^2 + 2GE_b \ln \frac{G}{E_b}}{2(E_b - G)^3 G}, & \omega = 0 \end{aligned} \right. \\ &= m v_t^2 f_J(E_b, G, \omega), \\ f_J &\rightarrow 4\pi^2 \frac{E_b^2}{G^2} \left\{ \begin{aligned} &\frac{1}{2\pi^2} \ln \frac{G}{E_b}, & G \gg E_b, \omega \approx \omega_{\text{ex}} \\ &\frac{1}{6\pi^2}, & G \approx E_b, \omega \approx 0 \\ &\frac{1}{2\pi^2}, & G \gg E_b, \omega \approx 0 \end{aligned} \right. \end{aligned} \quad (\text{S12})$$

Note that the Φ legs Fig. S2(d) have frequencies $\pm\omega$.

The c_{em} term (Fig. S2(e)) gives the coupling to the in-plane electric field represented by the dynamical vector potential (A_x, A_y) . The physical meaning is that dynamics of the excitonic field is accompanied by in plane electrical currents, i.e., the s-excitons are optically active. The sum of the ‘intraband current’ (left diagram of Fig. S2(e)) and ‘interband current’ (right

FIG. S3. (a) Four representative points are chosen on the non-equilibrium phase diagram. (b) The potential $V_P(\eta)$ plotted for the four points in (a) with correspondence labeled by their colors. The dots in (b) are the minima of the curves.

diagram of Fig. S2(e)) gives the coefficient

$$\begin{aligned}
 c_{\text{em}}(\omega) &= \frac{1}{2} v_t \sum_k \varphi_k \frac{(\omega_{\text{ex}} - 2\xi_k)(v_x k_x - \xi_k)}{(\omega - 2\xi_k)\xi_k^2} = 2\pi v_t \frac{1}{2} \sum_k \sqrt{\frac{2}{\pi}} \frac{q_0^2}{(q_0^2 + k^2)^{3/2}} \frac{(E_b + 2\varepsilon_k)(G/2)}{(\omega - 2\xi_k)\xi_k^2} \\
 &= -2\pi v_t \frac{GE_b}{\sqrt{m}} \sqrt{\frac{2}{\pi}} \sum_k \frac{1}{(E_b + 2\varepsilon_k)^{1/2}(-\omega + G + 2\varepsilon_k)(G + 2\varepsilon_k)^2} \\
 &= \sqrt{mv_t^2/E_b} f_{\text{em}}(E_b, G, \omega), \\
 f_{\text{em}} &\rightarrow 2\pi \frac{GE_b^{3/2}}{(2\pi)^{3/2}} \begin{cases} \frac{(E_b + 2G)(E_b - G) + 3G\sqrt{E_b(G - E_b)} \arccos(\sqrt{E_b/G})}{\sqrt{E_b}G(E_b - G)^3}, & \omega_1 \approx \omega_{\text{ex}} \\ \frac{2E_b^{3/2}\sqrt{G - E_b} - 5G\sqrt{E_b(G - E_b)} + 3G^2 \arccos(\sqrt{E_b/G})}{4G^2(-E_b + G)^{5/2}}, & \omega \approx 0 \end{cases} \\
 &\rightarrow \frac{2}{(2\pi)^{1/2}} \frac{E_b}{G} \begin{cases} 1, & G \gg E_b, \omega \approx \omega_{\text{ex}} \\ 1/5 \sqrt{\frac{E_b}{G}}, & G \approx E_b, \omega \approx 0 \\ \frac{3\pi}{16} \sqrt{\frac{E_b}{G}}, & G \gg E_b, \omega \approx 0 \end{cases}. \quad (\text{S13})
 \end{aligned}$$

Note that to derive the above expression, we subtracted the $\omega = 0$ limit of the diagrams to obtain the current proportional to ω , which gives the ∂_t in Eq. (S8). This ‘renormalization’ works because the current response to a static field should be zero.

The $\delta_{\text{ex}0}$ term comes from the weak electron-hole exchange V_{ex} (Fig. S2(f)) that requires a nonzero overlap between the conduction and valence band orbitals residing on different layers:

$$\begin{aligned}
 \delta_{\text{ex}0}(\omega) &= V_{\text{ex}0}^*(\omega) \left[\sum_k \varphi_k \frac{\omega_{\text{ex}} - 2\xi_k}{\omega - 2\xi_k} \right]^2 \xrightarrow{\omega \rightarrow \omega_{\text{ex}}} V_{\text{ex}0}^* \left[\sum_k \varphi_k \right]^2 = 128\pi^3 V_{\text{ex}0}^* \frac{1}{a_0^2}, \\
 V_{\text{ex}0}^*(\omega) &= \frac{V_{\text{ex}0}}{1 + V_{\text{ex}0} 2 \sum_k \frac{1}{\omega - 2\xi_k}} \approx V_{\text{ex}0}. \quad (\text{S14})
 \end{aligned}$$

Taking the appropriate frequency arguments and neglecting the $\delta_{\text{ex}0}$ term in Eq. (S8), one obtains Eq. (1) in the main text. Note that the above formalism works for both interlayer excitons in bilayers and intralayer excitons in monolayers. In the latter case, one may choose to work in the band diagonalized basis where there is no explicit interband tunneling term for the electrons, but the interaction will have interband terms that contribute the same Josephson couplings in Eq. (1) of the main text.

