Despite widespread interest in the phase-change applications of vanadium dioxide (VO₂), the fabrication of high-quality VO₂ thin films with elevated transition temperatures (T_{IMT}) and high Insulator-Metal-Transition resistance switching still remains a challenge. This study introduces a two-step atmospheric oxidation approach to fabricate bilayer VO_{2-x}/VO₂ films on a c-plane sapphire substrate. To quantify the impact of the VO₂ buffer layer, a single-layer VO₂ film of the same thickness was also fabricated. The bilayer VO_{2-x}/VO₂ films wherein the top VO_{2-x} film was under-oxidized demonstrated an elevation in T_{IMT} reaching ~97 °C, one of the highest reported to date for VO₂ films and is achieved in a doping-free manner. Our results also reveal a one-order increase in resistance switching, with the optimum bilayer VO₂/VO₂ film exhibiting ~3.6 orders of switching from 25 °C to 110 °C, compared to the optimum single-layer VO₂ reference film. This is accompanied by a one-order decrease in the on-state resistance in its metallic phase. The elevation in T_{IMT} , coupled with increased strain extracted from the XRD characterization of the bilayer film, suggests the possibility of compressive strain along the c-axis. These VO_{2-x}/VO₂ films also demonstrate a significant change in the slope of their resistance vs temperature curves contrary to the conventional smooth transition. This feature was ascribed to the rutile/monoclinic quasi-heterostructure formed due to the top VO_{2-x} film having a reduced T_{IMT} . Our findings carry significant implications for both the lucid fabrication of VO₂ thin film devices as well as the study of phase transitions in correlated oxides.

I. INTRODUCTION

Vanadium dioxide (VO₂) is a Mott-Peierls insulator that undergoes Insulator-Metal-Transition (IMT) accompanied by a Structural Phase Transition (SPT) from low-temperature insulating monoclinic (M1, $P2_1/c$) to high-temperature metallic tetragonal rutile (R, $P4_2/mnm$) phase around 68 °C (~341 K) under ambient pressure¹. The monoclinic (M1) and tetragonal rutile (R) structures are significantly different, with the M1 phase having double the unit cell volume as compared to the Rphase². The formation of V–V dimers takes place along the c-axis during the R to M1 phase transition². This structural transition is accompanied by a temperature-driven change of several orders of magnitude in the resistance², as well as the optical reflectance³. These properties not only make VO₂ a promising material for devices such as neuromorphic oscillators⁴, steepslope phase FETs⁵, volatile memory⁶, and optical metasurfaces⁷ but also ensure that VO₂ serves as a sandbox for studying the

evolving physics underlying electronic correlation, transport, and phase-transition time-scales in Mott insulators⁸. Recent efforts have focused on harnessing this emergent correlated physics to realize neurobiological systems⁹ and fabricate high-frequency RF circuits¹⁰. To ensure the widespread adoption of VO₂ films in the fabrication of the aforementioned devices, a triad of requirements must be met: firstly, a simple methodology to fabricate pure-phase VO₂ films that involve a limited thermal budget while attaining low on-state resistance values in their metallic rutile phase; secondly, increasing the magnitude of resistance switching without incurring significant trade-offs; and finally, the development of doping-free techniques to manipulate IMT transition temperatures. Our work in this paper aims to address these pertinent challenges.

Vanadium (V) exhibits multiple valence states, out of which +5, +4, +3, and +2 are commonly observed. This gives rise to at least 22 stable phases of the V–O system, such as VO₂, V₂O₃, V₂O₅, V₆O₁₃, and V₃O₅¹¹. These pose a significant challenge in the growth of pure-phase VO₂ thin films and normally require exacting control over environmental pressure and gas concentrations. Contrary to the traditional methods reported in the literature, such as chemical vapor deposition (CVD)¹², atomic layer deposition (ALD)¹³, molecular beam epitaxy (MBE)¹⁴⁻¹⁶, and pulsed laser deposition (PLD)¹⁷⁻¹⁸, we previously reported a novel, simple methodology involving the atmospheric pressure thermal oxidation (APTO) of sputtered V films on a c-plane sapphire substrate (Al₂O₃) to achieve pure-phase VO₂ films¹⁹. This decreased the oxidation duration and thermal budget required and allowed the oxidation to be carried out under atmospheric pressure while attaining around three orders of resistance switching. However, for two main reasons, low on-state resistance values could not be attained in these VO₂ films. Firstly, due to the low thermal budget, smaller grain sizes were observed in the films, which may result in undesirable high on-state resistance values¹⁷. Secondly, the lattice parameter mismatch between the Al₂O₃ substrate (a = b = 4.75 A°, c = 12.99 A°) and the VO₂ film (a = b = 4.54 A°, c = 2.88 A°) may degrade the overall film quality²⁰.

