Abstract

We study the multi-agent multi-armed bandit (MAMAB) problem, where m agents are factored into ρ overlapping groups. Each group represents a hyperedge, forming a hypergraph over the agents. At each round of interaction, the learner pulls a joint arm (composed of individual arms for each agent) and receives a reward according to the hypergraph structure. Specifically, we assume there is a local reward for each hyperedge, and the reward of the joint arm is the sum of these local rewards. Previous work introduced the multi-agent Thompson sampling (MATS) algorithm (Verstraeten et al. 2020) and derived a Bayesian regret bound. However, it remains an open problem how to derive a frequentist regret bound for Thompson sampling in this multiagent setting. To address these issues, we propose an efficient variant of MATS, the ϵ -exploring Multi-Agent Thompson Sampling (ϵ -MATS) algorithm, which performs MATS exploration with probability ϵ while adopts a greedy policy otherwise. We prove that ϵ -MATS achieves a worst-case frequentist regret bound that is sublinear in both the time horizon and the local arm size. We also derive a lower bound for this setting, which implies our frequentist regret upper bound is optimal up to constant and logarithm terms, when the hypergraph is sufficiently sparse. Thorough experiments on standard MAMAB problems demonstrate the superior performance and the improved computational efficiency of ϵ -MATS compared with existing algorithms in the same setting.

1 Introduction

Reinforcement learning (RL) is a fundamental problem in machine learning, where an agent learns to make optimal decisions in an environment by trial and error. A specific instance of RL is the multi-armed bandit (MAB) problem, in which an agent must choose between a set of arms, and each of the arms has a random reward distribution. The agent's goal is to maximize its total reward over time. In standard MAB problems, an agent is provided with a set of arms [K] := 1, 2, ..., K, and each arm, when pulled, generates a reward following a 1-subgaussian distribution with an unknown mean. The agent's objective is to maximize its overall rewards within a specified time frame.

We consider the multi-agent MAB (MAMAB) problem, where there are m agents. At each round of the interaction, each agent chooses an arm from its own arm set [K]. We define the concatenation of these arms as the joint arm. The bandit learner aims to coordinate with all agents and choose joint arms that maximize the cumulative rewards obtained from pulling those joint arms. It is important to note that the size of the joint arm space is exponential in the number of agents, specifically $A = K^m$. This exponential growth poses computational challenges in coordination and arm selection. To address this issue, it was proposed to factor all agents into ρ possibly overlapping groups (see wind farm application), which forms a hypergraph over the agents with each agent representing a node and each group representing a hyperedge (an illustration can be found in Section 2 and Figure 1). Instead of pulling the joint arm, the learner only needs to pull the local arms, where each pulled local arm is defined as the concatenation of the arms chosen by agents within the same group. We assume each group has d agents, and thus the total number of local arms A_{loc} is at most ρK^d , which is much smaller than the number of joint arms when the groups are small. This approach gives rise to MAMAB problems with specific coordination graph structures, which have found practical applications in various domains such as traffic light control (Wiering et al. 2000), warehouse commissioning (Claes et al. 2017), and wind farm control (Gebraad and van Wingerden 2015; Verstraeten et al. 2019).

We evaluate a learning strategy based on its cumulative rewards obtained by interacting with the environment for a total of T rounds. This evaluation can be equivalently measured by calculating the regret of the strategy compared to an oracle algorithm that always selects the arm with the highest reward. Mathematically, the regret is defined as $R_T =$ $T\mu^* - \mathbb{E}[\sum_{t=1}^T f(\mathbf{A}_t)]$, where μ^* is the mean of the optimal arm and $f(\mathbf{A}_t)$ represents the reward obtained when pulling the joint arm \mathbf{A}_t at time t according to the given strategy. The goal of the algorithm (or learner) is to coordinate with all agents to determine the joint arm to pull in order to minimize this regret.

Thompson sampling (Thompson 1933), introduced by Thompson in 1933, has emerged as an attractive algorithm for bandit problems. It is favored for its simplicity of implementation, good empirical performance, and strong theoretical guarantees (Chapelle and Li 2011; Agrawal and Goyal 2017; Jin et al. 2021a). The key idea behind Thompson sampling is to sample reward estimates for each possible arm

Copyright © 2024, Association for the Advancement of Artificial Intelligence (www.aaai.org). All rights reserved.

from a posterior distribution and select the arm with the highest estimated value for pulling. In the single-agent setting, Thompson sampling has been shown to achieve nearoptimal regret with respect to the worst possible bandit instance (Agrawal and Goyal 2017). In the context of multiagent MAB with a coordination graph, the MATS (Multi-Agent Thompson Sampling) algorithm was proposed by Verstraeten et al. (2020). Unlike traditional Thompson sampling, where estimated rewards are sampled for each joint arm, MATS samples rewards for each local arm. This approach reduces the computational complexity, particularly in cases where the coordination hypergraph is sparse. Verstraeten et al. (2020) provided a Bayesian regret bound for MATS, which measures the average performance given the probability kernel of the environment. However, in practical scenarios, it may not always be feasible for the learner to possess knowledge or access to the probability kernel of the environment. In such cases, the frequentist regret bound, which measures the worst-case performance across all environments, is often considered. It is worth noting that a frequentist regret upper bound implies a Bayesian regret bound, but not vice versa. Deriving a frequentist regret bound for the MATS algorithm in the multi-agent MAB problem with a coordination hypergraph remains an open question.

There are several technical challenges in the analysis of the frequentist regret for MATS. The first challenge emerges when applying the regret analysis of single-agent Thompson Sampling (Agrawal and Goyal 2012) to our context. This occurs due to a dependence issue among different joint arms. Although rewards for each local arm are independently drawn from their respective reward distributions, the average rewards of the joint arms might be influenced by the other joint arms when they share some local arms (see Section 4 for detailed discussion). As a result, it is difficult to analyze the distribution of the average reward of the optimal arm or apply any concentration/anti-concentration inequalities, while all existing frequentist regret analyses of Thompson sampling (Agrawal and Goyal 2012, 2017; Jin et al. 2021a, 2022; Korda, Kaufmann, and Munos 2013; Kaufmann, Korda, and Munos 2012) heavily rely on the specific form of the distribution of the average reward of the optimal arm. A naive method of removing the dependence involves maintaining a posterior distribution for each joint arm and updating the distribution only when this joint arm is pulled. However, this method could result in significant computational complexity and regret due to the large joint arm space.

In this paper, we tackle the issue using two strategies: 1) We carefully partition the entire arm set into subsets, ensuring each arm within a subset shares the same local arms with the optimal arm, and 2) We conduct a regret analysis at the level of local arms. Specifically, let 1 denote the optimal joint arm. We consider two events: 1) The local arm 1^e of the optimal arm 1 is not underestimated, meaning the posterior sample of 1^e is larger than $1^e - \Delta/\rho$, and 2) The local arm a^e of the suboptimal arm a is not overestimated, meaning the posterior sample of a^e is lower than $a^e - \Delta/\rho$. Crucially, these events ensure that the sum of posterior samples for any suboptimal joint arms is lower than the sum of posterior samples of 1, which leads to a lower regret.

Another challenge in our local arm level analysis arises when we aim to establish a lower bound for the probability that the posterior sample of all local arms of 1 exceeds their means by Δ/ρ . Leveraging the original Thompson Sampling analysis, we can establish this probability's lower bound as $(\Delta/\rho)^{2\rho}$, leading to $(\rho/\Delta)^{2\rho}$ suboptimal arm pulls. In terms of worst-case regret, this amounts to $O(T^{\frac{2\rho-1}{2\rho}})$. We improve this result by applying two innovative techniques (for ease of presentation, these are elaborated in full detail in Section 4), reducing the number of pulls to C^{ρ} , where C is a universal constant. Using these novel techniques, we are able to offer a \sqrt{T} -type worst-case regret.

Main contributions. We summarize our main contributions as follows.

- We propose the ϵ -exploring Multi-Agent Thompson Sampling (ϵ -MATS) algorithm, which only samples from the posterior distribution with probability ϵ and acts greedily with probability 1ϵ . When $\epsilon = 1$, our algorithm reduces to the MATS algorithm (Verstraeten et al. 2020). When $\epsilon \ll 1$, our algorithm ϵ -MATS only needs a small amount of exploration, and thus is much more computationally efficient than MATS in practice.
- We establish a frequentist regret bound for ϵ -MATS in the order of $\tilde{O}(\sqrt{(C/\epsilon)^{\rho}A_{\text{loc}}T})$, where *C* is some universal constant and $\tilde{O}(\cdot)$ ignores constant and logarithmic factors. Here ρ denotes the number of hyperedges, A_{loc} represents the total number of local arms, and *T* is the time horizon. Remarkably, when $\epsilon = 1$, our result also provides the first frequentist regret bound for MATS (Verstraeten et al. 2020). Despite having *A* joint arms, our regret bound grows as $O(\sqrt{A_{\text{loc}}})$, which is much smaller than the total number of joint arms.
- We also derive an $\Omega(\sqrt{A_{\text{loc}}T}/\rho)$ lower bound for the worst-case regret in our setting, showing that ϵ -MATS is minimax optimal in terms of the total number of local arms and the time horizon when the the number of groups ρ is small. When $\epsilon = 1$, we show that the regret bound of MATS has an unavoidable C^{ρ} dependence on the number of groups ρ , which further implies that the regret bound $\tilde{O}(\sqrt{(C/\epsilon)^{\rho}A_{\text{loc}}T})$ is optimal in terms of the number of groups as well.
- We further conduct extensive experiments on various MAMAB problems, including the Bernoulli 0101-Chain, the Poisson 0101-Chain, the Gem Mining problem, and the Wind Farm Control problem (Roijers, Whiteson, and Oliehoek 2015; Bargiacchi et al. 2018; Verstraeten et al. 2020). Through empirical evaluation, we demonstrate that the regret of ϵ -MATS can be significantly lower compared to MATS as ϵ decreases, outperforming existing methods in the same setting. We also find that ϵ -MATS.

2 Preliminary and Background

In this section, we present the preliminary details of our setting. We also provide a notation table in Table 1 for the convenience of our readers. We adopt the MAMAB (Multi-Agent Multi-Armed Bandit) framework introduced by Verstraeten et al. (2020), where there are m different agents, who are grouped into ρ potentially overlapping groups. Each group can be represented as a hyperedge in a hypergraph, where the agents correspond to the nodes. Figure 1 provides an example for easier visualization. During each round, every agent $i \in [m]$ selects an arm from their respective arm set \mathcal{A}_i , which is referred to as the "*individual*" arm played by agent *i*. For simplicity, we assume that each agent *i* has the same number of arms, denoted as $K = |\mathcal{A}_i|$. However, it is straightforward to extend the framework to accommodate varying numbers of arms $|\mathcal{A}_i|$. The arms chosen by all agents are concatenated to form a "*joint*" arm denoted by a, which belongs to the set $\mathcal{A}_1 \times \cdots \times \mathcal{A}_m$. Consequently, the total number of joint arms is defined as $A := |\mathcal{A}_1 \times \cdots \times \mathcal{A}_m|$.

We define a "local" arm as the concatenation of individual arms for a specific group $e \in [\rho]$. In other words, if agents $i_1, \ldots, i_d \in [m]$ form a hyperedge, then the local arm $a^e \in \mathcal{A}_{i_1} \times \cdots \times \mathcal{A}_{i_d}$ represents the *d*-tuple of arms selected by these agents. We shall denote the set of local arms for group *e* as \mathcal{A}^e . Let A_{loc} be the total number of local arms. It is straightforward to see that $A_{\text{loc}} \leq \rho K^d$, with equality when the groups don't overlap. It is important to note that the arm space grows exponentially with the number of agents, leading to computational challenges in arm selection. To address this combinatorial complexity, we employ variable elimination techniques, which will be further explained in the subsequent sections.