IV. DYNAMICAL ORBITS AND THE EFFECTIVE POTENTIAL

In this section, we solve the equation of motion $i\partial_t \Phi = \partial_{\Phi^\dagger} H - i\Gamma \partial_{\Phi^\dagger} F$ to obtain the leading order correction of H_f to the dynamical orbit of the order parameter, and to compute the effective potential that determines the phase diagram. Changing

the variables into phases and amplitudes: $(\Phi_1, \Phi_3) = (\sqrt{\eta}, \sqrt{1-\eta}e^{i\theta_a})\sqrt{\rho}e^{i\theta}$ (Eq. (7) of the main text), the Lagrangian density from Eq. (1) is written as

$$L = \rho\dot{\theta} + (1-\eta)\rho\dot{\theta}_a + \omega_0\rho + g\rho^2 + c_4\rho^2\eta(1-\eta)\sin^2\theta_a + c_J\rho\cos 2\theta. \quad (\text{S15})$$

where $g = (U_0 + c_4)/2$. The equation of motion Eq. (8) is expanded as

$$\begin{aligned} \dot{\theta} &= -\omega_0 - 2g\rho - (1-\eta)\dot{\theta}_a - 2c_4\rho\eta(1-\eta)\sin^2\theta_a - c_J\eta\cos 2\theta, & \dot{\rho} &= -2c_J\eta\rho\sin 2\theta + 4\rho_0\Gamma(-\partial_\rho H + \mu), \\ \rho\dot{\theta}_a &= c_4\rho(1-2\eta)\sin^2\theta_a + c_J\rho\cos 2\theta, & \partial_t[\rho(1-\eta)] &= c_4\rho^2\eta(1-\eta)2\sin\theta_a\cos\theta_a. \end{aligned} \quad (\text{S16})$$

Note that the main effect of the device-bath tunneling Γ is to maintain the chemical potential μ . As long as it exists and is not too large, it does not affect the phase diagram qualitatively. For simplicity, we keep only the amplitude (ρ) direction of the damping term $\Gamma\partial_{\Phi^\dagger}F \rightarrow \Gamma\partial_{\Phi^\dagger}F|_{\rho}$, which does not change the qualitative conclusion.

The solution (orbit) to Eq. (S16) may be written as $S = (\theta, \rho, \theta_a, \eta)_t = S_0 + (\theta^{(1)}, \rho^{(1)}, \theta_a^{(1)}, \eta^{(1)}) + O(c_J^2)$, where $S_0 = (\theta_0(t), \rho_0, 0, \eta_0)$ is the zeroth order orbit and $\theta_0(t) = -\mu t$. The $O(c_J)$ correction is an oscillating term with frequency $\pm 2\mu$. Its 2μ components are

$$\begin{aligned} \theta_a^{(1)}(2\mu) &= \frac{i}{4\mu}c_J, & \rho^{(1)}(2\mu) &= \frac{\eta}{-i2\mu + \gamma}\left(-\frac{\gamma}{2g} + 2i\rho\right)\frac{c_J}{2}, \\ \theta^{(1)}(2\mu) &= \frac{i}{2\mu}\left(-2g\rho^{(1)}(2\mu) - \frac{c_J}{2}\right), & \eta^{(1)}(2\mu) &= (1-\eta)\frac{\rho^{(1)}(2\mu)}{\rho_0} + \frac{1}{i2\mu}c_4\rho\eta(1-\eta)2\theta_a^{(1)}(2\mu) \end{aligned} \quad (\text{S17})$$

where we have defined the damping rate $\gamma = 8g\rho_0\Gamma$. The static (Ponderomotive) force for η is thus

$$\begin{aligned} F_P(\eta) &= -\langle\partial_\eta L\rangle_t = -\langle c_J\rho\cos 2\theta - \rho\dot{\theta}_a + c_4\rho^2(1-2\eta)\sin^2\theta_a\rangle_t \\ &\xrightarrow{O(c_J^2)} -c_J\frac{1}{2}(\rho^{(1)}(2\mu) - i2\rho\theta^{(1)}(2\mu) + c.c.) + (\rho^{(1)}(2\mu)i2\mu\theta_a(-2\mu) + c.c.) - c_4\rho_0^2(1-2\eta)\frac{c_J^2}{8\mu^2} \\ &= -c_J\frac{1}{2}(-i2\rho_0\theta^{(1)}(2\mu) + c.c.) - c_4\rho_0^2(1-2\eta)\frac{c_J^2}{8\mu^2} = c_J^2\rho_0\left[\frac{2\mu - 4g\rho_0\eta + (1-\eta)\frac{\gamma^2}{2\mu}}{4\mu^2 + \gamma^2} + c_4\rho_0\frac{2\eta - 1}{8\mu^2}\right] \end{aligned} \quad (\text{S18})$$

which is just Eq. (10) of the main text. Note that naively speaking, $\partial_\eta L$ should be zero at every order of c_J since this is what the equation of motion (the third equation in Eq. (S16)) says. From this perspective, the static force F_P should act on the variable θ_a at order c_J^2 , giving $\dot{\theta}_a = F_P$. However, note that there is a strong potential term $c_4\rho^2\eta(1-\eta)\sin^2\theta_a$ in Eq. (S15) that bounds θ_a , meaning that the ‘zero frequency’ component of θ_a cannot be increasing. Moreover, there are actually dissipative terms in the equation of motion for θ_a and η due to the environment: $\dot{\theta}_a - \Gamma\dot{\eta} \sim F_P/\rho_0$, $-\dot{\eta} + \Gamma\dot{\theta}_a \sim \theta_a$. As a result, the slow component of θ_a stabilizes at a certain value $\sim F_P/\Gamma$, and the static force $F_P(\eta)$ equals $-\Gamma\partial_t\eta$. Therefore, F_P is the actual Ponderomotive force for η .