Apart from high IMT resistance switching and low on-state resistance, different phase-change applications demand varied transition temperatures. While recent reports have emphasized the fabrication of VO₂ films with low transition temperatures (30 - 40 °C) for thermochromic smart window applications²¹, it is imperative to note that several specialized devices require high operating temperatures exceeding the bulk VO₂ phase transition temperature of ~68 °C. This includes electronics employed in commercial and defense applications, which need to operate above 85 °C and 125 °C, respectively²², high-temperature micro-bolometers operating around 95 °C²³, and high-temperature electronics used in data centers²⁴. The field of reconfigurable RF devices has also emerged as a crucial area, garnering substantial interest from the scientific community, especially in relation to phase-change materials possessing high transition temperatures¹⁰. However, RF devices like RF switches and oscillators necessitate a minimum transition temperature of ~80 °C, rendering conventional VO₂ films unsuitable¹⁰. For all the aforementioned applications, increased transition temperatures are normally achieved by the

stoichiometric doping of VO₂ films with elements such as Fe²⁵, Cr²⁶, and Ge²⁷. Although these reports demonstrate elevated transition temperatures, a clear monotonic decrease in the magnitude of IMT resistance switching is often observed with the increase in doping percentage. The Ge-doped Ge_xV_(1-x)O₂ film reported by A. Krammer *et al.*²⁷ with the highest doping concentration demonstrated only ~1.5 orders of resistance switching. This decrease in switching with increasing doping is also evident in the Cr-doped Cr_xV_(1-x)O₂ films reported by B. L. Brown *et al.*²⁶, which demonstrate a slight decrease in the difference between the carrier concentrations in the insulating and metallic phases, implying a reduction in the IMT resistance switching. Thus, achieving elevated transition temperatures while also maintaining or improving IMT resistance switching is a pertinent challenge in the fabrication of phase-change devices²⁸.

Several studies have documented the utilization of buffer layers or virtual substrates to fabricate high-quality VO₂ films devoid of doping in the quest to achieve desirable properties. For instance, E. Breckenfeld *et al.*²⁸ introduced a TiO₂ buffer layer for the growth of VO₂ films on an m-cut sapphire substrate, resulting in a lowered transition temperature of 44 °C due to partial strain between the TiO₂ buffer layer and the VO₂ film. Similarly, H. Kim *et al.*²⁹ investigated a VO₂/SnO₂/Al₂O₃ system that relied on epitaxial strain between the VO₂ film and the SnO₂ buffer to modulate the IMT transition temperature. C. Kang *et al.*³² demonstrated the use of a TiO₂ buffer layer on a soda lime glass substrate to enhance photoelectric properties. However, most studies employing buffer layers mainly focus on reducing transition temperatures and are often accompanied by a decrease in the magnitude of IMT resistance switching. Only a handful of studies have explored the use of buffer layers such as (110) TiO₂³³ to elevate the transition temperature of VO₂ films or enhance the magnitude of IMT resistance switching using Al₂O₃³⁰ or yttria-stabilized zirconia³¹ buffer layers. Although scarce, these reports suggest that the high crystallinity and improved lattice parameter matching between the buffer layer and the VO₂ film contribute to overall film quality improvement. Furthermore, a few bilayer systems have also been employed to gain fundamental insights into the switching dynamics and sub-nanosecond time scales of the phase transitions occurring in VO₂³⁴.

This study investigates bilayer VO_{2-x}/VO_2 films fabricated on a c-plane sapphire substrate, employing a two-step atmospheric pressure thermal oxidation (APTO) technique with VO_2 acting as a buffer layer. These VO_{2-x}/VO_2 films are oxidized for varying durations and subsequently characterized by Raman Spectroscopy and four-probe measurements to pinpoint the optimum oxidation duration that yields pure-phase bilayer VO_2/VO_2 films. A single-layer VO_2 film of a comparable thickness was synthesized using conventional single-step APTO as a reference for comparison. The optimum bilayer VO_2/VO_2 film showed a nearly one-order increase in IMT resistance switching compared to its single-layer counterpart. In addition, a notable one-order reduction in on-state resistance in the metallic rutile phase was also observed. Aside from the optimum VO_2/VO_2 film, the under-oxidized VO_{2-x}/VO_2 films demonstrated increased transition temperatures between 81.6 °C and 96.9 °C, which was tuneable by varying the oxidation duration of the top VO_{2-x} film. This is among the highest reported transition temperatures for VO_2 films and is also achieved in a completely doping-free manner. Moreover, the under-oxidized VO_{2-x}/VO_2 films also demonstrate a significant change in the slope of the resistance vs temperature plots during the phase transition, contrary to the conventional smooth phase transition observed in VO_2 .

