High-quality factor microwave resonators operating in a magnetic field are a necessity for some quantum sensing applications and hybrid platforms. Losses in microwave superconducting resonators can have several origins, including microscopic defects, usually known as two-level-systems (TLS). Here, we characterize the magnetic field response of NbTiN resonators patterned on sapphire and observe clear absorption lines occurring at specific magnetic fields. We identify the spin systems responsible for these features, including a yet unreported spin with g = 1.85 that we attribute to defects in the NbTiN thin film. We develop mitigation strategies involving namely an aluminum etch mask, resulting in maintaining quality factors above $Q > 2 \times 10^5$ in the range 0 T to 0.3 T.

Superconducting circuits are promising candidates for quantum information processing (OIP), as well as highprecision sensing. Recently, the interest in circuits able to operate under magnetic fields has increased to enable hybrid QIP platforms[1, 2] or quantum sensing applications such as magnetic resonance detection[3, 4]. These applications require developing high-quality factor superconducting resonators resilient to magnetic fields. Detrimental effects for microwave superconducting resonators have been largely studied [5], with evidence that obtaining highquality factors at zero magnetic field requires shielding from quasi-particles[6], preventing vortex nucleation[7], using lowloss dielectric substrates[8, 9], and mitigating microscopic defects[10]. This last effect arises from so-called two-levelsystems (TLS) which can be saturated to recover a higher quality factor at high power[11]. They can have different origins, including spurious spin systems[10]. When the spin Larmor frequency is tuned on resonance by the application of a magnetic field, an increase in losses can be observed which allowed to identify these spin systems partly as hydrogen and oxygen adsorbates on sapphire substrates[12, 13]. In addition to representing a source of losses when operating under magnetic field, these spins are also believed to be responsible for frequency noise as well as flux noise [11] limiting for example the sensitivity of SQUID magnetometers[14, 15] or the coherence of flux qubits[12, 16, 17]. Here, we evidence similar field-dependent losses for superconducting resonators deposited on sapphire, and show that a hard-mask nanofabrication technique mitigates the contribution of some of these spurious spin systems.

TLS defects can be either electric dipoles or magnetic dipoles whose interaction strength with the resonator field depends on their location [10], and range from weak to strong coupling[18]. These defects can be located in the substrate or at the surfaces of the substrate and superconducting electrodes. Electric-TLS can be for instance trapped charges, dangling bonds or tunneling atoms located either on the substrate or in an oxide layer capping the superconductor. Many works have now demonstrated that surface dielectric losses are far more detrimental than dielectric bulk losses[8, 19], and shown that the impact of these electric-TLS can be minimized by improving materials and fabrication techniques as well as opti-

FIG. 1. (a) Fabrication steps for NbTiN superconducting resonators: 50-nm films sputtered on EFG or HEM grown sapphire, coated by a resist or Al mask, dry etched with CHF₃ chemistry, and then cleaned and possibly annealed at 300 °C under N₂ atmosphere. (b) Resonator geometries used in this work, nicknamed circle (left) and microwire (right). The microwire drawing is cut along the red lines for clarity. The blue arrow B_0 shows the applied in-plane magnetic field. (c) Measured intrinsic quality factors at zero field, depending on the fabrication technique, filled (open) markers indicate circle (microwire) design, their colors indicate their Q_i/Q_c ratio as given by the color bar in inset. X-coordinate scattering is only for clarity. *Al mask indicates the wafer was covered by photoresist during dicing, but that an Al mask was used during etching.

mizing the design to reduce their contribution [5, 10, 20].