In this paper, the global reward f(a) associated with each joint arm a is decomposed into ρ local rewards $f^e(a^e)$, where a^e represents the local arm for group e. This decomposition takes advantage of the hypergraph structure. Specifically, for a given hypergraph with ρ hyperedges, we have the relationship $f(a) = \sum_{e=1}^{\rho} f^e(a^e)$. The mean reward of a group e is denoted as $\mu_{a^e} = \mathbb{E}[f^e(a^e)]$. Consequently, the mean reward of a joint arm a is given by $\mu_a = \sum_{e=1}^{\rho} \mu_{a^e} = \mathbb{E}[f(a)]$. We assume the local rewards $f^e(a^e)$ to be 1-subgaussian, i.e. $\mathbb{P}(|f^e(a^e)| \ge \epsilon) \le 2e^{-\epsilon^2}$. As a result, the global reward f(a) is $\sqrt{\rho}$ -subgaussian.

Our objective is to maximize the expected cumulative global rewards obtained over a horizon of T rounds of interaction with the environment. Without loss of generality, we assume that 1 is the optimal joint arm that yields the highest expected global reward. It is important to note that the goal is defined based on the performance of the best joint arm. In other words, even if a local arm a^e has a high local reward, it may not be selected frequently by an optimal policy if it is not part of joint arms with high mean rewards. To quantify the performance of a bandit strategy, we use the concept of regret denoted by R_T , defined as the expected difference between the cumulative rewards obtained by always selecting the optimal joint arm 1 and the actual rewards obtained by following a specific strategy. Mathematically, the regret R_T is given by:

$$R_T = \mathbb{E}\left[\sum_{t=1}^T (\mu_1 - f(\mathbf{A}_t))\right] = \sum_{t=1}^T (\mu_1 - \mu_{\mathbf{A}_t}), \quad (2.1)$$

where A_t represents the joint arm selected at round t. The regret captures the deviation from the cumulative rewards that would have been obtained if the optimal joint arm was chosen at each round. Minimizing regret is a key objective in

Figure 1: The hypergraph representation of a bandit environment with 8 agents and 3 groups. Each agent is represented by a vertex numbered by $\{1, 2, ..., 7\}$ and each group is represented by a hyperedge. In this case, there are three hyperedges with each with size 3. Letting a_i be the action taken by player *i*, the reward for the joint action $(a_1, ..., a_7)$ is decomposed as $f(a_1, a_2, ..., a_7) = f^1(a_1, a_2, a_6) + f^2(a_2, a_3, a_4) + f^3(a_5, a_6, a_7)$, where a_i is the individual arm picked by agent *i*.

designing effective strategies for the hypergraph MAMAB problem.

Remark 2.1. Although the results of our paper hold true regardless of the coordination hypergraph structure between the agents, they are most meaningful when the graph is sparse (i.e. the number of agents in each group is small). In particular, as there are A joint arms, if one were to consider a different reward function for each arm, the regret and implementation complexity would be on the order of A. However, our results exploit the fact that there are only A_{loc} local reward functions, and thus our regret bound is in terms of A_{loc} , which is much smaller than A when the groups are small.

3 The ε-Exploring Multi-Agent Thompson Sampling Algorithm

In this section, we present the ϵ -exploring Multi-Agent Thompson Sampling Algorithm (ϵ -MATS), whose pseudocode of ϵ -MATS is displayed in Algorithm 1. ϵ -MATS is a combination of the MATS algorithm (Verstraeten et al. 2020) and a greedy policy. The idea of adding a greedy policy to Thompson Sampling was initially proposed in Jin et al. (2022) and subsequently explored in Jin et al. (2023). In ϵ -MATS, at each round $t \in [T]$, similar to MATS, Algorithm 1 maintains a posterior distribution $\mathcal{N}(\widehat{\mu}_{a^e}(t), \frac{c}{n_{a^e}(t)})$ for each local arm a^e , $e \in [\rho]$, where $\widehat{\mu}_{a^e}(t)$ is the average reward of arm a^e , $n_{a^e}(t)$ represents the number of pulls of arm a^e , and c is a scaling parameter. Both MATS and ϵ -MATS maintain estimated rewards $\theta_{a^e}(t)$ for each local arm, and select the joint arm that yields the highest sum of estimated local rewards, i.e., $A_t = \arg \max_{a \in \mathcal{A}} \sum_{e \in [\rho]} \theta_{a^e}(t)$. After receiving the true rewards, the algorithms update the average reward $\widehat{\mu}_{a^e}(t)$ and the number of pulls of A_t accordingly.

The difference between MATS and ϵ -MATS lies in the way they construct the estimated rewards $\theta_{a^e}(t)$ for each local

arm. In particular, MATS samples $\theta_{a^e}(t)$ from the respective posterior distribution for local arm a^e . In contrast, the proposed ϵ -MATS algorithm only samples $\theta_{a^e}(t)$ from the posterior distribution with a probability of ϵ , and it directly sets $\theta_{a^e}(t) = \widehat{\mu}_{a^e}(t)$, i.e., as the empirical mean reward. Here $\epsilon \in (0,1]$ is a user-specified parameter that controls the level of exploration. For small values of ϵ , ϵ -MATS significantly reduces the level of exploration in MATS, which leads to improved computational efficiency.

 ϵ -Exploring. The idea of ϵ -exploring is inspired from the recent work of Jin et al. (2023). We prove in the next section that ϵ -MATS achieves the same order of finite-time regret bound as the MATS algorithm, even though it only needs to perform a small fraction of TS-type exploration. Furthermore, this algorithm runs faster since it doesn't have to sample each local arm from the Gaussian distribution as frequently as MATS. We also show that for specific applications the regret of ϵ -MATS converges much faster than MATS and other algorithms in the same setting.

Variable Elimination. In Line 9 of Algorithm 1, ϵ -MATS needs to find the joint arm a that maximizes the sum of the estimated local rewards. However, this step can be computationally expensive if naively implemented, as it would require considering all possible joint arms, resulting in a complexity of $O(K^m)$ since the joint space size is K^m . Following (Verstraeten et al. 2020), we use variable elimination (Guestrin, Koller, and Parr 2001) to reduce this computation burden. The key idea behind variable elimination is to optimize over one agent at a time instead of summing all estimated local rewards for each joint arm and then performing the maximization. By doing so, we can significantly reduce the computational burden. To explain how variable elimination works, let us rewrite the maximum sum of the local estimates as follows:

$$\max_{\boldsymbol{a}} f(\boldsymbol{a}) = \max_{\boldsymbol{a}} \sum_{e=1}^{\rho} f^{e}(\boldsymbol{a}^{e}) = \max_{\boldsymbol{a}} \left[\underbrace{\sum_{\boldsymbol{a}^{e} \in \boldsymbol{a}: a_{m} \notin \boldsymbol{a}^{e}}}_{I_{1}} f^{e}(\boldsymbol{a}^{e}) + \underbrace{\max_{\boldsymbol{a}^{e}: a_{m} \in \boldsymbol{a}^{e}}}_{I_{2}} \sum_{\boldsymbol{a}^{e} \in \boldsymbol{a}: a_{m} \in \boldsymbol{a}^{e}} f^{e}(\boldsymbol{a}^{e}) \right], \qquad (3.1)$$

where a_m represents an individual arm of agent m. In Equation (3.1), we decompose the sum of the rewards into two cases based on the optimization variable a. In I_1 , we consider all the groups a^e that do not contain agent m. The maximization in this case is performed independently of the selection of individual arm a_m . Thus, the remaining agents can be optimized separately, resulting in a smaller optimization problem involving at most m-1 agents. In I_2 , we focus on the groups that contain agent m. Here, we aim to find the individual arm a_m that maximizes the sum of the local rewards for the joint arms containing a_m . This sum depends on the individual arms of the other agents that share a group with agent m. After determining the optimal a_m , the rest of the maximization is performed independently on the remaining agents in I_1 . For more examples and details on variable elimination, please refer to (Guestrin, Koller, and Parr 2001).

We have the following result for variable elimination.

Lemma 3.1. Let G_1, \ldots, G_ρ be the set of agents that belong to group $1, \ldots, \rho$ respectively. Then we have $A_{\text{loc}} =$ $\sum_{e=1}^{\rho} \prod_{i \in G_e} |\mathcal{A}_i|$. At every round in Algorithm 1, following the above variable elimination procedure, the complexity of searching for the optimal arm is $O(A_{loc}) =$ $O\left(\sum_{e=1}^{\rho}\prod_{i\in G_e}|\mathcal{A}_i|\right).$

As we discussed, without variable elimination, one would naively add up all the estimated local rewards θ_{a^e} for each joint arm a and find the joint arm with the largest posterior θ_a , leading to computational complexity in the order of $O(A) := O(\prod_{i=1}^{\rho} |\mathcal{A}_i|)$ at each round, which grows exponentially in the number of agents. In contrast, Lemma 3.1 indicates that by using variable elimination, ϵ -MATS only needs A_{loc} computation to find the joint arm with the largest estimated reward. Note that this theoretical guarantee is of independent interest to MATS as well since none was given in the original paper (Verstraeten et al. 2020).

Finite-Time Frequentist Regret Analysis 4

In this section, we present the proof of the frequentist regret bound for ϵ -MATS.

Finite-Time Frequentist Regret Bound of ϵ -MATS

For convenience, we use $\Delta_{a} = \mu_{1} - \mu_{a}$ to denote the suboptimality gap between joint arm a and the optimal joint arm. We let $\Delta_{\min} = \min_{\boldsymbol{a} \in \times_{i=1}^{m} \mathcal{A}_i \setminus \{1\}} \Delta_{\boldsymbol{a}}$ and $\Delta_{\max} = \max_{\boldsymbol{a} \in \times_{i=1}^{m} \mathcal{A}_i} \Delta_{\boldsymbol{a}}$ be the minimum and maximum gap respectively. Moreover, let $\Delta_{\boldsymbol{a}^e} = \min\{\Delta_{\boldsymbol{a}} \mid \boldsymbol{a}^e \in \boldsymbol{a}\}$ be the minimum reward gap between joint arm a which contains a^e and 1. We present the regret of ϵ -MATS as follows.

Theorem 4.1. Let $c = \log T$. The regret of ϵ -MATS satisfies the following results.

1. There exists some universal constant C_1 such that

$$R_T \leq \frac{C_1(C_1/\epsilon)^{\rho} \rho^2 \log^2(TA_{\text{loc}})}{\Delta_{\min}} + C_1 \sum_{e \in [\rho]} \sum_{\boldsymbol{a}^e \in \mathcal{A}^e \setminus \{\mathbf{1}^e\}} \frac{\rho^2 \log^2(TA_{\text{loc}})}{\Delta_{\boldsymbol{a}^e}} + C_1 \Delta_{\max}.$$

2. There exists some universal constant C_2 such that

$$R_T \leq C_2 \Delta_{\max} + C_2 \rho \sqrt{\left((C_2/\epsilon)^{\rho} + A_{\text{loc}} \right) T \log^2 (TA_{\text{loc}})}.$$

Note that when $\epsilon = 1$, ϵ -MATS reduces to MATS, which gives the first frequentist regret bound of MATS. In particular, our bound is in the same order as the Bayesian regret bound (Verstraeten et al. 2020, Theorem 1) in terms of the order of T and $A_{\rm loc}$. Compared with the Bayesian regret in Verstraeten et al. (2020), our worst-case regret has an additional $\sqrt{\log T}$ factor because we inflate the variance of posterior distribution by $\log T$, which is a common trick in deriving the worst case regret bound of Thompson sampling (Agrawal and Goyal 2017; Jin et al. 2021a). The derivation of $(C_2/\epsilon)^{\rho}$ is provided in the following subsection.