II. MATERIALS AND METHODS

A. Thin Film Fabrication

To synthesize the bilayer VO_{2-x}/VO₂ films, a two-step APTO of DC sputtered V films was carried out as illustrated in Fig. 1. Initially, a c-plane sapphire substrate was sonicated in acetone and isopropyl alcohol (IPA) for ten minutes each, followed by blow drying using dry nitrogen. A 40 nm metallic V film was deposited on these cleaned substrates using DC sputtering. A V sputtering target with a diameter of four inches and a purity of 99.95% was used for the same. Prior to the deposition, the sputtering chamber was pumped to a base pressure of 0.5 mPa. Following this, Ar gas was released into the chamber to maintain a deposition pressure of 3 Pa. Throughout the deposition, the DC power was maintained at 90 W. Sputtering was carried out for four minutes to achieve a film thickness of 40 nm¹⁹. These V sputtered c-plane sapphire substrates were diced into six pieces. These were placed on a hot plate maintained at 450 °C and oxidized for different durations (Toxd) under atmospheric pressure to obtain six VO_{2-x} films with varying degrees of oxidation. To accurately control oxidation times, each sample was quenched on a metallic cold plate immediately after heating¹⁹. Four-probe temperature-dependent resistance measurement was utilised to quantify the IMT resistance switching ($R_{25 \circ C}/R_{110 \circ C}$) for all six samples. IMT resistance switching is defined as the ratio of the resistance of the sample at 25 °C ($R_{25 \circ C}$) and at 110 °C ($R_{110 \circ C}$). The sample with the highest magnitude of switching was identified as the pure-phase VO₂ film with an optimum oxidation time (T_{axd}^*) out of all the VO_{2-x} films obtained¹⁹. This optimum 80 nm VO₂ film was utilized as the buffer layer for further deposition. A second round of DC sputtering was carried out to deposit a 40 nm metallic V film on top of this buffer layer. This c-plane sapphire substrate with a VO₂ buffer layer and a metallic V top film was further diced into six pieces and again oxidized at different T_{oxd} . Thus, six samples of bilayer VO₂- $_{\rm x}$ /VO₂ films were obtained. Raman spectroscopy and four-probe temperature-dependent resistance measurements were repeated on all the samples to identify the pure-phase bilayer VO_2/VO_2 film with the highest resistance switching¹⁹.

To fabricate a control sample for comparison, a single-layer VO₂ film of the same 160 nm thickness was synthesized as the reference film using the conventional single-step APTO process. An 80 nm metallic V film was initially deposited on a fresh c-plane sapphire substrate, followed by dicing and APTO at 450 °C for different T_{oxd} to obtain single-layer VO_{2-x} films. Out of these, the optimum single-layer VO₂ film was identified and selected as our reference film. Optical images of all the samples are presented in Fig. 2.

FIG. 1. Two-step atmospheric pressure thermal oxidation (APTO) methodology used to fabricate bilayer VO_2/VO_2 films on a c-plane sapphire substrate.

FIG. 2. Graphical illustration of the optimum bilayer and single-layer reference films accompanied by the optical images of all the samples oxidized for different durations.

B. Characterization Methods

All the temperature-dependent resistance measurements mentioned above were carried out using a four-point probe setup coupled with a temperature-controlled oven in a range of 25 °C to 120 °C. A constant current of 10 μ A was applied across the outer probes, while the voltage across the inner probes was measured to calculate the resistance of the films. The crystallinity and phase formation of all the samples were characterized using Raman Spectroscopy with an excitation laser of 532 nm wavelength (Acton Research Corporation Spectra Pro 2500i). X-Ray Diffraction (XRD) using Cu K α radiation (Rigaku Miniflex Pro) was used to characterize the crystallite planes. To further probe the crystallite size and strain in both the bilayer VO₂/VO₂ film, as well as the single-layer VO₂ reference film, the Scherrer formula (Eq. 1) and the Williamson-Hall (W-H) formula (Eq. 2) were employed³⁵:

$$D_s = \frac{k \cdot \lambda}{B_r \cdot \cos(\theta)} \tag{1}$$

$$B_r \cdot \cos(\theta) = \frac{k \cdot \lambda}{D_{WH}} + \eta \cdot \sin(\theta)$$
⁽²⁾

Here, k represents the Scherrer constant (0.94), λ represents the wavelength of the X-ray radiation (0.154060 nm), B_r represents the full-width half-maxima (FWHM) of the respective diffraction peaks, θ represents the Bragg's angle, D_s represents the crystallite size found using the Scherrer formula (Eq. 1), whereas, D_{WH} represents the crystallite size found using the W-H formula (Eq. 2). The strain in the films is represented by η . In the W-H formula, D_{WH} and η are found by plotting $B_r \cdot \cos(\theta)$ vs $\sin(\theta)$, fitting the data linearly, and extracting the intercept and slope of the plot, respectively.