Magnetic-TLS arise from nuclear and electronic spins lying at the surfaces or in the bulk of the substrate, such as spin donors for silicon[21], or metal contaminants in sapphire[22]. Their contribution to the resonator intrinsic loss and flux noise is maximum when their transitions are brought to resonance by the application of a magnetic field. Several superconductors, such as Nb[23], NbN[13, 24], NbTi[25], NbTiN[26], GrAl[27] and YCBO[28], have proven able to yield highquality factor resonators ($Q > 10^5$) at moderate (< 1 T) and large magnetic fields (6T). Yet, in most works reporting resonators resilient to magnetic fields, a drop in their intrinsic quality factors appears at specific magnetic fields. Using resonators of various frequencies fabricated in NbTiN on Si, NbN on SiO₂, and granular Al on sapphire, previous works[24, 26, 27] observed losses corresponding to a near perfect spin 1/2 bath with a g-value $g = \hbar \gamma_{\rm eff} / \mu_{\rm B} =$ 2.0 ± 0.3, where $\gamma_{\rm eff} = \partial \omega_{\rm s} / \partial B_0$ is the effective gyromagnetic ratio governing the measured spin frequency ω_s dependence on the applied magnetic field B_0 . Besides, Kroll and coworkers[29] also observed a similar effect for NbTiN on sapphire, but at a value slightly lower than 2 (about g =1.9). For NbN on sapphire[13], a spin 1/2 absorption line $\omega_{\rm s}(B_0)$ was observed, along with satellite lines corresponding to hydrogen physiosorbed on the surface, which creates a spin system with a signature hydrogen hyperfine splitting of $A/(2\pi) = 1.42$ GHz. These hydrogen atoms absorbed on the surface are also thought to contribute significantly to flux noise in [12] in superconducting circuits. Additionally, contribution from O₂ adsorbates and superoxide systems embedded into the surface of the sapphire lattice was reported[13], further confirmed by high-field EPR studies [30] and DFT calculations [31]. They show that spin systems respectively create a broad absorption at $g \approx 2.04$ and constant losses occurring for $g \in [1.5, 4]$. Here, we show that using an aluminum mask instead of a photoresist mask when patterning NbTiN thin films prevents the appearance of most of these TLS, except for a signal we attribute to defects within the NbTiN films.

We pattern NbTiN resonators using a dry etching process (Fig. 1a) by starting from a 50-nm-thick NbTiN film sputtered on a 2" sapphire wafer. The wafer is either an edgedefined-grown wafer (EFG, University Wafers), or grown by a heat-exchanger method (HEM, Crystec). The wafer is then diced in rectangular dies of $5 \text{ mm} \times 7 \text{ mm}$, protected using either photoresist (EFG wafers), or a 50-nm-thick Al layer covered in photoresist (HEM wafers). For each die, we pattern using optical lithography either a photoresist mask (Shipley S1813) or an aluminum mask. The latter is realized by safekeeping the Al layer deposited pre-dicing, or by depositing 50-nm of aluminum after cleaning the photoresist off the die post-dicing. The pattern from the photoresist is transferred to the Al layer by an acid wet-etching (Transene Type A) and the photoresist is cleaned off. The NbTiN layer is then etched using an ICP-RIE tool (Sentech) using CHF₃/Ar/N₂/O₂ atmosphere (30/100/10/3 sccm). If an Al mask is present, it is then wet etched with the same etch as above. A final cleaning is then performed using N-Methyl-2-pyrrolidone followed by isopropanol rinsing. On some devices, to remove the identified contribution of the physiosorbed hydrogen, we performed

FIG. 2. (a) Magnetic-field induced dissipation rate of circle resonators for different fabrication runs as a function of magnetic field, error bar per point is less than 5 ms⁻¹. Red, NbTiN on EFG substrate etched through a resist mask ("EFG Resist"); green, same sample with 2 days aging ("EFG Resist Aging"); orange, change to an Al mask with annealing ("EFG Al mask Anneal"); blue, change to HEM substrate, no resist coating during dicing ("HEM Al mask Anneal"). For direct comparison, the magnetic field is rescaled (see main text). (b) Frequency-diagram of all absorption peaks: each marker y-coordinate is given by the frequency of a resonator, and its x-coordinate corresponds to the occurrence field of a given feature. Blue dashed lines model an electronic spin 1/2 coupled to a nuclear spin 1/2 with a hydrogen hyperfine coupling, gray, black and red lines are linear fits corresponding respectively to $\Delta_0/(2\pi) =$ 1.07, 1.04, 0.28 GHz and g = 4.66, 1.77, 1.85.

an annealing at 300 °C or 600 °C in N₂ atmosphere. On one die, we performed a buffered oxide etch of 20 min at roomtemperature to remove the oxides formed on top of the NbTiN layer before performing an annealing in Ar atmosphere. In total, we prepared 9 dies, with various preparation conditions summarized in the supplementary material. Out of these 2 dies, two were subjected to open air aging and were measured twice.