Technical Challenges in Frequentist Regret Analysis and the Proof Outline

For simplicity, this part assumes $\epsilon = 1$ (which reduces to MATS given in Verstraeten et al. (2020)). First, let's introduce some notations to simplify our discussion. We denote S_r as the set of joint arms with gaps in the interval $(2^{-r}, 2^{-r+1}]$ and let $\delta_r = 2^{-(r+2)}$. The regret incurred by pulling the arms in S_r is represented as $R(S_r)$. Furthermore, we define $S_r(t)$ as the set of joint arms not overestimated at time t, formally given by:

$$S_r(t) = \{ \boldsymbol{a} \mid \boldsymbol{a} \in S_r, \forall e \in [\rho] \\ \text{and } \boldsymbol{a}^e \neq \boldsymbol{1}^e, \theta_{\boldsymbol{a}^e}(t) \leq \mu_{\boldsymbol{a}^e} + \delta_r / \rho \}.$$

The regret $R(S_r)$ can be expressed as

$$R(S_r) \le 8\delta_r \cdot \Big(\underbrace{\sum_{t=1}^T \mathbb{1}\{A_t \in S_r(t)\}}_{I_1} + \underbrace{\sum_{t=1}^T \mathbb{1}\{A_t \notin S_r(t)\}}_{I_2}\Big).$$

The term I_2 is relatively straightforward. It's important to note that whenever we pull the arm $A_t \notin S_r(t)$, we inevitably pull a local arm whose posterior sample has not yet converged to its true mean. After sufficient pulls of each local arm (due to pull A_t with $A_t \notin S_r(t)$), and by employing the maximal inequality for the reward distribution along with the concentration bound for the posterior distribution, we can demonstrate that the event $A_t \notin S_r(t)$ occurs with an exceedingly small probability.

We now discuss how to bound term I_1 and the associated challenges. In the regret analysis for single agent Thompson Sampling (TS) by Agrawal and Goyal (2012); Jin et al. (2022), the term I_1 is bounded as follows.

$$\sum_{t=1}^{T} \mathbb{1}\left\{\boldsymbol{A}_{t} \in S_{r}(t)\right\} \leq \mathbb{E}_{\hat{\mu}_{1,s}}\left[1/\mathbb{P}(\theta_{1,s} \geq \mu_{1} - \delta_{r})\right], \quad (4.1)$$

where $\hat{\mu}_{1,s}$ is the empirical mean of arm 1 after being pulled s times, $\theta_{1,s}$ is the posterior sample from $\mathcal{N}(\hat{\mu}_{1,s}, c\rho/s)$, and $1/\mathbb{P}(\theta_{1,s} \ge \mu_1 - \delta_r)$ represents the expected maximum number of posterior samples from $\mathcal{N}(\hat{\mu}_{1,s}, c\rho/s)$ such that one sample is larger than $\mu_1 - \delta_r$.

However, in a multi-agent setting, we can't decompose it in the same way due to two main reasons:

- 1. Since arm 1 might share some local arms with other joint arms, the number of pulls of each local arm of 1 could be different at time t. This contrasts with $\hat{\mu}_{1,s}$ in Equation (4.1), where we assume that arm 1 is pulled exactly s times.
- 2. More importantly, while the samples of each local arm are independently drawn from their respective reward distributions, a dependency issue arises in the case of the joint arm. To explain, if each local arm 1^e is pulled a fixed number of times, N_e , the mean reward of 1 follows the $\left(\sqrt{\sum_{e \in [\rho]} (N_e)^{-1}}\right)$ -subgaussian with a mean of $\sum_{e \in [\rho]} \hat{\mu}_{1^e,Ne}$. Leveraging the properties of subgaussian random variables, it can be demonstrated that the mean reward of joint arm 1 converges to its true mean as the number of pulls increases. However, this is not true when the pulls of local arms are history-dependent. In such cases, MATS is more likely to pull suboptimal arms that share overestimated local arms of 1 (the posterior samples from these local arms could surpass those from other underestimated local arms of 1). If this situation occurs, $\hat{\mu}_1(t)$ is likely to be underestimated, making its distribution challenging to ascertain. Therefore, it will be difficult to derive the concentration results for $\hat{\mu}_{1}(t)$ and consequently, the probability of $\theta_1(t) \ge \mu_1 - \delta_r$ would also be hard to establish.

We solve the above issues by 1: carefully dividing S_r into subsets, where the arms in each subset share the same local arms with 1 (total 2^{ρ} subsets); and 2: bounding term I_1 in local arms level. These two methods allow us to prove that

$$\sum_{t=1}^{T} \mathbb{1}\{\boldsymbol{A}_{t} \in S_{r}(t)\}$$

$$\leq 2^{\rho} \sum_{s=1}^{\tau} \prod_{e=1}^{\rho} \mathbb{E}_{\hat{\mu}_{1^{e},s}} \left[1/\mathbb{P}(\theta_{1^{e},s} \ge \mu_{1^{e}} - \delta_{r}/\rho)\right] + \Theta(1). \quad (4.2)$$

In the right hand of inequality, 2^{ρ} is due to the existence of 2^{ρ} subsets, and τ is defined as $\Theta(\rho^2(\log(TA_{\text{loc}}))^2/(\delta_r)^2)$. The term $\Theta(1)$ exists because after each local arm is pulled more than τ times, the event $\mathbb{P}(\theta_{1^e,s} \ge \mu_{1^e} - \delta_r/\rho)$ is highly likely to occur. The cost for the non-occurrence of this event can be bounded by $\Theta(1)$. Follow Agrawal and Goyal (2012); Jin et al. (2022), one can show that

$$\prod_{e=1}^{\rho} \mathbb{E}_{\hat{\mu}_{\mathbf{1}^e,s}} \left[1/\mathbb{P} \left(\theta_{\mathbf{1}^e,s} \geq \mu_{\mathbf{1}^e} - \frac{\delta_r}{\rho} \right) \right] \leq \left(\frac{\rho \sqrt{\log T}}{\delta_r} \right)^{2\rho}.$$

The above results are underwhelming, particularly in regards to the worst-case regret, which is $\tilde{O}(T^{2\rho/(2\rho-1)})$. In order to enhance these outcomes, we are introducing two innovative techniques:

1. First, deriving from the concentration bound, we obtain that with high probability $\hat{\mu}_{1^e,s} \ge \mu_{1^e} - \sqrt{2\log T/s}$. Instead of considering the expectation over the entire real line for $\hat{\mu}_{1^e,s}$, we confine $\hat{\mu}_{1^e,s}$ to the interval $(\mu_{1^e} - \sqrt{2\log T/s}, \infty)$. 2. Secondly, we marginally increase the variance of the posterior distribution by $\log T$. According to the anticoncentration bound of the Gaussian posterior, the likelihood of $\theta_{1^e,s}$ exceeding $\hat{\mu}_{1^e,s} + \sqrt{2\log T/s}$ remains constant. In conjunction with the condition $\hat{\mu}_{1^e,s} \ge \mu_{1^e} - \sqrt{2\log T/s}$, we can ascertain that $\mathbb{P}(\theta_{1^e,s} \ge \mu_{1^e})$ is also a constant.

With the above two methods, we can prove $I_1 \leq \tau \cdot C^{\rho}$, where C is some constant. Finally, by summing over all possible values of r (i.e., $\sum_r R(S_r)$), we derive our regret bound.

Lower Bound on the Worst-Case Regret Bound

We now present some lower-bound results on the worst-case regret in our setting. The first theorem states a lower bound in terms of the horizon length T and the total number of local arms across all groups $A_{\rm loc}$ when $\rho > 0$ is treated as a fixed constant.

Theorem 4.2. For any policy π , there exists a mean vector $\mu \in [0, 1]^{A_{\text{loc}}}$ (where each component corresponds to the mean of a local arm) such that $R_n(\pi, \nu_{\mu}) = \Omega(\sqrt{A_{\text{loc}}T/\rho})$.

Recall that our worst-case regret bound in Theorem 4.1 is $\tilde{O}(\sqrt{C^{\rho}A_{\text{loc}}T})$, with C representing a universal constant. According to Theorem 4.2, when the number of groups ρ is constant, indicating a sparse hypergraph, our worst-case regret for ϵ -MATS is nearly optimal up to constant and logarithmic terms.

The next theorem shows the worst possible dependence of the regret bound of ϵ -MATS on the number of groups, i.e., ρ .

Theorem 4.3. For $c = \epsilon = 1$, there is a bandit instance such that the regret of Algorithm 1 is $\Omega(C^{\rho})$, where C > 1 is some constant.

Theorem 4.3 shows that C^{ρ} regret is unavoidable for original Multi-Agent Thompson Sampling, which further proves the optimality of our regret bound $\tilde{O}(\sqrt{C^{\rho}A_{\text{loc}}T})$.

Figure 2: The hypergraph on a 0101-Chain with 10 agents. Each hyperedge (a group of two agents) is denoted by a black oval.

5 Experiments

In this section, we evaluate the proposed ϵ -MATS algorithm on benchmark MAMAB problems including the Bernoulli 0101-Chain and the Poisson 0101-Chain. We also conducted experiments on the Gem Mining problem and the Wind Farm Control problem, which can be found in Appendix G (Roijers, Whiteson, and Oliehoek 2015; Bargiacchi et al. 2018; Verstraeten et al. 2020). We compare ϵ -MATS with the vanilla MATS (Verstraeten et al. 2020), MAUCE (Bargiacchi et al. 2018), and the random policy. We also provide a thorough ablation study of ϵ -MATS to find the optimal trade-off between greedy and Thompson sampling exploration in practice. We run all our experiments on Nvidia RTX A5000 with 24GB RAM and each experiment setting is averaged over 50 trials. Please refer to Appendix G for detailed experimental setup, ablation studies, and more experimental results. The implementation of our ϵ -MATS algorithm is available at https://github.com/panxulab/eps-Multi-Agent-Thompson-Sampling.

Bernoulli and Poisson 0101-Chain

In this subsection, we conduct experiments on the Bernoulli and Poisson 0101-Chain problems, which are commonly studied in the MAMAB literature (Bargiacchi et al. 2018; Verstraeten et al. 2020). An illustration is provided in Figure 2, where the agents are positioned along a 1-dimensional path forming a graph. Specifically, the graph consists of magents and m - (d - 1) edges (or groups), where d is the number of agents within each hyperedge. The agents i to i + d - 1 in the group i are connected to a local reward function $f^i(a_i, a_{i+1}, ..., a_{i+d-1})$, where a_i denotes the individual arm of agent i. Each agent can has two arms: 0 and 1.

We consider two settings where d = 2 and d = 3 respectively. For each setting, we conduct experiments for two types of reward distributions (Bernoulli and Poisson), which results in the **Bernoulli 0101-Chain** problem and the **Poisson 0101-Chain** problem respectively. Due to the space limit, we defer the details of the reward generation to Appendix G.

We first perform an ablation study to show the effect of different ϵ on the performance of ϵ -MATS. The results are presented in Figures 3(a) and 3(b). It can be seen that with ϵ decreasing from 1 (this corresponds to the MATS algorithm) to 0.1, the cumulative regret of ϵ -MATS also becomes lower. When ϵ gets smaller than 0.1, the regret rapidly increases due to insufficient exploration. In the rest of the experiments in this subsection, we fix $\epsilon = 0.1$ for the best performance. We also compare the runtime complexity of ϵ -MATS for different ϵ , which is presented in Figures 3(c) and 3(d) for the setting d = 2 and d = 3 respectively. In particular, we calculate the ratio between the runtime of ϵ -MATS and MATS $(\epsilon = 1)$ for running 1000 iterations. Figure 3(c) shows that lower value of ϵ decreases the runtime complexity of ϵ -MATS in both Bernoulli 0101 and Poisson 0101 problems. Comparing Figure 3(c) and Figure 3(d), we can see that the computational efficiency is adversely affected by the size of each group. In Figure 4, we compare the regret of ϵ -MATS with MATS, MAUCE, and Random for both Bernoulli 0101 and Poisson 0101 tasks, which demonstrate that ϵ -MATS can significantly outperform baseline methods.