II. RESULTS AND DISCUSSIONS

Prior to the sputtering of the top V layer to form the bilayer films, the IMT resistance switching ratios of the buffer layer at different T_{oxd} were measured to help identify the optimum VO₂ film. As illustrated in Fig. 3 (a), these samples demonstrate a typical behavior with a low magnitude of IMT resistance switching (~one order) initially up to $T_{oxd} = 10 \text{ s}^{19}$. This is ascribed to the high V content in these samples due to partial oxidation. A narrow window can be observed at $T^*_{oxd} = 12$ s which shows a maximum resistance switching magnitude of 2.2 orders. A significant decrease in switching can be observed following $T^*_{oxd} = 12$ s with samples having $T_{oxd} = 14$ s, 17 s, and 20 s demonstrating decreasing switching magnitudes of 1.8, 1.3, and 0.2 orders respectively due to the gradual increase of V₂O₅ content in these films. Thus, we conclude that the sample with $T^*_{oxd} = 12$ s is the closest to the desired pure-phase VO₂ as it demonstrates the highest magnitude of resistance switching. This sample is selected as the buffer layer. As described previously, a second round of 40 nm V was sputtered, followed by dicing, and APTO at different T_{oxd} was repeated to fabricate the top VO_{2-x} film, thus completing the bilayer VO_{2-x}/VO₂ films oxidized for different durations.

FIG. 3. The insulator-metal phase transition induced resistance switching ratios as a function of oxidation duration for: (a) Buffer film prior to top layer deposition, (b) Bilayer film, (c) Single-layer reference film. (d) IMT resistance switching comparison between the optimum VO₂/VO₂ bilayer film and the optimum single-layer film. Derivative of $Log_{10}{R(T)}$ for: (e) Heating cycle, (f) Cooling cycle.

Amongst these, to further identify the optimum bilayer VO₂/VO₂ film, the IMT resistance switching of all the VO_{2-x}/VO₂ films are presented in Fig. 3 (b). The samples oxidized for very short durations, such as $T_{oxd} = 9$ s, 12 s, and 15 s, show moderately good switching of ~1.3, ~1.9, and ~2 orders, respectively. During APTO of the top V film, the presence of the VO₂ buffer layer may cause oxygen diffusion from both the atmosphere, as well as the buffer layer, resulting in faster oxidation of the top film and reasonably low V content even with short durations of oxidation. This is in agreement with the Raman characterization presented in the following paragraphs. The bilayer film with $T^*_{oxd} = 20$ s demonstrates ~3.6 orders of IMT resistance switching and is clearly the highest amongst all the bilayer films. Thus, we conclude that the sample with $T^*_{oxd} = 20$ s is the closest to a pure-phase bilayer VO₂/VO₂ film and is further confirmed by Raman spectroscopy in the following sections. Moreover, a wider oxidation window is also observed, with samples having $T_{oxd} = 18$ s and 24 s also showing reasonably high values of ~3 and ~2.5 orders, respectively. To carry out a quantitative comparison, the IMT resistance switching measurements for the single-layer VO₂ reference film with a comparable thickness are presented in Fig. 3 (c). We observe a typical behavior with samples oxidized for short durations showing less than one order of switching with a gradual increase peaking at T_{oxd}^* = 30 s which demonstrates ~2.7 orders of IMT resistance switching and can be identified as the optimum single-layer VO₂ reference film. A stark improvement of close to one order is visible, with the optimum bilayer film demonstrating ~3.6 orders of IMT resistance switching compared to the optimum single-layer reference film demonstrating ~2.7 orders of switching. To further enunciate this one-order improvement, the resistance as a function of temperature between 25 °C and 120 °C for both films is illustrated in Fig. 3 (d). These results clearly indicate a significant improvement in IMT resistance switching with the insertion of a VO₂ buffer layer via two-step APTO. To extract IMT parameters such as transition temperature (T_{IMT}), transition interval (ΔT_{Tr}), and transition hysteresis (ΔT_{Hys}), the first derivative of Log₁₀{R(T)} for the temperature-dependent resistance presented in Fig. 3 (d) is plotted in Fig. 3 (e-f) and fitted with Gaussians. The center and width of the Gaussian fits define T_{DAT} (T_{MTT}) and ΔT_{Tr} , respectively⁴². A distinct shift towards the right is observed in the Gaussian plot for the heating cycle of the bilayer film (Fig. 3 (e)), signifying a major increase in the T_{IMT} (81.6 °C) compared to the single-layer reference film (68.2 °C). This further elucidates that the optimum bilayer VO₂/VO₂ film achieves a one-order increase in resistance switching while elevating T_{IMT} by nearly 14 °C in a completely doping-free manner. A similar increase in the T_{MTT} during the cooling cycles (Fig. 3 (f)) of both the films is also observed with the bilayer film and single-layer reference film demonstrating a T_{MTT} of 58.2 °C and 46.8 °C, respectively. The difference between the T_{IMT} (heating cycle) and T_{MTT} (cooling cycle) further defines ΔT_{Hys} .