We have used two types of resonator geometry: low impedance resonators ($Z_c \approx 20 - 40 \Omega$) targeted for electron spin resonance (ESR) sensing (circle), and higher impedance ($Z_c \approx 200 \Omega$) resonators targeted for resilience to magnetic field (microwires) see Fig 1b. The first geometry comprises a circular interdigitated capacitor of pitch 20 µm surrounding an inductive loop or a short microwire. The second is an inductive ribbon of width 10 µm whose ends are capacitively coupled. The resonators are capacitively or inductively coupled to a coplanar waveguide (CPW). The measurement is done either in hanger geometry with the CPW running through the

chip, or in reflection with the CPW terminated on chip. The width of the ground plane surrounding the CPW is reduced to $70 \,\mu\text{m}$ so that all resonators are free floating and not encased in a superconducting ground plane. This is done to minimize the nucleation of magnetic vortices nearby the resonators [7] and prevent vortices induced losses when applying a dc magnetic field.

On each die, 6 to 8 resonators were patterned. Using wellestablished fitting procedures [32–34], we extract for each resonance its frequency $\omega_r/2\pi$, and its intrinsic and coupling quality factors Q_i and Q_c at low intra-resonator photon number ($\bar{n} \sim 1 - 10$). The intrinsic quality factors Q_i^0 obtained at zero magnetic-field for the different fabrication techniques are shown in Fig. 1c and range from 10⁴ to 10⁶. All fabrication techniques exhibit at least a few resonators with Q_i exceeding 5×10^5 . All devices fabricated using HEM wafers, and whose NbTiN layer was not in contact with resist, obtain Q_i consistently larger than 10⁵ at zero magnetic fields. With annealing, the intrinsic quality factors improve slightly.

We next study the behavior of each resonator under magnetic field. To isolate the dependence of the resonator intrinsic decay rate κ_s on the magnetic field, we subtract the loss rate ω_r/Q_i^0 observed at zero-field and the additional loss rate $\omega_{\rm r}/Q_i^{wb}$ occurring when the Al wire bonds connecting the die to the sample holder transit from superconducting to normal state at $B_0 \sim 10 \,\mathrm{mT}$. We plot $\kappa_{\rm s}(\tilde{B}_0)$ in Fig. 2a for resonators made with different fabrication techniques, using a re-scaled x-axis $\tilde{B}_0 = B_0 \tilde{\omega}_r / \omega_r$ with $\tilde{\omega}_r / 2\pi = 8$ GHz for easier comparison. Focusing first on a NbTiN resonator patterned on an EFG wafer using a photoresist mask (green), we observe 4 different peaks, as well as the onset of a large plateau at $\tilde{B}_0 = 50 \text{ mT}$. To identify these features, we build their frequency-field diagram using all the resonators we have measured (see Fig. 2b). We find that the absorption peak frequency of each feature depends linearly on the magnetic field, allowing us to extract a zero-field splitting Δ_0 and an effective g value for each feature: $\omega_{\rm r} = \Delta_0 + g \frac{\mu_B}{\hbar} B_0.$

The first peak lying at $\tilde{B}_0 = 100 \text{ mT}$ is very sharp compared to the others, and corresponds to a *g*-value of 4.7 (gray, Fig. 2b). We attribute it to a response from the sapphire substrate. Indeed, while this effective *g*-value does not correspond to typical contaminants (Fe,Cr), less typical impurities (V,Mo,Mn,Ti,Gd) or known defects in sapphire which are magnetically active (V and F₂ centers), this line has already been observed without being identified in other studies using HEMEX sapphire [22] and Verneuil grown sapphire [35]. We thus note that it cannot be tied to a particular growth technique. We nevetheless observe its disappearance when switching from EFG to HEM-grown sapphire. Note that we also observe a faint line at g = 3.3 that also disappears and that we cannot identify.

Next, we turn to the spin 1/2 line surrounded by an upper and lower satellite peaks (blue markers in Fig. 2b). These three lines have been observed in Ref[13] and have been attributed to water adsorption on the sapphire surface resulting in imperfect hydroxylation of the surface and the creation of radicals and unpaired hydrogens. The radicals create the central spin 1/2 line (g = 2), and the coupling of a large part of