6 Conclusion and Future Work

In this paper, we studied the problem of multi-agent multiarmed bandits. We proposed ϵ -MATS which combines the MATS exploration with probability ϵ and greedy exploitation with probability $1 - \epsilon$. We provided a frequentist finite time regret bound for ϵ -MATS, which is in the order of $\tilde{O}(\sqrt{C^{\rho}A_{\text{loc}}T})$. When $\epsilon = 1$, our result yields the first frequentist regret bound for MATS in the coordination hypergraph setting (Verstraeten et al. 2020). We also de-

Figure 3: Ablation study on ϵ -MATS. (a) and (b): Regret performance (m = 10, and d = 2) with different ϵ in Bernoulli 0101 and Poisson 0101 tasks. Note when $\epsilon = 1.0$, ϵ -MATS reduces to MATS. (c) and (d): The relative computational time of ϵ -MATS with different ϵ compared with MATS.

Figure 4: Regret performance compared with other algorithm baselines in Bernoulli 0101 and Poisson 0101 with different agents in a group (d = 2 or d = 3).

rived a lower bound for this environment in the order of $\Omega(\sqrt{A_{\text{loc}}T/\rho})$, implying ϵ -MATS is near optimal when ρ is assumed to be small, i.e., the coordination hypergraph is sparse. Empirical evaluations demonstrate the superior performance of ϵ -MATS compared with existing algorithms for MAMAB problems with a coordination hypergraph.

Our experimental findings present a notable observation: the performance of ϵ -MATS frequently surpasses that of MATS. Nevertheless, the regret bound presented in our main theorem suggests that MATS has a slightly better worstcase regret bound compared to ϵ -MATS. This discrepancy offers a compelling avenue for future research to explore the potential for ϵ -MATS to achieve the same regret bound as MATS. Additionally, while this paper focuses on the worstcase regret bound, it would be intriguing to investigate if ϵ -MATS could exhibit a more favorable regret bound in some easier bandit instances, leading to the analysis of instancedependent regret bounds. Finally, it would be intriguing to investigate the potential of applying the core concepts of coordination hypergraph and epsilon-exploring in our paper to enhance Thompson sampling-based algorithms within more complex settings, such as linear bandits, neural contextual bandits, and Markov decision processes (Xu et al. 2022b,a; Zhang et al. 2020; Ishfaq et al. 2023).

A Related Works

There is a rich literature on multi-agent bandits, particularly focusing on scenarios governed by dependency graphs, similar to the one studied in this paper (Bargiacchi et al. 2018; Wang et al. 2020b; Landgren, Srivastava, and Leonard 2016; Sankararaman, Ganesh, and Shakkottai 2019; Agarwal, Aggarwal, and Azizzadenesheli 2022; Zhu et al. 2021; Szorenyi et al. 2013). These works utilize coordination graphs, where agents can communicate and coordinate their arms. Each agent is represented as a vertex, and edges between agents indicate coordination possibilities. These coordination graph schemes have also been applied to multi-agent Markov decision processes (Guestrin, Koller, and Parr 2001; Kok and Vlassis 2006; Stranders et al. 2012; De Hauwere, Vrancx, and Nowé 2010; Scharpff et al. 2016; Zhang et al. 2023). The applications of such frameworks include wind turbine optimization (Verstraeten et al. 2021), generative flow models (Hayes et al. 2022), contextual bandits (Han and Arndt 2021; Elahi et al. 2021), and latent bandits (Pal et al. 2023).

Another area of research focuses on collision sensing in bandits, where agents receive no rewards if they choose the same arm. Numerous algorithms have been proposed to find optimal matchings given collision sensing information (Magesh and Veeravalli 2019; Nayyar, Kalathil, and Jain 2016; Mehrabian et al. 2020; Shi et al. 2021; Wang et al. 2020a). There are also works that consider scenarios where collision sensing information is not available (Shi et al. 2020; Lugosi and Mehrabian 2022; Huang, Combes, and Trinh 2022), as well as cases involving statistical sensing (Boursier and Perchet 2020; Wei and Srivastava 2018; Besson and Kaufmann 2018). In statistical sensing, agents cannot detect collisions directly but can sense the quality of an arm before taking it. Additionally, there are multi-agent studies on information asymmetry (Chang, Jafarnia-Jahromi, and Jain 2022), where agents independently select arms to form a joint arm without communication, aiming to identify the optimal joint arm despite differing feedback for each agent.

In our study, the graph structure is a hypergraph, where vertices represent agents and hyperedges correspond to groups. There are other types of graph structures considered in bandit problems as well. For example, in works such as (Gentile, Li, and Zappella 2014; Ma, Huang, and Schneider 2015; Li, Karatzoglou, and Gentile 2016; Yang, Toni, and Dong 2020; Gupta et al. 2021; Thaker et al. 2022; Deng et al. 2023), the graphs capture the similarity between arm rewards. By utilizing the graph, the agent can infer arm rewards without extensive sampling. Specifically, they often employ the graph Laplacian, where vertices represent arms and weighted edges indicate similarity. This type of graph structure is also seen in spectral bandits (Kocák and Garivier 2021; Yang, Toni, and Dong 2020; Valko et al. 2014), where vertices represent signals and edges represent the proximity of means.

Frequentist regret bounds for Thompson sampling have been extensively studied in the single-agent setting. One line of work focuses on the minimax optimality of Thompson sampling (Agrawal and Goyal 2017; Jin et al. 2021a, 2022, 2023), analyzing the optimality of gap-independent frequentist regret bounds. Another line of research examines the asymptotic optimality of Thompson sampling (Kaufmann, Korda, and Munos 2012; Korda, Kaufmann, and Munos 2013; Agrawal and Goyal 2017), investigating the optimality of gap-dependent frequentist regret bounds.

B Table of notations

In Table 1 we listed the most commonly used notations and their definitions.

C Frequentist Regret Analysis of MATS

In this section, we provide the proof of Theorem 4.1. Following the notations in Verstraeten et al. (2020), we let A_{loc} be the number of local arms, that is $A_{\text{loc}} = \sum_{e \in [\rho]} \sum_{a^e \in \mathcal{A}^e} 1$. For any $r = 0, 1, \ldots$, let $\delta_r = 2^{-(r+2)}$ and

$$S_r = \{ \boldsymbol{a} \mid \Delta_{\boldsymbol{a}} \in (2^{-r}, 2^{-r+1}] \}$$

We then decompose the regret as follows,

$$R_T = \sum_{r=0}^{\infty} \sum_{t=1}^{T} \sum_{\mathbf{A}_t \in S_r} \Delta_{\mathbf{A}_t}.$$

For simplicity, we let $R(S_r) = \sum_{t=1}^T \sum_{A_t \in S_r} \Delta_{A_t}$. In what follows, we focus on bounding the term $R(S_r)$. Let \mathcal{F}_t be the history up to time t. We define $S_r(t)$ to be the set of arms that are not overestimated at time t by the local prior $\theta_{a^e}(t)$.

$$S_r(t) = \left\{ \boldsymbol{a} \mid \boldsymbol{a} \in S_r, \forall e \in [\rho] \text{ and } \boldsymbol{a}^e \neq \boldsymbol{1}^e, \theta_{\boldsymbol{a}^e}(t) \leq \mu_{\boldsymbol{a}^e} + \frac{\delta_r}{\rho} \right\}.$$

Start with regret decomposition

$$R(S_r) \leq 8\delta_r \sum_{t=1}^T \mathbb{E}[\mathbb{1}\{\boldsymbol{A}_t \in S_r\}]$$

Table 1: Table of notations.

Symbol	Description
m	total number of agents.
K	number of arms per agent
A	number of joint (global) arms (i.e., K^m)
ho	number of (possibly overlapping) groups.
d	number of agents in each local group
$A_{\rm loc}$	number of local arms, i.e., $\sum_{e=1}^{\rho} \sum_{a^e: \text{ for some joint arm } a} 1$
\boldsymbol{a}	joint arm across m agents.
1	optimal joint arm.
$oldsymbol{A}_t$	joint arm taken at time t.
\mathcal{A}_i	set of individual arms for agent $i \in [m]$.
\mathcal{A}^e	set of local arms for group $e \in [\rho]$.
$oldsymbol{a}^e$	local arm of a corresponding to group e .
$f^e(oldsymbol{a}^e)$	stochastic reward for local arm a^e .
$f(oldsymbol{a})$	sum of local stochastic rewards for arm a , ie. $\sum_{e=1}^{p} f^{e}(a^{e})$.
$\mu_{oldsymbol{a}^e}$	true mean of local reward for local arm a corresponding to group e .
μ_{a}	sum of local true mean rewards for joint arm a , i.e. $\sum_{e} \mu_{a^{e}}$.
$\hat{\mu}_{\boldsymbol{a}^{e},s}$	the empirical mean of local arm a^e after its s-th pull.
Δ_{a^e}	the minimum reward gap between joint arm a which contains a^e and 1, i.e., $\Delta_{a^e} =$
	$\min\{\Delta_{\boldsymbol{a}} \mid \boldsymbol{a}^e \in \boldsymbol{a}\}.$
$\Delta_{\boldsymbol{a}}$	gap between global reward of joint arm a and optimal arm 1.
Δ_{\min}	minimum reward gap across all joint arms, i.e. $\min_{a \in \times_{i=1}^{m} A_i \setminus \{1\}} \Delta_a$.
Δ_{\max}	maximum reward gap across all joint arms, i.e. $\max_{a \in \times_{i=1}^{m} A_i} \Delta_a$.
$\theta_{a^e}(t)$	sampling posterior corresponding to local arm a^e at time t.
$\theta_{a}(t)$	sum of posteriors for joint arm a , i.e. $\sum_{e} \theta_{a^{e}}$.
$n_{a^e}(t)$	number of times local arm a^e has been pulled up to time t.
$n_{\underline{a}}(t)$	number of times joint arm a has been pulled up to time t .
R_T	regret up to time T.

$$\leq 8\delta_r \underbrace{\sum_{t=1}^T \mathbb{E}[\mathbbm{1}\{\boldsymbol{A}_t \in S_r(t)\}]}_{I_1} + 8\delta_r \underbrace{\sum_{t=1}^T \mathbb{E}[\mathbbm{1}\{\boldsymbol{A}_t \in S_r, \boldsymbol{A}_t \notin S_r(t)\}]}_{I_2}, \quad (C.1)$$

where the first inequality is because for any $a \in S_r$, it holds that $\Delta_a \leq 8\delta_r$. Now, we bound these terms separately.

Bounding term *I*₁

This part requires the following supporting lemma.