The phase diagram—The Ponderomotive force corresponds to an effective potential for η , coined the Ponderomotive potential [51]: $V_P(\eta) = -\int d\eta F_P$. Its value of the bright state relative to the dark one is found to be

$$\delta V_P = V_P(0) - V_P(1) = c_J^2\rho_0\frac{\mu + \omega_{\text{ex}} + \frac{\gamma^2}{4\mu}}{4\mu^2 + \gamma^2}. \quad (\text{S19})$$

In the limit of $\gamma = 0$, δV_P equals the time-averaged Lagrangian [51] of the bright state relative to the dark one, see Eq. (S30). If one further takes $\mu = \omega_{\text{ex}}$, it reduces to the energy splitting between a single bright and dark exciton due to the c_J term.

Minimizing $V_P(\eta)$ gives the mean field steady state, yielding the phase diagram. Surprisingly, in most of the ‘bright’ phase of Fig. S3(a), the energy minimum lies somewhere at $(0 < \eta_0 < 1)$ determined by $F_P(\eta_0) = 0$, as shown by the profile of the potential in Fig. S3(b). This means that the order parameter is a coherent hybrid of the bright and dark condensate. Since this mixture emits light, we still call it a ‘bright’ condensate although it also has a dark component.

In the limit of $\gamma \rightarrow 0$, the phase diagram is simpler to discuss. The region of the hybrid bright state is $-\frac{c_4}{4 - \frac{c_4}{2g}}\omega_{\text{ex}} < \mu < -(\frac{8g}{c_4} - 1)\omega_{\text{ex}}$ whose boundary is shown by the two red dashed lines in Fig. S3(a). Here one has $F_P(0) > 0$ and $F_P(1) < 0$, so that the energy minimum lies at

$$\eta_0 = \frac{\frac{\mu}{\mu - \omega_{\text{ex}}} - \frac{c_4}{8g}}{1 - \frac{c_4}{4g}} = \frac{\frac{\mu}{\mu - \omega_{\text{ex}}} - \frac{c_4}{4(c_4 + U_0)}}{1 - \frac{c_4}{2(c_4 + U_0)}} \xrightarrow{U_0 \ll c_4} \frac{2\mu}{\mu - \omega_{\text{ex}}} - \frac{1}{2}, \quad (\text{S20})$$

as shown in Fig. S3. At the upper and lower boundaries, the phase transitions are continuous, and the hybrid bright condensate breaks more symmetries than the ‘pure’ condensates. In the experimentally relevant limit of $U_0 \ll c_4$, the region of the hybrid bright state simplifies to $-\frac{1}{3}\omega_{\text{ex}} < \mu < -3\omega_{\text{ex}}$. The condensate is a pure bright one in the lower region $\mu < -\frac{1}{3}\omega_{\text{ex}}$ and a pure dark one in the upper region $\mu > -3\omega_{\text{ex}}$.

Note that for a constant dimensionless Γ in Eq. 2 of the main text, the physical tunneling rate $\gamma = 8g\rho_0\Gamma$ defined below Eq. 10 of the main text should depend on the exciton density. However, this only weakly affects the phase diagrams in Fig. 3(a) of the main text and Fig. S3(a) (bottom left corner of the ‘bright’ region), and we plot the phase diagrams for a constant $\gamma = 0.1 \text{ eV}$ for simplicity.

A. The effect of light emission

In this subsection, we discuss the radiation of free space photons due to the c_{em} term in the bright condensate. We show that because c_{em} is suppressed by the fine structure constant α , its effect on the Ponderomotive potential is small compared to the c_j term, such that its effect on the phase diagram can be neglected for the device in free space.

The phase winding of the bright condensate leads to oscillation of the in-plane electrical polarization $(P_x, P_y) = 2c_{\text{em}}(-\text{Re}[\Phi_0], \text{Im}[\Phi_3])$ which emits free space radiation with the electric field $E = \frac{2\pi}{c}\partial_t P$ (a result of solving the Maxwell’s equation with the correct boundary conditions on the 2D plane), see Fig. S4(a). Therefore, the electric field has a $\pi/2$ phase difference with the polarization. In other words, it is anti-parallel with the oscillating current, doing negative work to the system whose power is just the radiation power:

$$P_r = \frac{c}{4\pi} E^2 = \gamma_r \mu \rho, \quad \gamma_r = \frac{4\pi}{c} c_{\text{em}}^2 \mu \approx 2\alpha \frac{m v_t^2 E_b}{G^2} \mu \quad (\text{S21})$$

which also implies a tunneling charge current: $I_{\text{bright}} = P_r/\mu = \gamma_r \rho$. The electric field feeds back on the dynamics through the c_{em} term in Eq. (1) of the main text, and distorts the orbit. Note that the magnetic field of the emitted light is in-plane and does not couple to the Φ_0 or Φ_3 excitons, since their in-plane spin magnetic moment is zero.