All the bilayer VO_{2-x}/VO₂ films oxidized for different T_{oxd} were further characterized using Raman Spectroscopy, as illustrated in Fig. 4 (a). The films oxidized for $T_{oxd} = 10$ s and 12 s already show several strong VO₂ peaks, signifying the possibility of a nearly complete conversion from the elemental metallic V phase to the VO₂ phase. As discussed previously, this fast oxidation time may be ascribed to the oxidation of the top VO_{2-x} film occurring from both the top, due to the atmosphere, and the bottom, due to the buffer layer. Weak V₂O₅ peaks start to appear at $T_{oxd} = 15$ s and 24 s at 709.24 cm⁻¹ and 996.73 cm⁻¹. However, we still observe the VO₂ peaks dominating the entire oxidation range, both in terms of number and intensity compared to the competing V₂O₅ peaks. To contrast this, the Raman characterization for all the single-layer VO_{2-x} reference films is presented in Fig. 4 (b). The pure V film ($T_{oxd} = 0$ s) does not show any Raman peaks due to its pure metallic phase. The reference film oxidized for $T_{oxd} = 10$ s only demonstrates four VO₂ peaks at 150.12 cm⁻¹, 201.52 cm⁻¹, 227.09 cm⁻¹, and 616.86 cm⁻¹. With an increase in oxidation times, more VO₂ peaks start appearing. The films with $T_{oxd} = 20$ s, 25 s, and 30 s demonstrate only VO₂ peaks, except the sample with $T_{oxd} = 30$ s, which begins to show signatures of weak V₂O₅ peaks. At $T_{oxd} = 40$ s, a significant increase in V₂O₅ content as well as the emergence of a mixed phase of V₂O₅ and VO₂ can be observed. This monotonic progression is in agreement with previous reports, which attribute this behavior to the kinetics involved in the oxidation process³⁶.

FIG. 4. Raman spectroscopy data recorded for all the films oxidized for different T_{oxd} for both: (a) VO_{2-x}/VO₂ bilayer films; and (b) VO_{2-x} single-layer reference films.

FIG. 5. (a) XRD data recorded for the optimum bilayer film ($T_{oxd}^* = 20$ s) and the optimum single-layer reference film ($T_{oxd}^* = 30$ s). (b) Linear fitting of $B_r \cdot \cos(\theta)$ vs sin(θ) to extract the strain from the XRD characterization of the samples using the W-H formula (Eq. 2).

TABLE I. Average particle sizes obtained from XRD characterization of the samples.

Sample	Peak Centre	Crystal Plane	FWHM	Scherrer Formula		Williamson-Hall Formula	
				Crystallite Size	Average Crystallite Size	Average Crystallite Size	Strain
Reference Film $T_{oxd}^* = 30 s$	18.04 °	(100)	0.18	44.68 nm	37.25 nm	45.82 nm	0.0016
	27.04 °	(110)	0.20	36.03 nm			
	44.68 °	(012)	0.32	35.02 nm			
	55.36 °	(220)	0.36	34.44 nm			
Bilayer Film $T_{oxd}^* = 20 s$	17.92 °	(100)	0.18	44.68 nm	41.09 nm	58.15 nm	0.0036
	26.94 °	(110)	0.24	40.85 nm			
	44.56 °	(012)	0.26	40.51 nm			
	55.29 °	(220)	0.31	40.34 nm			

FIG. 6. Metallic on-state and insulating off-state resistance values as a function of oxidation times for: (a) Bilayer film, and (b) Single-layer reference film. IMT properties such as T_{IMT} , ΔT_{Tr} , and ΔT_{Hys} as a function of oxidation times for: (c) Bilayer film, and (d) Single-layer reference film. (e) Comparison of the bilayer VO_{2-x}/VO₂ film and optimum VO₂/VO₂ film presented in this paper with previous reports on doped-VO₂ films with elevated transition temperatures.