Lemma C.1. Let $\hat{\mu}_s$ be the empirical mean of s random variable i.i.d from $\mathcal{N}(\mu, 1)$. Then

$$\mathbb{P}\left(\exists s \in [T], \hat{\mu}_s + \sqrt{\frac{2\log(\rho T)}{s}} \le \mu_1\right) \le \frac{1}{\rho T}$$

Let \mathcal{E}_3 be the event that for any $s \leq T$ and $e \in [\rho]$, $\hat{\mu}_{\mathbf{1}^e,s} \geq \mu_{\mathbf{1}^e} - \sqrt{\frac{2\log(\rho T)}{s}}$, i.e.,

m

$$\mathcal{E}_3 = \bigcap_{s \in [T]} \bigcap_{e \in [\rho]} \left\{ \hat{\mu}_{\mathbf{1}^e, s} \ge \mu_{\mathbf{1}^e} - \sqrt{\frac{2\log(\rho T)}{s}} \right\}.$$

From Lemma C.1, we have

$$\mathbb{P}(\mathcal{E}_3) \ge 1 - \frac{1}{T}$$

Now, we bound term I_1 . We have

$$I_{1} = \sum_{t=1}^{T} \mathbb{E} \left[\mathbbm{1} \{ \mathbf{A}_{t} \in S_{r}(t) \} \right]$$

$$\leq T \cdot \mathbb{P}((\mathcal{E}_{3})^{c}) + \sum_{t=1}^{T} \mathbb{E} \left[\mathbbm{1} \{ \mathbf{A}_{t} \in S_{r}(t) \} \cdot \mathbbm{1} \{ \mathcal{E}_{3} \} \right]$$

$$\leq 1 + \sum_{t=1}^{T} \mathbb{E} \left[\mathbbm{1} \{ \mathbf{A}_{t} \in S_{r}(t) \} \cdot \mathbbm{1} \{ \mathcal{E}_{3} \} \right].$$
(C.2)

We first define some useful notations. Suppose J is a subset of $2^{[\rho]}$. Subsequently, we define S_{rJ} as a specific subset of S_r , characterized by the condition that every arm in S_r exclusively shares local arms of 1 for groups in J, i.e.,

$$S_{rJ} = \left\{ \boldsymbol{a} \mid \boldsymbol{a} \in S_r, \forall e \in J, \boldsymbol{a}^e = \boldsymbol{1}^e \text{ and } \forall e \in [\rho] \setminus J, \boldsymbol{a}^e \neq \boldsymbol{1}^e
ight\}$$

We also define

$$S_{rJ}(t) = \{ \boldsymbol{a} \mid \boldsymbol{a} \in S_{rJ}, \boldsymbol{a} \in S_r(t) \}$$

Let $\mathcal{E}_1(t)$ be the event that the local arms of the optimal joint arm are not underestimated. Namely,

$$\mathcal{E}_1(t) = \bigcap_{e=1}^{\rho} \left\{ \theta_{\mathbf{1}^e}(t) \ge \mu_{\mathbf{1}^e} - \frac{\delta_r}{\rho} \right\}.$$

Similar to $S_{rJ}(t)$, we define

$$\mathcal{E}_{1J}(t) = \bigcap_{e:e \in [\rho] \setminus J} \left\{ \theta_{\mathbf{1}^e}(t) \ge \mu_{\mathbf{1}^e} - \frac{\delta_r}{\rho} \right\}.$$

Additionally, we introduce $\mathcal{E}_{2J}(t)$, which represents the event where arms that are associated with local arms labeled by 1 in $[\rho] \setminus J$ are not overestimated.

$$\mathcal{E}_{2J}(t) = \bigcap_{\boldsymbol{a}:\boldsymbol{a}\in S_{rJ}} \left\{ \forall e \in [\rho] \setminus J, \theta_{\boldsymbol{a}^e}(t) \le \mu_{\boldsymbol{a}^e} + \frac{\delta_r}{\rho} \right\}$$

Let $A_t(J) = \max_{a \in S_{rJ}} \theta_a(t)$. For term $\mathbb{1}\{A_t \in S_r(t)\}$, we bound it as follows.

$$2^{\rho} \cdot \mathbb{P}(\boldsymbol{A}_{t} = 1 \mid \mathcal{F}_{t-1}) \geq \sum_{J \subseteq 2^{[\rho]}} \mathbb{P}\left(\forall \boldsymbol{a} \in S_{rJ}, \sum_{e \in [\rho] \setminus J} \theta_{1^{e}}(t) \geq \sum_{e \in [\rho] \setminus J} \theta_{a^{e}}(t) \mid \mathcal{F}_{t-1} \right)$$

$$\geq \sum_{J \subseteq 2^{[\rho]}} \mathbb{P}(\boldsymbol{A}_{t}(J) \in S_{rJ}(t), \mathcal{E}_{1J}(t) \mid \mathcal{F}_{t-1})$$

$$\geq \sum_{J \subseteq 2^{[\rho]}} \left(\mathbb{P}(\boldsymbol{A}_{t} \in S_{rJ}(t) \mid \mathcal{F}_{t-1}) \cdot \mathbb{P}(\mathcal{E}_{1}(t) \mid \mathcal{F}_{t-1}) \right)$$

$$\geq \mathbb{P}(\mathcal{E}_{1}(t) \mid \mathcal{F}_{t-1}) \cdot \sum_{J \subseteq 2^{[\rho]}} \mathbb{P}(\boldsymbol{A}_{t} \in S_{rJ}(t) \mid \mathcal{F}_{t-1})$$

$$= \mathbb{P}(\mathcal{E}_{1}(t) \mid \mathcal{F}_{t-1}) \cdot \mathbb{P}(\boldsymbol{A}_{t} \in S_{r}(t) \mid \mathcal{F}_{t-1}). \quad (C.3)$$

The first inequality is due to the fact that if there exists $a \in S_{rJ}$, $\sum_{e \in [\rho] \setminus J} \theta_{1^e}(t) < \sum_{e \in [\rho] \setminus J} \theta_{a^e}(t)$, then $\theta_1(t) < \theta_a(t)^{-1}$, which means $A_t \neq 1$. The second inequality is due to the fact that if the events $A_t(J) \in S_{rJ}(t)$ and $\mathcal{E}_{1J}(t)$ occur, then for any $a \in S_{rJ}$,

$$\begin{split} \sum_{e \in [\rho] \setminus J} \theta_{\mathbf{1}^e}(t) &\geq \sum_{e \in [\rho] \setminus J} \left(\mu_{\mathbf{1}^e} - \frac{\delta_r}{\rho} \right) \\ &\geq \sum_{e \in [\rho] \setminus J} \left(\mu_{(\boldsymbol{A}_t(J))^e} + \frac{\delta_r}{\rho} \right) \\ &\geq \sum_{e \in [\rho] \setminus J} \theta_{(\boldsymbol{A}_t(J))^e}(t) \\ &\geq \sum_{e \in [\rho] \setminus J} \theta_{\boldsymbol{a}^e}(t), \end{split} \quad \text{which means } \boldsymbol{A}_t \in S_{rJ}(t) \text{ occur} \end{split}$$

where the first inequality is from the definition of the event $\mathcal{E}_{1J}(t)$ and the second inequality is due to $A_t(J) \in S_{rJ}$ and $\Delta_{A_t(J)} \ge 4\delta_r$. The third inequality of (C.3) is due to $A_t(J) \in S_{rJ}(t)$, as well as $\mathcal{E}_{1J}(t)$ and $A_t(J) \in S_{rJ}(t)$ being conditionally independent given \mathcal{F}_{t-1} . Rearranging (C.3), we obtain

$$\mathbb{P}(\boldsymbol{A}_{t} \in S_{r}(t) \mid \mathcal{F}_{t-1}) \leq \frac{2^{\rho} \cdot \mathbb{P}(\boldsymbol{A}_{t} = 1 \mid \mathcal{F}_{t-1})}{\mathbb{P}(\mathcal{E}_{1}(t) \mid \mathcal{F}_{t-1})}.$$
(C.4)

Let $\tau = \frac{8\rho^2 \log^2(TA_{\text{loc}})}{\delta_r^2}$. Continuing on inequality (C.2), we further bound I_1 as follows.

$$I_{1} \leq 1 + \sum_{t:t \in [T]} \mathbb{E} \left[\mathbbm{1} \{ \boldsymbol{A}_{t} \in S_{r}(t) \} \mathbbm{1} \{ \mathcal{E}_{3} \} \right]$$

$$\leq 1 + \sum_{t:n_{1}(t) \leq \tau} \mathbb{E} \left[\mathbbm{1} \{ \boldsymbol{A}_{t} \in S_{r}(t) \} \mathbbm{1} \{ \mathcal{E}_{3} \} \right] + \sum_{t:n_{1}(t) > \tau} \mathbb{E} \left[\mathbbm{1} \{ \boldsymbol{A}_{t} \in S_{r}(t) \} \right]$$

$$\leq 1 + \underbrace{\sum_{t:n_{1}(t) \geq \tau} \mathbb{E} \left(\frac{2^{\rho}}{\mathbb{P}(\mathcal{E}_{1}(t) \mid \mathcal{F}_{t-1})} \mathbbm{1} \{ \mathcal{E}_{3} \} \cdot \mathbbm{1} [\boldsymbol{A}_{t} = 1] \right)}_{I_{11}}$$

$$+ \underbrace{\sum_{t:n_{1}(t) > \tau} \mathbb{E} \left[\mathbbm{1} \{ \boldsymbol{A}_{t} \in S_{r}(t) \} \right]}_{I_{12}}, \quad (C.5)$$

where the last inequality is due to (C.4). We bound L_{\perp} and L_{\perp} separately

We bound I_{11} and I_{12} separately.

¹This follows from the fact that $\theta_{a^e} = \theta_{1^e}$ for $e \in J$ when $a \in S_{rJ}$.

Bounding term I_{11} . We have

$$\frac{\mathbb{1}\{\mathcal{E}_{3}\}}{\mathbb{P}(\mathcal{E}_{1}(t) \mid \mathcal{F}_{t-1})} = \prod_{e=1}^{\rho} \frac{1}{\mathbb{P}\left(\theta_{\mathbf{1}^{e}}(t) \ge \mu_{\mathbf{1}^{e}} - \frac{\delta_{r}}{\rho} \mid \hat{\mu}_{\mathbf{1}^{e}}(t) \ge \mu_{\mathbf{1}^{e}} - \sqrt{\frac{2\log T}{n_{\mathbf{1}^{e}}(t)}}\right)}$$
$$\leq \prod_{e=1}^{\rho} \frac{1}{\mathbb{P}\left(\theta_{\mathbf{1}^{e}}(t) \ge \mu_{\mathbf{1}^{e}} \mid \hat{\mu}_{\mathbf{1}^{e}}(t) \ge \mu_{\mathbf{1}^{e}} - \sqrt{\frac{2\log T}{n_{\mathbf{1}^{e}}(t)}}\right)}.$$
(C.6)

Note that with probability ϵ , $\theta_{\mathbf{1}^e}(t) \sim \mathcal{N}(\hat{\mu}_{\mathbf{1}^e}(t), \log T/(n_{\mathbf{1}^e}(t)+1))$. By letting $z = \sqrt{2(n_{\mathbf{1}^e}(t)+1)/n_{\mathbf{1}^e}(t)} \leq 4$ and $\sigma = \sqrt{\log T/(n_{\mathbf{1}^e}(t)+1)}$ in Lemma F.1, we have

$$\mathbb{P}\left(\theta_{\mathbf{1}^{e}}(t) \geq \mu_{\mathbf{1}^{e}} \middle| \hat{\mu}_{\mathbf{1}^{e}}(t) \geq \mu_{\mathbf{1}^{e}} - \sqrt{\frac{2\log T}{n_{\mathbf{1}^{e}}(t)}}\right) \\
\geq \mathbb{P}\left(\theta_{\mathbf{1}^{e}}(t) \geq \hat{\mu}_{\mathbf{1}^{e}}(t) + \sqrt{\frac{2\log T}{n_{\mathbf{1}^{e}}(t)}}\right) \\
\geq \frac{\epsilon}{3 \times 10^{4}}.$$
(C.7)

By substituting (C.7) to (C.6), we obtain

$$\frac{1}{\mathbb{P}(\mathcal{E}_1(t) \mid \mathcal{F}_{t-1})} \mathbb{1}\{\mathcal{E}_3\} \le (3 \times 10^4 / \epsilon)^{\rho}.$$

Finally, we can bound I_{11} as

$$I_{11} = \sum_{t:n_1(t) \le \tau} \mathbb{E}\left(\frac{2^{\rho}}{\mathbb{P}(\mathcal{E}_1(t) \mid \mathcal{F}_{t-1})} \mathbb{1}\{\mathcal{E}_3\} \cdot \mathbb{1}[\mathbf{A}_t = 1]\right)$$
$$\leq \sum_{t:n_1(t) \le \tau} \mathbb{E}\left((6 \times 10^4 / \epsilon)^{\rho} \cdot \mathbb{1}[\mathbf{A}_t = 1]\right)$$
$$\leq \tau \cdot (6 \times 10^4 / \epsilon)^{\rho}.$$

Bounding term I_{12} . If $n_1(t)$ is pulled more than τ times, the posterior sample of each local arm $\mathbf{1}^e$ is concentrated on $\mu_{\mathbf{1}^e}$ and thus we can prove the following lemma.