To compute the distorted orbit, we consider the pure bright condensate for simplicity with, e.g., only $\Phi_3 = \sqrt{\rho} e^{i\theta}$ nonzero. Similar to the dark condensate, the orbit wiggles around the perfect circle $S_0 = (\theta_0(t), \rho_0)$ due to the feed back force of the emitted electric field. However, the main effect is an overall reduction of the exciton density due to the photon emission. For simplicity, we assume an incoherent emission that provides a constant friction to reduce the density with rate γ_r , and the equation of motion is simplified to

$$\dot{\theta} = -\omega_0 - 2g\rho, \quad \dot{\rho} = -\gamma(\rho - \rho_0) - \gamma_r \rho. \quad (\text{S22})$$

The solution is a smaller orbit as shown in Fig. 2(a) of the main text, with the density reduced by $\delta\rho \approx \frac{\gamma_r}{\gamma} \rho_0$. Its correction to the average free energy is $\delta F_{\text{EM}} \approx g\delta\rho^2 \sim g\rho_0^2 \alpha^2 \frac{m^2 v_t^4 E_b^2}{G^4} \frac{\mu^2}{\gamma^2}$. Compared to the effective potential (δV_P in Eq. (S19)) caused by the Josephson coupling c_j , it is smaller by a factor of

$$\delta F_{\text{EM}}/\delta V_P \xrightarrow{\gamma_R \ll \gamma \ll \mu} \frac{\mu^4}{E_b^2 \gamma^2} \alpha^2 \xrightarrow{E_b \sim \mu} \frac{\mu^2}{\gamma^2} \alpha^2. \quad (\text{S23})$$

In the interested parameter regime, $\mu/\gamma \sim 10$ while the fine structure constant is $\alpha \approx 1/137$, leading to $\delta F_{\text{EM}}/\delta V_P \ll 1$. Although δF_{EM} is not exactly the effective potential contributed by the c_{em} term that the steady state minimizes, the latter should be at the same order. Therefore, it is safe to neglect the c_{em} terms when determining the phase diagram in Fig. 3(a) of the main text.

V. THE DEVICE IN A FABRY-PÉROT CAVITY

In this section, we compute the oscillating EM field in the cavity (Fig. 3(b) in the main text and Fig. S1) in response to the dynamical polarization $P e^{-i\omega t}$ of the device, where $\omega = \mu$. This is done by solving the Maxwell’s equation with appropriate boundary conditions.

Without loss of generality, we assume the polarization is along the x direction, which induces an electric/magnetic field along the x/y direction, as shown in Fig. S4(b). Close to the mirrors ($z = -h$), the electric field vanishes, meaning $E_x(\omega) = E_0 \sin k(z+h)$ for $-h < z < 0$ where $k = \sqrt{\epsilon}\omega/c$. This together with Maxwell’s equation leads to the magnetic field $B_y(\omega) = -i\sqrt{\epsilon}E_0 \cos k(z+h)$.

FIG. S4. (a) Illustration of the photon radiation of the dynamical bright condensate in free space. (b) Illustration of the 2D system (x-y plane) placed in the middle of a Fabry-Pérot cavity. The red/blue lines are the dynamical electric/magnetic fields in response to the dynamical 2D electrical polarization (gray arrow).

Right above and below the 2D plane, E_x is continuous, so that the electric/magnetic field in the upper half space $0 < z < h$ is symmetric/anti-symmetric with respect to that in the lower half space, as shown in Fig. S4(b). Ampère's circuital law applied to the 2D plane leads to $-2i\sqrt{\epsilon}E_0 \cos kh = \frac{4\pi}{c}\partial_t P$, so that $E_0 = \frac{4\pi\omega}{2c\sqrt{\epsilon}}P/\cos kh$. Therefore, the electric field on the 2D plane is $E = \frac{2\pi\omega}{\sqrt{\epsilon}c}P \tan kh = \frac{2\pi\omega}{\sqrt{\epsilon}c}P \tan \frac{\sqrt{\epsilon}\omega}{ch}$. To qualitatively incorporate the damping of the cavity modes, we simply replace ω by $\omega + i\gamma_p$.

An equivalent description is that, the cavity has discrete photon modes which are Harmonic oscillators. Each oscillator is linearly driven by the dynamical polarization $Pe^{-i\omega t}$ and responds by contributing an EM field. The total response field is the sum of all of them, which is just the solution of Maxwell's equation.

VI. THE ROTATING FRAME

To compute the tunneling current of the dynamical condensate, it is more convenient to perform a gauge transformation in time to the 'rotating' frame: $\Phi \rightarrow \Phi e^{-i2\mu t}$. Afterwards, the exciton energy is shifted to $\omega_{\text{ex}} \rightarrow \omega'_{\text{ex}} = \omega_{\text{ex}} - \mu$ and H_0 in Eq. (1) leads to a static condensate if the parameters are in the colored the region of Fig. 3, while H_J becomes a periodically driving term:

$$H_0 = \text{Tr} \left[\Phi^\dagger \left(\omega'_{\text{ex}} + \frac{p^2}{4m} \right) \Phi + c_4 (\Phi^\dagger \Phi)^2 \right] + \frac{1}{2} \int dr dr' \rho(r) U(r-r') \rho(r'),$$

$$H_J = c_{\text{em}} \left(E_x \Phi_0 e^{-i\mu t} + iE_y \Phi_3 e^{-i\mu t} + c.c. \right) + \mathcal{C} \left[\frac{1}{2} (\Phi_1^2 + \Phi_2^2) e^{-i2\mu t} + c.c. + \rho \right]. \quad (\text{S24})$$

The equation of motion simplifies to

$$i\partial_t \Phi = (1 - i\Gamma)\partial_{\Phi^\dagger} H, \quad H = H_0 + H_J \quad (\text{S25})$$

where H_0 and H_J are from Eq. (S24). The system has now become formally a periodically driven system. Discussions in the following sections will be in the rotating frame.