The XRD plots for the optimum (T_{oxd}^*) bilayer as well as the single-layer reference film, are presented in Fig. 5 (a). VO₂ peaks are observed at 17.92°, 26.94°, 45.64°, and 55.36° in both the bilayer and single-layer films. These correspond to the (100), (110), (012), and (220) VO₂ planes, respectively. The resultant average particle sizes for both samples are presented in

Table I. The bilayer film and the single-layer reference film demonstrate crystallite sizes of 41.09 nm and 37.25 nm, respectively, using the Scherrer formula (Eq. 1) and crystallite sizes of 58.15 nm and 45.82 nm, respectively, using the W-H formula (Eq. 2). Slight deviations are often observed in the crystallite sizes extracted using these formulas. However, in both cases, a clear increase in grain size is observed in the bilayer film. Moreover, these sizes agree with previous reports for VO₂ films of a similar thickness³⁴. To extract the strain in the films, the line fits for the $B_r \cdot \cos(\theta)$ vs $\sin(\theta)$ plots for both the bilayer and the single-layer films are presented in Fig. 5 (b). A significantly greater strain is observed in the bilayer film with $\eta = 0.0036$, while the single-layer reference film demonstrated an $\eta = 0.0016$.

Apart from the close to one-order increase in IMT resistance switching, the bilayer film also demonstrates significantly lower on-state resistance in its metallic phase as compared to the single-layer reference film. An on-state resistance of ~100 Ω was observed for the optimum bilayer film ($T_{oxd}^* = 20$ s), which is one order lower than the on-state resistance observed for the single-layer reference film ($T_{oxd}^* = 30$ s) (Fig. 6 (a-b)). This may be attributed to the crystallinity of the VO₂ buffer layer, which provides a better virtual substrate for the growth of the top VO₂ film as compared to c-plane sapphire due to improved lattice constant matching and higher crystallinity, resulting in the growth of a high-quality quasi-homogenous bilayer VO₂/VO₂ film with larger grain sizes. In addition, all the bilayer films oxidized at various other T_{oxd} also show low on-state resistance values, as presented in Fig. 6 (a). This radically differs from the typical resistance trends observed in the single-layer reference films presented in Fig. 6 (b). At low T_{oxd} , due to the presence of unoxidized V in these single-layer reference films, they demonstrate low on-state resistance due to the metallic character of V. Following this, at T_{oxd}^* and higher T_{oxd} , a gradual increase in both, the on-state resistance values of the bilayer film only show a slight variation with increasing T_{oxd} values.

The plots illustrating the variation of T_{IMT} , ΔT_{Tr} , and ΔT_{Hys} with different T_{oxd} are illustrated in Fig. 6 (c-d). The highest T_{IMT} achieved in bilayer VO_{2-x}/VO₂ films was 96.9 °C ($T_{oxd} = 15$ s), which is one of the highest transition temperatures achieved in VO₂ films to date and is also demonstrated in a completely doping-free manner. The optimum bilayer VO₂/VO₂ film ($T_{oxd}^* = 20$ s) also exhibited a high T_{IMT} of 81.6 °C, which is notably higher than that of the optimum reference film (68.3 °C), while also demonstrating higher IMT resistance switching. This significant increase in the transition temperature may be attributed to the increased strain observed in the bilayer film relative to the single-layer reference film extracted via the W-H method (Eq. 2) in the previous section (Fig. 5 (a-b)). Based on prior reports, an elevation in transition temperature, when accompanied by increased strain in a VO₂ film, often suggests the existence of compressive strain along the c-axis of the film³⁸. As experimentally demonstrated by Y. Muraoka *et al.*³⁸ with a VO₂ film grown on a TiO₂ (001) buffer layer, a compressive strain

developed along the c-axis, which induced an increase in VO₂ transition temperatures. This strain was epitaxial in nature and was ascribed to the lattice parameter mismatch between the buffer layer and the VO₂ film^{38,43}. However, contrary to this, in the bilayer sample, the c-axis compressive strain is possibly non-epitaxial in nature due to its significant film thickness and may be attributed to the evolution of stoichiometry of the top VO_{2-x} film during its APTO. This is further supported by the fact that the elevated transition temperatures are oxidation duration-dependent, indicating that the strain in the films is driven by T_{oxd} and depends on the non-stoichiometric nature of the top VO_{2-x} film. By adjusting the oxidation duration, the methodology presented in this paper enables the tuning of transition temperatures between roughly 74 °C and 97 °C, which is much higher than the original transition temperature of VO₂ at 68 °C. In addition, as presented in Fig. 6 (e), the bilayer samples displayed impressive performance when contrasted with prior reports regarding high transition temperature VO₂ films, which were predominantly accomplished by doping VO₂ with elements such as Cr⁴⁶, Ga⁴⁷, and Ge²⁷.