Lemma C.2. We have

$$\sum_{t:n_1(t)>\tau} \mathbb{E}\bigg[\mathbbm{1}\{\boldsymbol{A}_t \in S_r(t)\}\bigg] \leq 2.$$

From the above lemma, $I_{12} \leq 2$. By combining the results of term I_{11} and I_{12} together and then substituting them into (C.5), we obtain

$$I_1 \le 3 + \tau \cdot (6 \times 10^4 / \epsilon)^{\rho}. \tag{C.8}$$

Bounding term *I*₂

Let \mathcal{E} be the event that if any local arm a^e has been pulled more than τ times at t, then for this arm (which belongs in S_r) and any t, we have $|\theta_{a^e}(t) - \mu_{a^e}| \leq \frac{\delta_r}{\rho}$, i.e.,

$$\mathcal{E}(t) = \bigcap_{e=1}^{\rho} \bigcap_{\boldsymbol{a}^e: n_{\boldsymbol{a}^e}(t) \ge \tau} \left\{ |\theta_{\boldsymbol{a}^e}(t) - \mu_{\boldsymbol{a}^e}| < \frac{\delta_r}{\rho} \right\}.$$

The following lemma shows that \mathcal{E} happens with high probability. **Lemma C.3.** We have

$$\Pr(\mathcal{E}(t)) \ge 1 - \frac{4}{T}.$$

Let $Y_r(t)$ be the indicator on the event such that the joint arm taken at time t belongs in S_r and there exists a group such that the local arm of this group pulled less than τ times, i.e.,

$$Y_r(t) = \mathbb{1}\{\boldsymbol{A}_t = \boldsymbol{a}, \boldsymbol{a} \in S_r, \exists e \in [\rho] \text{ s.t. } n_{\boldsymbol{a}^e}(t) < \tau\}.$$

Recall that A_{loc} is the total number of local arms. Intuitively, if $Y_r(t) = 1$, then there is at least one local arm with $n_{a^e}(t) < \tau$ that has been pulled one more time at round t. Since there are a total A_{loc} local arms, after at most $\tau \cdot A_{\text{loc}}$ number of rounds t such that $Y_r(t) = 1$, the number of pulls of every local arm exceeds τ . Therefore, $Y_r(t)$ can only be 1 for at most $\tau \cdot A_{\text{loc}}$ time steps and is 0 for the rest of them. Therefore,

$$\sum_{t=1}^{T} Y_r(t) \le \tau \cdot A_r,$$

where A_r is the number of local arms a^e which satisfies $\exists a \in S_r, a^e \in a$. Finally, we can bound I_2 as follows,

$$I_{2} = \sum_{t=1}^{T} \mathbb{E} \left[\mathbbm{1} \{ \boldsymbol{A}_{t} \in S_{r}, \boldsymbol{A}_{t} \notin S_{r}(t) \} \right]$$

$$= \sum_{t=1}^{T} \mathbb{E} \left[\mathbbm{1} \{ \boldsymbol{A}_{t} \in S_{r}, \boldsymbol{A}_{t} \notin S_{r}(t), \mathcal{E}(t) \} \right] + \sum_{t=1}^{T} \mathbb{E} \left[\mathbbm{1} \{ \boldsymbol{A}_{t} \in S_{r}, \boldsymbol{A}_{t} \notin S_{r}(t), (\mathcal{E}(t))^{c} \} \right]$$

$$\leq \sum_{t=1}^{T} Y_{r}(t) + \sum_{t=1}^{T} \mathbb{P}((\mathcal{E}(t))^{c})$$

$$\leq \tau \cdot A_{r} + 4.$$
(C.9)

We use the following facts in the first inequality. From the definition of $S_r(t)$, we have for any $A_t \in S_r \setminus S_r(t)$,

$$\exists e \in [\rho], \mathbf{A}_t^e \neq \mathbf{1}^e, \theta_{\mathbf{A}_t^e}(t) > \mu_{\mathbf{A}_t^e} + \frac{\delta_r}{\rho}.$$
(C.10)

Moreover, if $\mathcal{E}(t)$ happens, (C.10) implies that

$$\exists e \in [\rho], n_{\boldsymbol{A}_t^e}(t) < \tau, \tag{C.11}$$

which means $Y_r(t) = 1$. Therefore, $\mathbb{1}\{A_t \in S_r, A_t \notin S_r(t), \mathcal{E}\} \leq Y_r(t)$.

Putting Everything Together

By combining (C.8) and (C.9) together and then substituting them into (C.1), we obtain that there exists some universal constant C such that

$$R(S_i) \le 8\delta_r \cdot \tau \left(A_r + \left(6 \cdot 10^4 / \epsilon \right)^{\rho} \right) + 80\delta_r.$$

Therefore, by letting $\Delta_{\min} = \min_{a:a \neq 1} \Delta_a$ and $\Delta_{\max} = \max_a \Delta_a$, then there exists some universal constant C such that

$$\begin{aligned} R_T &= \sum_r R(S_r) \\ &\leq \sum_r \left(8\delta_r \cdot \tau \left(A_r + \left(6 \cdot 10^4 / \epsilon \right)^{\rho} \right) + 80\delta_r \right) \\ &= \sum_r \left(\frac{64\rho^2 \log^2(TA_{\text{loc}})}{\delta_r} \cdot \left(A_r + \left(6 \cdot 10^4 / \epsilon \right)^{\rho} \right) + 80\delta_r \right) \\ &\leq \frac{C(C/\epsilon)^{\rho} \rho^2 \log^2(TA_{\text{loc}})}{\Delta_{\min}} + C\Delta_{\max} + \sum_i \frac{C\rho^2 A_r \log^2(TA_{\text{loc}})}{\delta_r}, \end{aligned}$$

where in the last inequality $C\Delta_{\max}$ is from $\sum_r 80\delta_r$. We let $S(a^e) = \{r \mid \exists a \in S_r, a^e \in a\}$ and $\Delta_{a^e} = \min\{\Delta_a \mid a^e \in a\}$. For the last term $\sum_i \frac{C\rho^2 A_r \log^2(TA_{loc})}{\delta_r}$, we can rewrite it in the following way.

$$\sum_{r} \frac{C\rho^2 A_r \log^2(TA_{\text{loc}})}{\delta_r} = \sum_{e \in [\rho]} \sum_{\boldsymbol{a}^e \in \mathcal{A}^e \setminus \{\mathbf{1}^e\}} \sum_{r \in S(\boldsymbol{a}^e)} \frac{C\rho^2 \log^2(TA_{\text{loc}})}{\delta_r}$$

$$\leq 8 \sum_{e \in [\rho]} \sum_{\boldsymbol{a}^e \in \mathcal{A}^e \setminus \{\mathbf{1}^e\}} \frac{C\rho^2 \log^2(TA_{\text{loc}})}{\Delta_{\boldsymbol{a}^e}}.$$
(C.12)

Therefore, there exists some universal constant C_1 such that

$$R_T \leq \frac{C_1(C_1/\epsilon)^{\rho} \rho^2 \log^2(TA_{\text{loc}})}{\Delta_{\min}} + C_1 \sum_{e \in [\rho]} \sum_{\boldsymbol{a}^e \in \mathcal{A}^e \setminus \{\mathbf{1}^e\}} \frac{\rho^2 \log^2(TA_{\text{loc}})}{\Delta_{\boldsymbol{a}^e}} + C_1 \Delta_{\max}.$$

Worst Case Regret. We have that there exists some universal constant C_2 such that

$$R_T \leq \min\left\{T\Delta_{\min}, \frac{C_1(C_1/\epsilon)^{\rho}\rho^2\log^2(TA_{\text{loc}})}{\Delta_{\min}} + C_1\Delta_{\max} + \sum_i \frac{C_1\rho^2A_i\log^2(TA_{\text{loc}})}{\delta_i}\right\}$$
$$\leq \min\left\{T\Delta_{\min}, \frac{C_1(C_1/\epsilon)^{\rho}\rho^2\log^2(TA_{\text{loc}})}{\Delta_{\min}} + C_1\Delta_{\max} + \frac{C_1\rho^2A_{\text{loc}}\log^2(TA_{\text{loc}})}{\Delta_{\min}}\right\}.$$

Note that when $\Delta_{\min} < \sqrt{\frac{C_1((C_1/\epsilon)^{\rho} + A_{\text{loc}})\rho^2 \log^2(TA_{\text{loc}})}{T}}$, we have

$$T\Delta_{\min} \leq \sqrt{C_1((C_1/\epsilon)^{\rho} + A_{\text{loc}})\rho^2 T \log^2(TA_{\text{loc}})},$$

and when $\Delta_{\min} \geq \sqrt{\frac{C_1((C_1/\epsilon)^{\rho} + A_{\text{loc}})\rho^2 \log^2(TA_{\text{loc}})}{T}}$, we have

$$\frac{C_1(C_1/\epsilon)^{\rho}\rho^2\log^2(TA_{\text{loc}})}{\Delta_{\min}} + \frac{C_1\rho^2A_{\text{loc}}\log^2(TA_{\text{loc}})}{\Delta_{\min}} \le \sqrt{C_1((C_1/\epsilon)^{\rho} + A_{\text{loc}})\rho^2T\log^2(TA_{\text{loc}})}$$

Therefore, the worst-case regret of ϵ -MATS is bounded as follows.

$$R_T \le C_2 \Delta_{\max} + C_2 \rho \sqrt{\left((C_2/\epsilon)^{\rho} + A_{\text{loc}} \right) T \log^2 (TA_{\text{loc}})}.$$

D Proof of Supporting Lemmas

In this section, we provide the proofs for the technical lemmas we used in our main paper and the proof of the main theorem.

Proof of Lemma 3.1

Let G_1, \ldots, G_ρ be the sets of agents belonging to group $e \in [\rho]$, respectively. To simplify notation, we denote \mathcal{G} as the hypergraph where G_1, \ldots, G_ρ represent the hyperedges. Then, $A_{\text{loc}} = \sum_{e=1}^{\rho} \prod_{i \in G_e} |\mathcal{A}_i|$. We can prove the desired results by induction on the number of agents.

For the base case, when there is only one agent, the coordination graph consists of a single vertex with degree 0. Since we have $|A_1|$ arms to optimize over, the complexity is $|A_1|$, completing the base case.