In the condensed phase ($\omega'_{\text{ex}} < 0$), the mean field exciton density is $\rho_0 = \Phi_\mu^* \Phi^\mu = -\omega_{\text{ex}}/(2g)$. Assuming a dark condensate with only $\Phi_1 = \sqrt{\rho_0}$ nonzero, one may write the order parameter as its mean field value plus a small fluctuation: $\Phi_\mu + \delta\Phi_\mu$. The equation of motion for $\delta\Phi_1$ at linear order is expanded from Eq. (S25) as

$$G^{-1} \begin{pmatrix} \delta\Phi_1 \\ \delta\Phi_1^* \end{pmatrix} = \begin{pmatrix} \frac{-i}{1-i\Gamma}\partial_t + \frac{q^2}{4m} + 2g\rho_0 & 2g\rho_0 \\ 2g\rho_0 & \frac{i}{1+i\Gamma}\partial_t + \frac{q^2}{4m} + 2g\rho_0 \end{pmatrix} \begin{pmatrix} \delta\Phi_1 \\ \delta\Phi_1^* \end{pmatrix} = -\mathcal{C}\sqrt{\rho_0} \begin{pmatrix} e^{i2\mu t} \\ e^{-i2\mu t} \end{pmatrix} \quad (\text{S26})$$

where the retarded Green's function in the frequency basis reads

$$G(q, \omega) = \frac{1}{-\frac{\omega^2}{1+\Gamma^2} + (\frac{q^2}{4m} + 2g\rho_0)\frac{-2i\Gamma\omega}{1+\Gamma^2} + \omega_q^2} \begin{pmatrix} \frac{\omega}{1+i\Gamma} + \frac{q^2}{4m} + 2g\rho_0 & -2g\rho_0 \\ -2g\rho_0 & \frac{-\omega}{1-i\Gamma} + \frac{q^2}{4m} + 2g\rho_0 \end{pmatrix} \quad (\text{S27})$$

FIG. S5. (a) Linear response diagram of Φ to $t^2 e^{-i2\mu t}$ at the mean field level. The open Φ and Φ^* legs are their mean field values. (b) The linear coupling between the tunneling t_0 and the excitonic field Φ_0 in the case of first order Josephson tunneling. (c) Linear response diagram of Φ to $t_0 e^{-i\mu t}$ at the mean field level.

and

$$\omega_q = \sqrt{\frac{q^2}{4m} \left(\frac{q^2}{4m} + 4g\rho_0 \right)} \quad (\text{S28})$$

is the phase mode frequency at momentum q in the limit of $\Gamma = 0$ and $H_j = 0$.

VII. THE TUNNELING CURRENT

Since we focus on the dark condensate in this section, we neglect the c_{em} terms. The driving term H_j in Eq. (S24) would inevitably do work to the system, whose power supply comes from the bath, i.e., the leads in the bilayer case. Therefore, the power dissipation of the driving term corresponds directly to a DC tunneling current. The simplest contribution comes from the mean field driving term in Fig. S5(a), which says $\Phi_1^2 e^{-2i\mu t} \rightarrow 2\Phi_1 e^{-2i\mu t} \delta\Phi_1$ and its complex conjugate linearly drives the zero momentum condensate. It gives

$$I_{\text{dark}} = \frac{1}{\mu} P_{\text{drive}} = \frac{1}{\mu} 2\mu c_j^2 \Phi^* \Phi \text{Im}[G_\Phi(-2\mu)] = 2c_j \rho_0 \text{Im} \left[\frac{\frac{-2\mu}{1+i\Gamma} + 2g\rho_0}{-\frac{4\mu^2}{1+\Gamma^2} + 2g\rho_0 \frac{4i\Gamma\mu}{1+\Gamma^2}} \right] = \frac{c_j^2}{\mu} \Gamma \rho_0 \frac{\mu^2 + \omega_{\text{ex}}^2 + \frac{1}{16}\gamma^2}{\mu^2 + \frac{1}{16}\gamma^2} \quad (\text{S29})$$

where we have made use of the Green's function $G_\Phi = G_{11}$ from Eq. (S27) and defined the damping rate $\gamma = 8g\rho_0\Gamma$ with the unit of frequency, and c_j should take the value of $c_j(\omega = \mu \approx \omega_{\text{ex}})$ in Eq. (S12).

Note that the real part of Fig. S5(a) gives the time averaged Lagrangian of the dark condensate:

$$\langle L \rangle_t = c_j^2 \Phi^* \Phi \text{Re}[G_\Phi(-2\mu)] = c_j^2 \rho_0 \frac{1 - (\mu + \omega_{\text{ex}}) - 2g\rho_0\gamma^2}{\mu^2 + \frac{1}{16}\gamma^2} \xrightarrow{\gamma \rightarrow 0} c_j^2 \rho_0 \frac{1 - (\mu + \omega_{\text{ex}})}{\mu^2} \quad (\text{S30})$$

which agrees with Eq. (S19) in the zero damping limit.