FIG. 3. Integrated losses for the g = 1.85 peak depending on the participation ratio of the free sapphire surface (left) and of the NbTiN surface (right). Markers indicate various fabrication conditions: etch through an aluminum mask without post-annealing (green crosses), aluminum mask with post-annealing at 300 °C when the NbTiN was covered with resist during dicing (black crosses) or was never in contact with resist (red crosses), etch through aluminum mask with postannealing at 600 °C (blue triangles, ×0.5 for clarity), etch through an aluminum mask with argon post-annealing at 300 °C (cyan star). The green dash line is a linear fit using the black and green crosses, enabling to find the spin concentration giving rise to the g = 1.85 peak.

these radicals to atomic hydrogen gives rise to a hyperfine splitting of strength $A/(2\pi) = 1.45$ GHz leading to the appearance of the satellite peaks. These features can be removed by desorbing the sapphire surface, which was successfully done in previous work[30] by annealing at 300 °C under vacuum. We observe a similar disappearance using an annealing at the same temperature under both N₂ or Ar atmosphere in our measurements. Using the relative amplitude of the two satellite peaks, we can infer the polarization of the probed spin ensemble and deduce a spin temperature of 80 mK. This value is reasonable considering the limited attenuation we have placed on the input probe line (see supplementary material).

We now move to two correlated features linked to the adsorption of O₂ and H₂O on the sample surface: the peak at $\tilde{B}_0 = 270 \text{ mT}$ and the plateau appearing at $\tilde{B}_0 = 50 \text{ mT}$. Imperfect hydroxylation and defect sites in the sapphire located near the surface leads to the production of superoxides (O₂⁻ and HO₂⁻) contributing to the broad peak at g = 1.77 (black markers in Fig. 2b)[13, 30]. For O₂ molecules which are not reduced by interaction with the surface (either the sapphire or the NbTiN surface), they are expected to respond to ESR probing accordingly to their triplet state nature i.e., as a broad plateau resonance extending from g = 4.0 to low values. We see both features in our experiment, with the superoxide peak appearing more strongly for aged samples which were left in open air for 3 days.

The last feature lies at g = 1.85, with an extracted zerofield splitting $\Delta_0 = 0.28 \pm 0.12$ GHz (red markers in Fig. 2b). The absorption feature has an asymmetric shape, and has not been previously reported, though it may have been identified

as a spin 1/2 line in a similar study of NbTiN resonators on sapphire [29]. To identify its origin, we calculated for each resonator geometry the participation ratio p_i of each surface Σ_i to the total mode energy using finite-elements microwave simulations (see supplementary material) [8]. Namely, we wish to distinguish between two hypotheses: whether this spin system is located on the sapphire free surface Σ_f , or on the superconductor surface Σ_{sc} (see Fig. 1a). Using a multipeak fitting routine, we have calculated for each resonator the integrated absorption loss $\int \kappa_s / \omega_0 \, dB_0$. In Fig. 3, we plot this peak area versus $p_{\rm f}$ and $p_{\rm sc}$ for various fabrication protocols. Concentrating on the fabrication without annealing (green markers) for both a resist or an aluminum mask, we see that the peak area is proportional to p_{sc} , while its dependence on $p_{\rm f}$ is non-linear. We thus conclude that the defect is more likely to emanate from the NbTiN surface. From this linear fit, we can extract that the surface spin concentration is $3.1 \pm 0.2 \times 10^{12} \text{ cm}^{-2}$ (see supplementary material). Besides, the absorption does not depend on the in-plane orientation of the magnetic field so that the spins are either isotropic, or randomly orientated. We can explore a few hypotheses on the origin of these spins. The fluorine etch could leave paramagnetic residues on the edge of the superconducting electrodes[36, 37]. For instance, TiF₃ has a paramagnetic response, yet its g-value is anisotropic and would give rise to a broad line extending from 2 to 1.85[38], which does not agree with our measurements. Some electronic states of niobium and titanium exhibit a paramagnetic response, for instance electronic states Nb₂⁺ and Nb₄⁺ have a paramagnetic response with g-values around 1.85[39, 40], while Ti_3^+ is anisotropic, with principal g -values lying between 1.9 and 2. Yet, we note that the feature does not appear in Nb or NbN resonators [13, 23], so a contribution from Nb donor states seems unlikely, or deeply linked to the presence of Ti in the film.