For the induction step, let's assume that the result in Lemma 3.1 holds for a hypergraph with n-1 vertices. Now we consider a hypergraph \mathcal{G} with n agents. Similar to (3.1), we decompose the optimization problem as follows:

$$\max_{\boldsymbol{a}} f(\boldsymbol{a}) = \max_{\boldsymbol{a}} \sum_{e=1}^{\rho} f^{e}(\boldsymbol{a}^{e})$$
$$= \max_{\boldsymbol{a}} \bigg[\underbrace{\sum_{\boldsymbol{a}^{e} \in \boldsymbol{a}: a_{n} \notin \boldsymbol{a}^{e}}_{I_{1}} f^{e}(\boldsymbol{a}^{e})}_{I_{1}} + \underbrace{\max_{\boldsymbol{a}^{e}: a_{n} \in \boldsymbol{a}^{e}}_{I_{2}} \sum_{I_{2}} f^{e}(\boldsymbol{a}^{e})}_{I_{2}} \bigg], \tag{D.1}$$

where a_n represents an individual arm of agent n. Without loss of generality, let's assume that this agent belongs to l different groups, namely G_1, G_2, \ldots, G_l . Note that Term I_2 in (D.1) is a function that involves agents within this group. All the values for this function can be found in $\sum_{e=1}^{l} \prod_{i \in G_e} |\mathcal{A}_i|$ searches.

Now let's consider the graph $\mathcal{G}' = \mathcal{G} \setminus n$, which has the same coordination graph as \mathcal{G} but with vertex n and all its connections removed. Let G'_1, \ldots, G'_{ρ} be the new groups resulting from this reduction. It is clear that $\forall e \in [\rho], |G_e| \ge |G'_e|$. Since \mathcal{G}' has only n-1 vertices, by the inductive hypothesis, the complexity of finding the maximum of I_1 (using all of the values already given from computing I_2) is $\sum_{e=1}^{\rho} \prod_{i \in G'_e} |\mathcal{A}_i| \le \sum_{e=1}^{\rho} \prod_{i \in G_e} |\mathcal{A}_i| \le A_{\text{loc}}$. Adding these two upper bounds completes our induction.

Proof of Lemma C.1

Note that

$$\mathbb{P}\left(\exists s \in [T], \hat{\mu}_s + \sqrt{\frac{2\log(\rho T)}{s}} \le \mu_1\right) \le \sum_{s=1}^T \mathbb{P}\left(\hat{\mu}_s + \sqrt{\frac{2\log(\rho T)}{s}} \le \mu_1\right)$$
$$\le \sum_{s=1}^T e^{-2\log(\rho T)}$$
$$= \frac{1}{\rho^2 \cdot T},$$

where the second inequality is due to Lemma F.2.

Proof of Lemma C.2

Each local arm of 1 has been pulled more than τ times if $n_1(t) \ge \tau$. Besides,

$$\mathbb{P}\left(\exists s \geq \tau, \hat{\mu}_{1^{e},s} \leq \mu_{1^{e}} - \delta_{r}/(2\rho)\right)$$

$$\leq \exp\left(-\frac{\tau\delta_{r}^{2}}{8\rho^{2}}\right)$$

$$\leq \frac{1}{T\rho}.$$
 (D.2)

Applying union bound for all $e \in [\rho]$, we have

$$\mathbb{P}\left(\bigcup_{e\in[\rho]}\left\{\exists s\geq\tau,\hat{\mu}_{\mathbf{1}^e,s}\leq\mu_{\mathbf{1}^e}-\frac{\delta_r}{2\rho}\right\}\right)\leq\frac{1}{T}.$$
(D.3)

Let $E_1 = \cap_{e \in [\rho]} \{ \forall s \ge \tau, \hat{\mu}_{\mathbf{1}^e, s} > \mu_{\mathbf{1}^e} - \delta_r / (2\rho) \}.$ We have

$$\sum_{t:n_{1^{e}}(t)\geq\tau} \mathbb{P}\left(\exists e\in[\rho]:\theta_{1^{e}}(t)\leq\mu_{1^{e}}-\frac{\delta_{r}}{\rho},E_{1}\right)$$

$$\leq T\rho\cdot\mathbb{P}\left(\theta_{1^{e}}(t)\leq\mu_{1^{e}}-\frac{\delta_{r}}{\rho}\mid n_{1^{e}}(t)\geq\tau,\hat{\mu}_{1^{e}}(t)>\mu_{1^{e}}-\frac{\delta_{r}}{2\rho}\right)$$

$$\leq T\rho\cdot\mathbb{P}\left(\theta_{1^{e}}(t)\leq\hat{\mu}_{1^{e}}(t)-\frac{\delta_{r}}{2\rho}\mid n_{1^{e}}(t)\geq\tau\right)$$

$$\leq \frac{T\rho}{2}\cdot\exp\left(-\frac{\delta_{r}^{2}\cdot\tau}{8\log T}\right)$$

$$\leq \frac{1}{2},$$
(D.4)

where the third inequality is due to the fact that with probability $1-\epsilon$, $\theta_{\mathbf{1}^e}(t) = \hat{\mu}_{\mathbf{1}^e}(t) \geq \hat{\mu}_{\mathbf{1}^e}(t) - \delta_r/(2\rho)$ and with probability ϵ , $\theta_{\mathbf{1}^e}(t) \sim \mathcal{N}(\hat{\mu}_{\mathbf{1}^e}(t), \log T/(n_{\mathbf{1}^e}(t)+1))$ and then we use Lemma F.1 to bound the probability of $\theta_{\mathbf{1}^e}(t) \leq \hat{\mu}_{\mathbf{1}^e}(t) - \frac{\delta_r}{2\rho}$. Finally,

$$\sum_{t:n_{1}(t)>\tau} \mathbb{E}\left[\mathbbm{1}\left\{\boldsymbol{A}_{t}\in S_{r}(t)\right\}\right] \leq T \cdot E_{1}^{c} + \sum_{t:n_{1}(t)\geq\tau} \mathbb{E}\left[\mathbbm{1}\left\{\boldsymbol{A}_{t}\in S_{r}(t), E_{1}\right\}\right]$$
$$\leq 1 + \sum_{t:n_{1}(t)>\tau} \mathbb{P}\left(\exists e\in[\rho]: \theta_{\mathbf{1}^{e}}(t)\leq\mu_{\mathbf{1}^{e}}-\frac{\delta_{r}}{\rho}, E_{1}\right)$$
$$\leq 2,$$

where the third inequality is due to (D.3) and the last inequality is due to (D.4).

Proof of Lemma C.3

Recall that

$$\mathcal{E}(t) = \bigcap_{e=1}^{\rho} \bigcap_{\boldsymbol{a}^e: n_{\boldsymbol{a}^e}(t) \ge \tau} \left\{ |\theta_{\boldsymbol{a}^e}(t) - \mu_{\boldsymbol{a}^e}| < \frac{\delta_r}{\rho} \right\}.$$

Similar to (D.3), we have

$$\mathbb{P}\left(\bigcup_{e\in[\rho]}\bigcup_{\boldsymbol{a}^e:n_{\boldsymbol{a}^e}(t)\geq\tau}\left\{\left|\hat{\mu}_{\boldsymbol{a}^e,s}-\mu_{\boldsymbol{a}^e}\right|>\frac{\delta_r}{2\rho}\right\}\right)\leq\frac{2}{T}.$$
(D.5)

Let $E_2 = \bigcap_{e \in [\rho]} \bigcap_{\boldsymbol{a}^e: n_{\boldsymbol{a}^e}(t) \geq \tau} \{ |\hat{\mu}_{\boldsymbol{a}^e}(t) - \mu_{\boldsymbol{a}^e}| \leq \delta_r / (2\rho) \}.$ Now, we have

$$\begin{split} \mathbb{P}(\mathcal{E}(t)) &\geq \mathbb{P}(\mathcal{E}(t), E_{2}) \\ &= \mathbb{P}(\mathcal{E}(t) \mid E_{2}) \mathbb{P}(E_{2}) \\ &\geq \left(1 - \frac{2}{T}\right) \cdot \left(1 - \mathbb{P}\left(\exists \boldsymbol{a}^{e} : n_{\boldsymbol{a}^{e}}(t) \geq \tau, |\theta_{\boldsymbol{a}^{e}}(t) - \mu_{\boldsymbol{a}^{e}}| < \frac{\delta_{r}}{\rho} \mid E_{2}\right)\right) \\ &\geq \left(1 - \frac{2}{T}\right) \cdot \left(1 - \mathbb{P}\left(\exists \boldsymbol{a}^{e} : n_{\boldsymbol{a}^{e}}(t) \geq \tau, |\theta_{\boldsymbol{a}^{e}}(t) - \mu_{\boldsymbol{a}^{e}}| < \frac{\delta_{r}}{\rho} \mid |\hat{\mu}_{\boldsymbol{a}^{e}}(t) - \mu_{\boldsymbol{a}^{e}}| < \frac{\delta_{r}}{2\rho}\right)\right) \\ &\geq \left(1 - \frac{2}{T}\right) \cdot \left(1 - A_{\text{loc}} \mathbb{P}\left(n_{\boldsymbol{a}^{e}}(t) \geq \tau, |\theta_{\boldsymbol{a}^{e}}(t) - \hat{\mu}_{\boldsymbol{a}^{e}}(t)| < \frac{\delta_{r}}{2\rho}\right)\right) \\ &\geq \left(1 - \frac{2}{T}\right) \cdot \left(1 - A_{\text{loc}} \exp\left(-\frac{\tau \delta_{r}^{2}}{8\rho^{2}}\right)\right) \\ &\geq 1 - \frac{4}{T}, \end{split}$$

where the third inequality is due to (D.5) and the fifth inequality is due to Lemma F.1.

E Proof of the Lower Bound of MAMAB with Coordination Hypergraph

In this section, we derive a worst-case lower bound on the MAMAB considered in this paper.

Proof of Theorem 4.2. For any given group structure on the agents, suppose group 1 was the largest group. It follows that the number of local actions for this group satisfies $|\mathcal{A}^1| \geq \frac{A_{\text{loc}}}{\rho}$. Furthermore, suppose that local arms in the other groups $[\rho] \setminus 1$ possess a mean reward of 0, allowing only the local arms in group 1 to have a nonzero mean reward. Moreover, let $\mathbf{1}^1$ signify the local arm in group 1 possessing the highest mean. Since only group 1 has nonzero local mean rewards, the regret associated with pulling a suboptimal arm \boldsymbol{a} is calculated as follows:

$$\sum_{e \in [\rho]} (\mu_{\mathbf{1}^e} - \mu_{\mathbf{a}^e}) = \mu_{\mathbf{1}^1} - \mu_{\mathbf{a}^1}.$$

With these considerations, the problem is effectively simplified to a K-armed bandit problem with $K = |\mathcal{A}^1| \ge \frac{A_{\text{loc}}}{\rho}$. As it is widely established, the worst-case lower bound for a K-armed bandit is $\Omega(\sqrt{KT})$ (Auer et al. 2002). Hence, a MAMAB problem instance can be found where the regret is equivalent to $\Omega(\sqrt{KT}) = \Omega(\sqrt{TA_{\text{loc}}/\rho})$.