VIII. THE STATIC PHASE

In the case $\omega_{\text{ex}} = G_0 - V_g - E_b < 0$ such that the condensate exists even without a bias μ , the condensate may not be a dynamical one if the contact bias μ is very weak. From Eq. (S24) and the energy landscape in Fig. 2(d), the condensate is a static and dark one at $\mu = 0$ because its energy density at $\theta = \pm \frac{\pi}{2}$ is lower than the bright one by $c_j \rho_0$. At nonzero μ , the free energy landscape rotates according to Eq. (S24). Since we are discussing in the rotating frame, the system is in an actual dynamical state if the order parameter doesn't follow the rotation, and a static one if it follows it. For a very small μ , the rotation of the free energy landscape is slow, and the order parameter tends to follow the instantaneous minimum adiabatically, meaning the system is in a static state. At large enough μ , the system couldn't catch up with the rotation of the landscape, and would be a dynamical state. In this section, we speculate the transition point μ_c from the static to the dynamical condensate.

In the regime of $|\omega_{\text{ex}}| \gg c_j$, i.e., the superfluid density is not too small, one can integrate out the amplitude to obtain the Lagrangian for the phase. After transforming back to the 'lab frame', the phase Lagrangian reads

$$L = \frac{1}{4g} \left[-(\dot{\theta} + \mu)^2 - 2c_j \omega_{\text{ex}} \cos(2\theta) \right]. \quad (\text{S31})$$

FIG. S6. (a) Instantaneous dispersion of the four phase modes of the bright condensate at a certain time in the rotating frame such that $\theta = \theta_0 = 0$. The fastest one is the sound mode (fluctuations of the overall phase θ) and the other three are the valley pseudo-spin waves. At small momenta, they are the Goldstone modes modified by the H_J term. At large momenta, they crossover to the dispersion of the single excitons. Note that the dispersion of the modes are periodically modulated by the dynamical H_J term. (b) Same as (a) but for the dark condensate.

It is obvious that as μ increases, the static-dynamic transition is the temporal analogue of the commensurate-incommensurate transition [84] in charge density wave systems, and the dynamical state just above the transition is a train of temporal solitons in time satisfying $\partial_t^2 \theta = -2c_J \omega_{\text{ex}} \sin 2\theta$. Assuming a complete analogy with the commensurate-incommensurate transition in space, comparison of the average energy of this temporal soliton state with the static state says that the transition happens at $\mu = \mu_c = \frac{4}{\pi} \sqrt{-2c_J \omega_{\text{ex}}}$ [84] which is about 8 meV for $-\omega_{\text{ex}} = 0.1$ eV and the typical parameters used in this paper. However, since the transition is into a bright condensate as Fig. S3 whose phase action is no longer Eq. (S31), the actual μ_c is probably different although at the same order. This transition may also be viewed as a transition to a time crystal that breaks the continuous time translational symmetry and develops long range order in the temporal direction. We leave its details for future study.

IX. COLLECTIVE MODES

In this section, we discuss the dispersion of the collective modes of the dynamical condensates [28] in the dissipationless limit ($\Gamma \rightarrow 0$). On top of an arbitrary mean field order parameter, the collective modes are just the four Gaussian fluctuation modes expanded from Eq. (S24).

We start with the zero tunneling limit: $H_J = 0$ which essentially results in an equilibrium state. Around the state with only Φ_0 nonzero, the Lagrangian and dispersions for order parameter fluctuations ($\delta\Phi_0, \Phi_i$) are

$$\begin{aligned} L_{\Phi_0} &= \delta\Phi_0^* \left(-i\partial_t + \frac{q^2}{4m} + 2g\rho \right) \delta\Phi_0 + g(\Phi_0^2 \delta\Phi_0^{*2} + c.c.), \quad \omega(q)^2 = \frac{q^2}{4m} \left(\frac{q^2}{4m} + 4g\rho \right), \\ L_{\Phi_i} &= \Phi_i^* \left(-i\partial_t + \frac{q^2}{4m} \right) \Phi_i + \frac{c_4}{2} (\Phi_0^* \Phi_i + c.c.)^2, \quad \omega_a(q)^2 = \frac{q^2}{4m} \left(\frac{q^2}{4m} + 2c_4\rho \right) \end{aligned} \quad (\text{S32})$$

where $g = (U_0 + c_4)/2$ and $i = 1, 2, 3$. The same collective mode spectrum applies to any state in the $S_1 \times S_3$ ground state manifold since they can all be connected to the Φ_0 by symmetry operations.

With nonzero and dynamical H_J , the dispersion of the collective modes are periodically modulated by it. We can only describe their instantaneous dispersion at each time. It is now more convenient to represent the bright and dark condensates by

$$|\Phi\rangle e^{i\theta} \begin{pmatrix} e^{i\theta_a} & 0 \\ 0 & e^{-i\theta_a} \end{pmatrix}, \quad |\Phi\rangle e^{i\theta} \begin{pmatrix} 0 & e^{-i\theta_a} \\ e^{i\theta_a} & 0 \end{pmatrix} \quad (\text{S33})$$

which correspond to $(\Phi_0, \Phi_3 \neq 0; \Phi_1 = \Phi_2 = 0)$ and $(\Phi_0 = \Phi_3 = 0; \Phi_1, \Phi_2 \neq 0)$, respectively.