These features contribute to a background signal strongly dependent on the magnetic field, which complicates the identification of an ESR signal, and that also limits the overall achievable quality factor. We now review the impact of different fabrication processes on the different features to elaborate a mitigation strategy. We plot on Fig. 4 the peak height κ_s^J for each feature, depending on the fabrication protocol. The contribution for each feature was isolated using a multi-peak fit. (1) We note that similarly to measurements on NbN resonators on sapphire, annealing removes the hydrogen peaks (blue) as well as the central OH⁻ peak, independently of the annealing gas. (2) Avoiding contact between photoresist and NbTiN suppresses the plateau resulting from the contribution of triplet O₂: indeed for HEM wafers where only Al was in contact with NbTiN, the plateau is absent, but for EFG wafers, even when an Al mask is used, contact with the protective photoresist layer during dicing is enough for the plateau to be observed. (3) When cleaning the wafer with a long buffered oxide etch after removing the mask, the plateau reappears, with a reduced height. It also gives rise to a small g = 2 feature which is not removed by annealing. Putting aside the NbTiN feature, it thus looks like the optimal fabrication technique among those explored here is etching through an aluminum mask followed by an annealing.

FIG. 4. Feature peak height κ_s^f extracted from a multipeak fit for the following features: lowest hydrogen hyperfine peak (blue), O_2 plateau (orange, ×3, for visibility), OH⁻ radicals (black), and the unidentified feature related to the superconducting film (red) depending on each fabrication protocol. Markers indicate measured values, boxes show the standard deviation around the mean. *AI mask indicates the wafer was covered by photoresist during dicing, but that an AI mask was used during etching.

The NbTiN feature at g = 1.85 however shows a strong increase when the sample is annealed : for samples whose NbTiN was never covered by resist, we observe a factor 6 increase for a 300 °C annealing under N2 or Ar atmosphere (red), and a factor 45 increase for $600 \,^{\circ}\text{C}$ annealing under N_2 (see Fig. 3). Note that we observe that when heating NbTiN under N2 atmosphere at higher temperature, the film swells and gets enriched in nitrogen, moving away from a balanced two atoms face cubic-centered lattice with half of the lattice occupied by nitrogen atoms, and the other occupied by Nb and Ti atoms [41]. It could thus be that enrichment of the films in nitrogen and/or a depletion of the film in Ti creates donor niobium sites that give rise to the feature. Remarkably, the sample which was covered by resist for dicing, but etched with an aluminum mask does not show the same increase so that we postulate that an oxide passivation layer is sufficient to counteract the effect of annealing on the NbTiN feature.

Nevertheless, avoiding putting photoresist into contact with NbTiN for dicing and etching through an aluminum mask followed by an annealing results in the best combination to remove all magnetic field dependent features. It also ensures that we reach reproducible quality factors above $Q > 10^5$ at zero magnetic field, in particular for our low-impedance geometry resonator. Considering all sources of losses, including the contribution from aluminum wire bonds ($\sim 3 \times 10^5$) and of the NbTiN feature ($\sim 2 \times 10^5$), we can maintain a total quality factor above $Q > 10^5$ in the 0 T to 0.3 T range, an important step to develop an ESR spectrometer based on superconducting microwave resonators. Straightforward improvements to our setup could help reduce the length of the wire bonds so that their contribution is minimized ($>2 \times 10^6$). The behavior of the NbTiN feature also makes clear that developing a capping layer that would act as a barrier during the annealing without contributing to the oxygen features would help us

reach higher quality factors. Broader perspectives would be to probe the origin of the NbTiN feature by varying the stoichiometry of the NbTi sputtering target or comparing to TiN resonators.

ACKNOWLEDGMENTS

This work was supported by the LABEX iMUST (ANR-10-LABX-0064) and the project IDEXLYON of Université de Lyon, within the program "Investissements d'Avenir" (ANR-11-IDEX-0007 and ANR-16-IDEX-0005) operated by the French National Research Agency (ANR) and by the European Union (ERC, INDIGO, 101039953). We acknowledge IARPA and Lincoln Labs for providing a Josephson Traveling-Wave Parametric Amplifier. The NbTiN films were etched using the ICP-RIE tool of the Nanolyon platform. We thank the cleanroom of the SPEC at CEA-Saclay and Pief Orfila for sputtering NbTiN on our wafers.

I. APPENDIXES

A. Samples and measurement setup

The list of samples as well as their precise fabrication process is given in Table I.