To further probe the effect of the buffer layer on the IMT resistance switching characteristics of the bilayer VO_{2-x}/VO_2 films, the resistance vs temperature plots for all the bilayer samples oxidized for different T_{oxd} are presented in Fig. 7 (a-f). Under-oxidized bilayer films with $T_{oxd} = 10$ s, 12 s, and 15 s demonstrate a significant change in the slope during their heating and cooling cycles. This is similar to the step-like feature reported by D. Lee *et al.*⁴³ during the structural phase transition in their $VO_{2.\delta}/VO_2$ bilayer system grown on TiO₂ using PLD. Here, $VO_{2.\delta}$ represented the oxygen-deficient top vanadium dioxide film with intrinsic point defects, fabricated with the goal of achieving a lower T_{IMT} as compared to their ideal VO_2 bottom layer. Previously, C. H. Griffiths *et al.*⁴⁴ experimentally proved that oxygen-deficient $VO_{2.\delta}$ films have lower transition temperatures due to higher electron concentration as compared to perfectly stoichiometric VO_2 films. As a result of this difference between the T_{IMT} of the top $VO_{2.\delta}$, and the bottom VO_2 , D. Lee *et al.*⁴³ reported the existence of a transitional monoclinic/rutile heterostructure during the heating cycle, which stabilized a non-equilibrium metallic monoclinic phase responsible for the twostep structural phase transition.

FIG. 7. Temperature-dependent resistance switching between 25 °C and 120 °C for all the bilayer films with varying oxidation times: (a) $T_{oxd} = 10$ s, (b) $T_{oxd} = 12$ s, (c) $T_{oxd} = 15$ s, (d) $T_{oxd} = 17$ s, (e) $T_{oxd} = 20$ s, and (f) $T_{oxd} = 24$ s.

FIG. 8. Two-step IMT resistance transition illustrated in bilayer VO_{2-x}/VO₂ films with: (a) $T_{oxd} = 10$ s (b) $T_{oxd} = 12$ s, and (c) $T_{oxd} = 15$ s. The inset graphically illustrates the formation of a transitional rutile/monoclinic quasi-heterostructure.

Reasoning along these lines, for the bilayer VO_{2-x}/VO₂ films wherein the top layer was oxidized for less than the optimum duration ($T_{axd} = 10$ s, 12 s, and 15 s), we can presume that the T_{IMT} of the top VO_{2-x} film will be lower than the T_{IMT} of the buffer VO₂ film. Hence, the top film may undergo an earlier phase transition, resulting in the formation of a rutile/monoclinic heterostructure during the heating cycle, with the top VO_{2-x} film existing in a transitional or rutile phase, while the buffer VO₂ film still exists in the insulating monoclinic phase as illustrated in Fig. 8 (a). This quasi-hetero state may give rise to a transitional parallel resistor system where the top VO_{2-x} film and the buffer VO₂ film have substantially different resistivities at the same point of time during the heating cycle and may be considered as two resistors connected in parallel due to the configuration of the four-probe setup³⁹⁻⁴¹. Hence, the change in slope observed in the temperature-dependent resistance of the bilayer films may be ascribed to this transitional quasi-hetero bilayer formed. This is also in agreement with the IMT resistance switching curves observed for the bilayer films with $T_{oxd} = 17$ s, 20 s, and 24 s, where we see the change in slope disappear and observe a hysteresis pattern closer to that of a typical VO₂ film. As the T_{oxd} gradually increases, complete oxidation of the top VO_{2-x} film takes place, resulting in the top film and the buffer film having comparable T_{IMT} and thus demonstrating a smooth typical IMT resistance transition. This is further graphically illustrated in Fig. 8 (a-c), where we see the widths of ΔT_I and ΔT_2 monotonically increase and decrease respectively with increasing T_{oxd} , until the two merge and the change in slope disappears completely at $T_{oxd} = 17$ s.