The dark state corresponds to $\Phi_\mu = e^{i\theta}(0, a_1, a_2, 0)$. The c_J term reduces the $U(1) \times U(1)$ invariance of varying θ and θ_a to $U(1)$, such that the free energy looks like that in Fig. 2(b). After adding H_J to Eq. (S32) and integrating out the implicit EM

fields, the dispersions of the four modes around $\theta_a = 0$ are found to be

$$\begin{aligned}\omega_\theta(q)^2 &= \omega(q)^2 - \omega_J^2 \cos 2\theta, \quad \omega_{\theta_a}(q)^2 = \omega_a(q)^2, \quad \omega_{\Phi_T}(q)^2 = \omega_a(q)^2 - \frac{1}{2}\omega_{Ja}^2 \cos 2\theta - 2c_J \frac{q^2}{4m} \cos 2\theta, \\ \omega_{\Phi_L}(q)^2 &= \omega_a(q)^2 - \frac{1}{2}\omega_{Ja}^2 \cos 2\theta - 2c_J \frac{q^2}{4m} \cos 2\theta + 2c_{\text{em}}^2 \frac{2\pi q}{\epsilon} \left(\frac{q^2}{2m} + c_4(2\rho - \Phi_1^2 - \Phi_1^{*2}) \right)\end{aligned}\quad (\text{S34})$$

to lowest order in v_t^2 where $\omega_{Ja} = 2\sqrt{c_4 c_J \rho_0}$. The Φ_L, Φ_T modes are hybridizations of Φ_0, Φ_3 fluctuations with ‘chiral’ combination coefficients determined by the direction of momentum: $\Phi_L = \hat{q}_x \Phi_3 + i\hat{q}_y \Phi_0$, $\Phi_T = -\hat{q}_y \Phi_3 + i\hat{q}_x \Phi_0$, such that the dipole fluctuation of Φ_L is parallel to its momentum, while that of Φ_T is perpendicular. This physics is the same as LO-TO splitting of optically active excitons (A-exciton) in TMD monolayers [80]. Around the ground states $\theta = \pm\pi/2$ and at small momentum, the dispersion of the θ mode reduces to $\omega_q = \sqrt{v^2 q^2 + \omega_J^2}$, i.e., a Josephson plasmon [34] where $\omega_J = 2\sqrt{2g\rho_0 c_J}$ is the Josephson plasma frequency. The dispersion of θ_a is unchanged by the Josephson coupling. We note that for typical parameters such that $G \approx E_b$ and $U_0 \gg c_4$, one has $\omega_J = 4\sqrt{\frac{1}{3}m^2 v_t^2 v_0^2}$, in the THz range (see Table I).

The bright condensate corresponds to $\Phi_\mu = e^{i\theta}(ia_0, 0, 0, a_3)$. In the intravalley state, the symmetry of varying θ is accidentally preserved in our leading order approximation to the tunneling function in Eq. (S2), such that the energy is still $U(1)$ invariant on the complex plane, as shown in Fig. 2(a). The dispersions of the four modes are found to be

$$\begin{aligned}\omega_\theta(q)^2 &= \omega(q)^2 + 2D \frac{\cos^2(\theta)}{q\epsilon} (q_y \cos \theta_a + q_x \sin \theta_a)^2, \\ \omega_{\theta_a}(q)^2 &= \omega_a(q)^2 + 2D_a \frac{\sin^2(\theta)}{q\epsilon} (q_y \sin \theta_a - q_x \cos \theta_a)^2, \quad \omega_{\Phi_j}(q)^2 = \omega_a(q)^2 - \frac{1}{2}\omega_{Ja}^2 \cos 2\theta\end{aligned}\quad (\text{S35})$$

to the lowest order in v_t^2 . Note that we have neglected the Coulomb cross coupling ($\sim v_t^2$) between the θ and θ_a modes, which is negligible at large momenta but important at small momenta. The Φ_j modes are stable or unstable depending on the overall phase θ . It is obvious that the effect of θ_a is to rotate the dispersion of the θ, θ_a modes on the x-y plane by θ_a , while it does not affect the Φ_1, Φ_2 modes. Due to the locking between the phase and polarization, certain phase fluctuations are accompanied by local charge density fluctuations, and therefore experience Coulomb renormalization such that they are plasmon-like at small momenta. For example, the θ mode (exciton sound wave) dispersion is $\omega_q = \sqrt{v^2 q^2 + 2D q_y^2 / (\epsilon q)}$ at small momenta where $D = 8\pi(c_4 + U_0)P_0^2$ is a Drude weight. For $U_0 \gg c_4$, it is about $D = \frac{2^7 \pi}{25} \frac{m v_t^2}{e^2/d} \frac{\rho e^2}{m}$. As shown by the schematic dispersion along q_y in Fig. S6(a), it crossovers from $\omega \propto \sqrt{q}$ to $\omega \approx vq$ at the momentum scale $q_c \sim \frac{64}{25} m v_t^2 / (\epsilon e^2)$ which is about $2\pi/(130 \mu\text{m})$ for typical parameters.

X. SINGLE SPECIES STATE

If the exchange interaction c_4 is negative, the condensate prefers the single species state where only one component in Φ_{ij} is nonzero with the exciton density $\rho = (-\omega_{\text{ex}} - c_J v_t^2)/(2c_4 + U_0)$, and the ground state manifold has only one phase degree of freedom. This happens when the interlayer distance is large compared to the Bohr radius [9, 43].

In the intravalley state represented by, e.g., a nonzero $\Phi_{11} = \sqrt{\rho} e^{i\theta}$, the in plane polarization is $\mathbf{P} = P_0(\cos\theta \hat{x} + \sin\theta \hat{y})$ whose direction is locked with the phase. In the intervalley state represented by, e.g., a nonzero $\Phi_{12} = \sqrt{\rho} e^{i\theta}$, there is no in plane polarization.