After fabrication, the samples are wirebonded to a OFHC copper sample holder and inserted into a vector magnet anchored to the base plate of a dilution refrigerator operating at 12 mK for measurement. The microwave setup is shown on Fig. 5. The magnet is placed inside a cryoperm shield and calibrated using BDPA samples. The incoming signal is attenuated with a total of 43 dB. We include an Eccosorb filter in-front of the circulator before the device under test (DUT) to reduce quasi-particles caused by infrared radiation. The input power is chosen such that the intra-resonator photon number is of order 1. The outgoing signal is amplified by a Josephson traveling-wave parametric amplifier followed by a highelectron mobility transistor amplifier. The measurements are carried out using a vector network analyzer (VNA).

B. Resonator fitting

The resonators on the various samples are probed either in reflection or in a transmission hanger geometry. To extract the internal quality factor from the VNA measurements for these two coupling schemes, we model the reflection (R_R) and

FIG. 5. Microwave setup for transmission (red) and reflection measurements (blue).

hanger-mode (R_H) response as [33, 34]:

$$R_{R} = \left[1 - \frac{2Q_{l}/Q_{c}}{1 + 2iQ_{l}(\omega/\omega_{r} - 1)}\right]$$

$$R_{H} = \left[1 - \frac{(Q_{l}/Q_{c})e^{i\phi_{0}}}{1 + 2iQ_{l}(\omega/\omega_{r} - 1)}\right]$$
(1)

The complex phase ϕ_0 accounts for impedance mismatches in the coupling between resonator and measurement lines. We define $Q_l = [1/Q_i + 1/Q_c]^{-1}$ as the loaded loss of the resonator. The measured response of the resonator S_m at the VNA is actually convoluted with the response of the measurement lines. This response can be described as an overall complex scaling factor $Ae^{i\alpha}$ and an electrical delay τ giving a frequency-dependent phase $e^{i\omega\tau}$. To recover only the resonator response, we renormalize the data using $\tilde{S}_m = S_m(\omega)e^{-i\omega t}/S_m(\infty)$ so that $\tilde{S}_m(\omega)$ lies on a circle in the complex plane. We then estimate the best circle fitting the data in the complex plane, obtaining its radius R and center $z_c = x_c + iy_c$.

We perform the affine transformation $S_{21}^{\{R,H\}_C} = S_{21}^{\{R,H\}_N} - z_c$ and compute the phase of the transformed quantity, obtaining:

$$\phi_R = 2 \arctan \left[2(\omega/\omega_r - 1)Q_l \right]$$

$$\phi_H = 2 \arctan \left[2(\omega/\omega_r - 1)Q_l \right] - \phi_0$$
(2)

which can be fitted to extract the loaded quality factor and the resonant frequency of the resonator. Using the relations between (Q_i, Q_c) and (R, Q_l)

$$Q_c^R = Q_l^R / R \qquad 1/Q_i^R = 1/Q_l^R - 1/Q_c^R Q_c^H = Q_l^H / 2R \qquad 1/Q_i^H = 1/Q_l^H - 1/Q_c^H$$

it is possible to estimate the coupling and internal quality factors. As the determination of the quality factors involves three steps (re-normalization, circle fitting, and phase fitting), each step can contribute to the uncertainty. In practice, the errors due to the circle fitting, and in particular on the circle radius largely offset the other two. The Qc value is fixed to the average fitted value for all magnetic fields thus reducing its uncertainty. For the intrinsic quality factor, as $1/Q_i = (1 - rR)/(rRQ_c)$ we estimate $\Delta(1/Q_i) = \Delta(R)/(rR^2Q_c)$ where r =2 in hanger geometry and r = 1 in reflection. This analysis does not take into account Fano interferences or direct-direct port leakage which can introduce a systematic error in the determination. However, as we are only looking at extra-losses created into resonators of similar geometries, this systematic error does not particularly affect our study.

C. Modelling of surface spin losses for a superconducting resonator

In this section, we model losses created by spins lying either on the metallic area of a planar superconducting resonator, or on the nearby uncovered substrate surface.