For future investigations aimed at simultaneously enhancing both IMT resistance switching and transition temperatures, several approaches may be considered to further modify the VO_{2-x}/VO₂ bilayer films introduced in this study. The fabrication of these bilayer films could be explored on different crystalline substrates, including TiO₂, SnO₂, and CeO₂, with different crystal orientations to introduce additional strain effects. Furthermore, the fabrication of bilayer films with sophisticated methods that have reported some of the highest orders of switching, such as MBE¹⁴⁻¹⁶ and PLD¹⁷⁻¹⁸, might yield an increased magnitude of switching as compared to single-layer films with identical thicknesses. Achieving higher T_{IMT} is a considerable challenge as one will have to fabricate bilayer films with extremely high strain that is preserved. A possible future direction to surmount this challenge is to fabricate a tri-layer VO_{2-x}/VO_{2-y}/VO₂ film or a multi-layered VO₂ film, where *x* and *y* denote the non-stoichiometric nature of the films, by sequentially depositing each of the distinct oxide layers while maintaining a constant overall film thickness. By progressively increasing the number of buffer layers and maintaining a constant overall film thickness, the resulting structure begins to resemble a graded film commonly employed to preserve strain in thick films. This graded film structure may serve as an interesting future direction of study as increasing the number of buffer layers necessitates the optimization of several parameters, including the optimal number of buffer layers, the thickness of individual films, and the optimization conditions. Studying the exact layer-by-layer structural phase transition, their correlations, and their time

scales in a multi-layered strongly-correlated oxide structure may be of substantial interest. However, each additional layer would severely increase the complexity of the system, both with respect to fabrication as well as the overall structural phase transition. Furthermore, the continuous reduction in the thicknesses of individual buffer layers would significantly enhance epitaxial effects, thus further contributing to its complexity.

With respect to the bilayer films reported in this paper, the investigation of the exact structural phase transition occurring at the VO_{2-x}/VO₂ quasi-heterogenous interface may also be of significant interest. In bulk VO₂ films, a triple-phase point was previously reported in the form of a third intermediate monoclinic phase (M2) in between the well-established insulating monoclinic phase (M1) and the metallic rutile phase (R)⁴⁵. This intermediate M2 phase, often called the correlated metallic monoclinic phase, was previously stabilized with the help of a bilayer system⁴³. Several other reports investigating these intermediate phases in VO₂ have also relied on the study of bilayer films with the introduction of different buffer layers³⁴. Thus, the VO_{2-x}/VO₂ bilayer films introduced in this paper may also act as a sandbox for investigating and stabilizing correlated intermediate crystal phases in vanadium dioxide and other Mott insulators.

III. CONCLUSION

In this work, we introduced and studied the fabrication of a bilayer vanadium dioxide film with a self-buffer to elevate transition temperature while also increasing IMT resistance switching and decreasing on-state metallic resistance. Close to a one-order increase in IMT resistance switching was observed, with the optimum bilayer VO_2/VO_2 film demonstrating ~3.6 orders of resistance switching compared to the single-layer reference film. The introduction of the VO_2 buffer film also resulted in a one-order decrease in the on-state resistance. These features were attributed to the improved overall film quality and larger grain sizes due to the buffer VO_2 film acting as a highly suitable crystalline virtual substrate. A doping-free increase in transition temperature was also achieved with the under-oxidized bilayer VO_{2-x}/VO_2 film having $T_{oxd} = 15$ s, demonstrating a T_{IMT} of 96.9 °C, almost a 30 °C increase from the conventional transition temperature of VO_2 . The oxidation time served as a knob to fabricate VO_{2-x}/VO_2 films with varying elevated transition temperatures, making APTO an ideal methodology for the fabrication of VO_2 thin film devices for applications requiring elevated T_{IMT} . An intriguing change in slope was also observed in the temperature-dependent resistance hysteresis curves of the bilayer VO_{2-x}/VO_2 samples, wherein the top VO_{2-x} film was under-oxidized. Consequently, a quasi-heterostructure comprising a rutile/monoclinic interface was formed with the top film and the bottom film having different T_{IMT} . This heterogeneity manifests as a significant change in slope in the heating and cooling cycles of the temperature-dependent resistance plots. The results of this study should facilitate the adoption of bilayer VO_2/VO_2 films fabricated via APTO for applications requiring doping-free elevated transition temperatures, high magnitude

of IMT resistance switching, and a limited thermal budget. Additionally, the two-step resistance transition demonstrated in the bilayer VO_{2-x}/VO_2 films may also form the basis of future works investigating the correlated intermediate phases in Mott insulators.

ACKNOWLEDGMENTS

This project was supported by the Science and Engineering Research Board (SERB) India via Core Research Grant No. CRG/2022/005421 and used the Materials Science and Engineering (MSE) Raman characterization facility and the Advanced Center for Materials Science (ACMS) XRD facility.