XI. FIRST ORDER JOSEPHSON COUPLING

In a class of bilayers, the interlayer tunneling $t_k = t_0$ does not depend on momentum, leading to the scenario of first order Josephson effect. The Josephson coupling in the rotating frame Eq. (S24) is changed to

$$H_J = \int dr \left[c_t t_0 \Phi_0 e^{-i\mu t} + c_{t^2} t_0^2 \left(\rho + \Phi_\mu \Phi^\mu e^{-2i\mu t} \right) + c.c. \right]. \quad (\text{S36})$$

Symbol	Physical Meaning	Value
E_b	binding energy	271 meV
a_0	exciton size	2.1 nm
ρ	exciton density	$5.1 \times 10^{11} \text{ cm}^{-2}$
v	θ phase mode (sound) speed	$6.6 \times 10^4 \text{ m/s}$
v_a	valley-pseudo spin wave speed	$5.8 \times 10^4 \text{ m/s}$
Bright Condensate		
E	Radiated electric field	170 V/cm
P_r	Radiation power	$0.8 \mu\text{W}$
I_{bright}	Tunneling current	$\sim 1 \mu\text{A}$
P_0	Polarization density	$\frac{2/5}{(2\pi)^{1/2}} \frac{\hbar v_t}{e^2} \sqrt{\rho_0}$
D	Drude Weight for the phase ‘plasmon’	$\frac{2^7 \pi}{25} \frac{m v_t^2}{e^2/d} \frac{\rho_0 e^2}{m}$
Dark Condensate		
J_c	Josephson critical current	0.9 mA
ω_J	Josephson plasma frequency	4.4 meV
I_{dark}	Tunneling current	$\sim 0.1 \mu\text{A}$

TABLE I. Values of physical quantities using the parameters for WSe₂/MoSe₂ bilayer [25] without an hBN spacer or a cavity: $m = 0.5m_e$, $G_0 = 1.5 \text{ eV}$, $G = G_0 - V_g = 1 \text{ eV}$, $\mu = 0.754 \text{ eV}$, $\epsilon = 10$, $d = 0.6 \text{ nm}$, and $v_t = 10^4 \text{ m/s}$. The device size is $1 \mu\text{m}^2$. To compute I_{dark} , the device-lead tunneling rate is set to $\gamma = 0.1 \text{ eV}$.

The coefficient c_t is shown in Fig. S5(b), which reads

$$\begin{aligned}
 c_t = \chi_{t_0, \Phi}(0) &= \sum_k \varphi_k \frac{\omega_{\text{ex}} - 2\xi_k}{-2\xi_k} = \frac{\sqrt{8\pi}}{\sqrt{m}} \sum_k \frac{E_b}{(E_b + 2\varepsilon_k)^{1/2} (G + 2\varepsilon_k)} \\
 &= \begin{cases} \sqrt{\frac{2m}{\pi}} E_b \frac{\cos^{-1} \sqrt{\frac{E_b}{G}}}{\sqrt{G - E_b}} \xrightarrow{G \gg E_b} \sqrt{\frac{\pi m}{2}} \frac{E_b}{\sqrt{G}} = \frac{\sqrt{2\pi}}{a_0} \sqrt{\frac{E_b}{G}}, & G > E_b \\ \sqrt{\frac{2m}{\pi}} E_b \frac{\cosh^{-1} \sqrt{\frac{E_b}{G}}}{\sqrt{E_b - G}} \xrightarrow{G \approx E_b} \sqrt{\frac{\pi m}{2}} \sqrt{E_b} = \frac{\sqrt{2\pi}}{a_0}, & G < E_b \end{cases}. \quad (\text{S37})
 \end{aligned}$$

In the non equilibrium case $\mu \neq 0$, the c_t term linearly drives the order parameter Φ_0 . Setting $\Gamma = 0$ and integrating out this ‘fast’ degree of freedom gives a $O(t_0^2)$ driving energy through linear response (Fig. S5(c)):

$$V_{\text{singlet}} = c_t^2 t_0^2 2 \frac{-\mu + (c_4 + U_0)\rho}{\mu^2} = c_t^2 t_0^2 2 \frac{-\omega_{\text{ex}}}{\mu^2}, \quad V_{\text{triplet}} = c_t^2 t_0^2 2 \frac{-\mu + c_4 \rho}{\mu^2} \quad (\text{S38})$$

for the valley-singlet (Φ_0) and the valley-triplet (Φ_1, Φ_2, Φ_3) condensates, respectively.

We now speculate the phase diagram in the dissipationless limit. As shown in Ref. [51], without dissipation, this driving energy is what the steady state minimizes. Since $V_{\text{singlet}} > V_{\text{triplet}}$, the dynamical condensate would be the valley-triplet one. However, for $\mu < \mu_c \sim g c_t t_0 \sqrt{\rho_0}$, the system should be the static singlet condensate.

If the tunneling does not conserve the in plane momentum and valley index, the first order Josephson term becomes $c_t t_q \sum_q (\Phi_0 + \Phi_1)_q + c.c.$ with the ‘disordered’ tunneling matrix element satisfying $\langle t_q t_{-q} \rangle = f(q)$. This may be the case of two TMD monolayers separated by incommensurate spacers, which we leave for future study.

XII. TYPICAL PARAMETERS

The typical parameters for the TMDB bilayer devices are shown in Table I for the case of second order Josephson coupling.