1. Spin induced losses

Each family of spins can be described by its Hamiltonian $H_s(\vec{B})$ which can be diagonalized to extract the spin family eigenstates and eigenvalues. When a static magnetic field \vec{B}_0 is applied, a specific transition between states $||1\rangle$ and $|2\rangle$ occurring at frequency $\omega_s(B_0)$ can be brought to resonance. Each spin interacts with the resonator through a Jaynes-Cumming Hamiltonian. The interaction strength g_j of a single spin is given by $\hbar g = |\langle 1|H_s(\vec{\delta B}(\vec{r}))|2\rangle|$, where $\vec{\delta B}_{ac}(\vec{r})$ are the vacuum fluctuations of the resonator electromagnetic mode at the spin position \vec{r} . We consider that the spin ensemble has an inhomogenous distribution in frequency of linewidth Γ while each spin has a decoherence rate Γ_2 . We also introduce the collective coupling constant as $g_{ens} = \sum_j g_j^2$. In the limit of small cooperativity $4g_{ens}^2/(\kappa\Gamma) <<1$, assuming the spin frequency distribution is Lorentzian, the response

 $R(\omega)$ for the resonator is [42]:

$$R(\boldsymbol{\omega}) = 1 - \frac{r\sqrt{\kappa_c}}{\kappa + \kappa_s - 2i(\boldsymbol{\omega} - \boldsymbol{\omega}_r) + 2i\delta_s}$$
(4)

where $\kappa_s = 4g_{ens}^2 \Gamma/((\omega_s - \omega_r)^2 + \Gamma^2/4)$ and $\delta_s = 4g_{ens}^2 \Gamma(\omega_s - \omega_r)/((\omega_s - \omega_r)^2 + \Gamma^2/4)$, and r = 2 when measuring in reflection, and 1 when measuring in hanger geometry.

Eq. 4 shows clearly that the spins create an additional decay channel for the resonator, which depends on the spin frequency. Integrating the losses over the entire spin linewidth probed in magnetic field thus yields:

$$\int_{0}^{+\infty} \frac{\kappa_{\rm s}}{\omega_{\rm r}} d\omega_{\rm s} = \frac{4\pi g_{ens}^2}{\omega_{\rm r}} \tag{5}$$

2. Magnetic field participation ratio

These spin induced losses can be shown to be proportional to a magnetic field participation ratio, similarly to dielectric losses being proportional to an electrical participation ratio [8]. On one hand, we can calculate the magnetic field participation ratio as:

$$p = \frac{\frac{1}{\mu_0} \int_{V_s} |\delta B_\perp|^2 dV}{\frac{1}{\mu_0} \int_V |\delta B|^2 dV} = \frac{2}{\mu_0 \hbar \omega_r} \int_{V_s} |\delta B_\perp|^2 dV \qquad (6)$$

where V_s is the volume containing the spins of interest (either at the surface of the sapphire, or the surface of the NbTiN), and V is the entire mode volume. Assuming the Zeeman effect predominates in the spin Hamiltonian and that the spin system behaves closely to a spin 1/2, only the ac-field components orthogonal to the static field B_0 will induce a coupling to the spin, we thus only consider $|\delta B_{\perp}|^2$ for calculating the magnetic field participation ratio.

On the other hand, for a resonator-spin transverse coupling, the spin collective coupling constant can be calculated as :

$$g_{ens}^2 = \int_{V_s} c |\delta B_\perp|^2 \gamma_e^2 |\langle 1|S_x/2|2\rangle|^2 dV \tag{7}$$

where *c* is the spin volume concentration, γ_e is the spin transition gyromagnetic ratio, and S_x the dimensionless spin operator. We thus find:

$$\int_{0}^{B_{0}^{\max}} \frac{\kappa_{s}}{\omega_{r}} dB_{0} = h\mu_{0}c\gamma_{e}|\langle 1|S_{x}/2|2\rangle|^{2}p, \qquad (8)$$

giving a linear relation between peak area and participation ratio. To evaluate numerically the participation ratios for all designs, we performed microwave simulations (using HFSS Ansys software) modelling the NbTiN as a perfect conductive layer without any thickness. We extract the contribution of two zones, the free sapphire surface Σ_f and the NbTiN surface Σ_{sc} , to the overall magnetic mode energy

 $U_B = \frac{\int_V |B|^2 dV}{2\mu_0}$. We use the included field calculator to evaluate $p_{\Sigma} = t \int_{\Sigma} |B_{\perp}|^2 d\Sigma / (2\mu_0 U_B)$, where *t* represents the thickness of the considered surface. We take t = 3 nm, which is a fair assumption for radicals contribution at the sapphire surface [30], but a rather arbitrary choice for the NbTiN surface (that nevertheless allows for convenient comparison to the sapphire surface). This modeling also neglects the inhomogeneous current distribution within a superconducting sheet.