Proof of Theorem 4.3. Consider the following bandit instance: We have ρ groups. For each group, we have L + 1 local arms, where L local arms have mean X and 1 local arm has mean $X + \Delta$. Now, we construct the joint arm set, where we only have in total $L^{\rho} + 1$ joint arms, with L^{ρ} joint arms having mean ρX and one joint arm having mean $\rho(X + \Delta)$. For each L^{ρ} joint arms that have mean ρX , it is composed by ρ local arms with mean X. For the one joint arm with mean $\rho(X + \Delta)$, it is composed by ρ local arms with mean X. For the one joint arm with mean $\rho(X + \Delta)$, it is composed by ρ local arms with mean $\lambda + \Delta$. It is easy to see the joint arm with mean $\rho(X + \Delta)$ is the optimal one. We denote the optimal joint arm as **1**. All local arms follow the Gaussian reward distribution with unit variance. We use a normal distribution $\mathcal{N}(0, 1)$ as the prior for all local arms. We aim to compute the number of pulls of suboptimal joint arms before pulling the optimal joint arm for the first time. The posterior distribution of the optimal joint arm is $\mathcal{N}(0, \rho)$. From the concentration bound of Gaussian (Lemma F.1), we obtain that the probability of the sample from the optimal arm **1** being larger than ρ is bounded by

$$\mathbb{P}(\theta_1 \ge \rho) \le \frac{e^{-\rho/2}}{2}.$$

When we pull a local arm i with mean X for s times, then its posterior distribution is $\mathcal{N}(s\hat{\mu}_{i,s}/(s+1), 1/(s+1))$, where $\hat{\mu}_{i,s}$ is the empirical mean of local arm i after its s-th pull.

Assume X > 3. Note that $\hat{\mu}_{i,s} \sim \mathcal{N}(X, 1/s)$. Applying the maximum inequality (Lemma F.2), we obtain

$$\mathbb{P}(\exists s > 1, \hat{\mu}_{i,s} < 2) \le 1/\sqrt{e}.$$

We let y_e be the number of local arms with mean X in group e such that its empirical mean is always larger than 2. By Hoeffding's inequality,

$$\mathbb{P}(y_e \le L/(2\sqrt{e})) \le \exp\left(-\frac{L}{2e}\right).$$

We let E_e be the event $y_e > L/(2\sqrt{e})$ and $E := \bigcap_{e \in [\rho]} E_e$. Then, by applying union bound, we obtain

$$\mathbb{P}(E) \ge 1 - \rho \exp\left(-\frac{L}{2e}\right)$$

Let θ be a sample from $\mathcal{N}(0,1)$ and θ' be the sample from $\mathcal{N}(s\hat{\mu}_{i,s}/(s+1), 1/(s+1))$. When $\hat{\mu}_{i,s} > 2$,

$$\mathbb{P}(\theta' \le 1) \le \frac{1}{2} \le \mathbb{P}(\theta \le 1).$$

Denote $b = \mathbb{P}(\theta \le 1)$ and $\{\mathbf{a}_1^e, \cdots, \mathbf{a}_L^e\}$ for the local arms with mean X in group e. Let \mathcal{E}_e be the probability that the maximum sample from $\{\mathbf{a}_{1}^{e}, \cdots, \mathbf{a}_{L}^{e}\}$ is larger than 1. Then,

$$\mathbb{P}(\mathcal{E}_e \mid E) \ge 1 - b^{L/(2\sqrt{e})}$$

Applying the union bound over all group $e \in [\rho]$,

$$\mathbb{P}(\bigcap_{e \in [\rho]} \mathcal{E}_e \mid E) \ge 1 - \rho b^{L/(2\sqrt{e})}.$$

The above inequality means that conditional on event E, the probability that all samples from a joint arm with mean X are larger than ρ is bounded by $1 - \rho b^{L/(2\sqrt{e})}$.

By choosing $L = 2e\rho \log_{1/b} 2 + 2e \log_{1/b} \rho$, we have $\mathbb{P}(\bigcap_{e \in [\rho]} \mathcal{E}_e \mid E) \ge 1 - 1/2^{\rho}$, $\mathbb{P}(E) \ge 1 - \exp(-\rho)$. We note that

when $\theta_1 \leq \rho$, E, and $\bigcap_{e \in [\rho]} \mathcal{E}_e$ happen, then we do not pull the optimal arm. Therefore, for such a bandit instance, the probability of pulling the suboptimal joint arm before pulling the optimal joint arm is bounded by $2^{-\rho} + e^{-\rho/2} + e^{-\rho}$. This means that the regret incurs by pulling the suboptimal is at least $\frac{\Delta}{2^{-\rho} + e^{-\rho/2} + e^{-\rho}}$, which is exponential in ρ .

F Auxiliary Lemmas

In this section, we present some useful inequalities that are useful in our proof. **Lemma F.1** (Abramowitz and Stegun (1964)). For a random variable $Z \sim \mathcal{N}(\mu, \sigma^2)$

$$\frac{e^{-z^2/2}}{2} \ge \mathbb{P}(Z > \mu + z\sigma) \ge \frac{1}{\sqrt{2}} \frac{z}{z^2 + 1} e^{-\frac{z^2}{2}},$$

$$\frac{1}{2} \geq \mathbb{P}(Z > \mu + z\sigma) \geq \frac{1}{\sqrt{2\pi}} \frac{1}{z^2 + 1} e^{-z}$$
$$\mathbb{P}(Z < \mu - z\sigma) \leq \frac{e^{-z^2/2}}{2}.$$

Lemma F.2 (Lemma C.3 in Jin et al. (2021b)). Let N and M be two positive integers, let $\gamma > 0$, and let $\hat{\mu}_n$ be the empirical mean of n random variable i.i.d from 1-subgaussian with mean μ . Then for any $x \leq \mu$,

$$\mathbb{P}(\exists N \le n \le M, \hat{\mu}_n \le x) \le e^{-N(x-\mu)^2/2},$$

27/ 2/2

and for any $x \ge \mu$,

$$\mathbb{P}(\exists N \le n \le M, \hat{\mu}_n \ge x) \le e^{-N(x-\mu)^2/2}.$$

G Additional Experimental Details

In this section, we provide detailed settings of the local reward distribution for Bernoulli 0101-Chain and Poisson 0101-Chain. In addition to the experimental results shown in Section 5, we further investigate more ablation studies, including (i): a larger number of agents and (ii): different ϵ condition sampling to evaluate the proposed ϵ -MATS algorithm on Bernoulli 0101-Chain and Poisson 0101-Chain. Finally, we report our ϵ -MATS against other baselines in an additional real-world experiment: wind farm control (Bargiacchi et al. 2018; Verstraeten et al. 2020).

Reward Generation for Bernoulli and Poisson 0101-Chains

As discussed in Section 5, for d = 2, the reward of a joint arm in the Bernoulli and Poisson chains depends on the local rewards for each group of agents $\{a_i, a_{i+1}\}, i = 1, ..., n - 1$. Each local reward follows Bernoulli or Poisson distributions with the mean value $f(a_i, a_{i+1})$ given in Table 2(a) Table 2(b) respectively. It can be easily verified that the optimal joint arm for this setting is an alternating sequence of zeros and ones, starting with 0, i.e., (0, 1, 0, ...). For the setting where we have d = 3 agents in each group, the reward generation is given in Table 2(c), and the optimal joint arm is (1, 1, ..., 1, 1).

Table 2: (a) and (b): The distribution of local reward $f(a_i, a_{i+1})$ for group *i* in the chain graph. Here *i* is an even number. The table is transposed when *i* is odd. There are two agents (i, i+1) in each group, where *i* is even. Each entry shows the means for each local arm of agents *i* and i + 1. (c): the unscaled local reward distributions of 3-agents (i, i+1, i+2) per group, where *i* | 3. Each entry in the first 3 columns denotes the arm and the last column indicates the corresponding success probability for each local arm of agents i, i + 1 and i + 2. The table is shifted symmetrically when i = 3c + 1 or i = 3c + 2, where $c \in \mathbb{R}$.

$a_i = 1$ 0.2	0.1		1	1	1	1.0

Bernoulli and Poisson 0101-Chains with 20 Agents

Following the problem description in Section 5, we still consider two settings where d = 2 and d = 3 but with a larger number of agents: m = 20 agents in total. We demonstrate the improvement of regret performance with ϵ MATS in the Bernoulli 0101 and Poisson 0101 tasks with 20 agents compared with MATS, MAUCE, and Random in Figure 5, indicating the consistency of benefits of lower ϵ across a different number of agents.

Figure 5: Regret performance compared with other algorithm baselines in Bernoulli 0101 and Poisson 0101 with different agents in a group (d = 2 or d = 3) with **20 agents** in total.

Gem Mining

Now we consider a real-world application of MAMAB, e.g., the Gem Mining problem (Bargiacchi et al. 2018), (Verstraeten et al. 2020). In this problem, a mining company aims to maximize the total number of gems across multiple mines. The mine workers are represented by separate villages, each acting as an agent in the MAMAB setup. There is only one van available per village to transport all workers from that village to one of the nearby mines. This arrangement forms a coordination graph, where each village is connected to a specific range of adjacent mines. The company must decide which mine to send its workers to, and this decision corresponds to selecting a local arm in the MAMAB framework. Each mine is formulated as a single group, and the reward for each mine follows a Bernoulli distribution. The probability of finding a gem in a mine is defined as $1.03^{w-1}p$, where p represents the base probability of finding a gem (sampled uniformly from the interval [0, 0.5]), and w denotes the number of workers at that mine. The cooperation among workers from multiple villages aims to maximize the probability of finding gems in a mine. A number of workers sampled from $\{1, \ldots, 5\}$ live in the same village, and each village i is connected

Figure 6: Gem Mining experiment. (a): The hypergraph illustration. Each vertex is a village, and each hyperedge (group) corresponds to a mine. In this figure, a village is denoted as a black house while a group is denoted by a green circle. Note that there are some groups that contain the same agents (villages). (b): Regret performance compared with other algorithm baselines in Gem Mining.

to the mine *i* to $(i + m_i - 1)$, where m_i is sampled from [2, 4] while the last village is always connected to 4 mines. We conduct the experiments with 5 villages and 8 mines. The diagram for this is given in Figure 6(a). The agents, in this case, correspond to the village, and the groups are determined by which villages have access to a particular gem mine. Since there are 5 villages and 8 mines, therefore there are 5 agents and 8 groups.

Gem Mining is a more challenging problem due to the varying size of each group. We report the average cumulative regret of ϵ -MATS against the other algorithms in Figure 6(b), which again shows that ϵ -MATS with a small ϵ outperforms all baseline methods including vanilla MATS.

Wind Farm Control

We conducted additional experiments on a different real-world application known as the Wind Farm Control problem (Bargiacchi et al. 2018; Verstraeten et al. 2020). Following the settings of previous studies (Bargiacchi et al. 2018; Verstraeten et al. 2020), we developed a custom simulator to replicate the energy production of an 11-turbine wind farm (refer to Figure 7(a)). Among the turbines, 4 downstream ones (2, 5, 8, 11) are not controlled by any agents, while the remaining 7 turbines each have 3 distinct arms (angles) representing different turning positions. In this problem, cooperation among the 7 turbines forming 7 groups is essential to maximize the overall power production, as turbulence generated by upstream turbines negatively affects downstream ones, with the direction of turbulence depending on the angle between each turbine and the incoming wind vector.

To simulate the wind farm, we sample wind speeds from a normal distribution at each time step. The power production of each turbine depends on the current wind speed, the turbine's angle, and the net wind direction influenced by turbulence. We normalize the overall reward by the maximum attainable reward at the highest wind strength and the minimum reward per turbine at the lowest wind strength, as per the approach in Bargiacchi et al. (2018). It is important to note that this measure is not an exact form of regret since choosing the optimal action does not guarantee zero regret on average.

The Wind Farm Control problem poses additional challenges due to the independent angles of the controllable agents and the fixed angles of the 4 downstream turbines. However, even in this complex scenario, our ϵ -MATS algorithm outperforms baseline methods, including MAUCE and MATS, as demonstrated by the smaller cumulative regret shown in Figure 7(b).

Figure 7: Wind farm control experiment. (a): Wind farm setup. The incoming wind is denoted by an arrow. Agents (turbines) in a local group are listed on the left. The controllable turbines are in blue while the remaining 4 turbines are in green connected via dash lines. (b): Regret performance compared with baseline algorithms in Wind Farm Control.
