The antiferromagnetic layered compound EuCd_2As_2 is widely considered as a leading candidate of ideal Weyl semimetal, featuring a single pair of Weyl nodes in its field-induced ferromagnetic (FM) state[1–3]. Nevertheless, this view has recently been challenged by an optical spectroscopy study, which suggests that it is a magnetic semiconductor[4]. In this study, we have successfully synthesized highly insulating EuCd_2As_2 crystals with carrier density reaching as low as $2 \times 10^{15} \text{ cm}^{-3}$. The magneto-transport measurements revealed a progressive decrease of the anomalous Hall conductivity (AHC) by several orders of magnitude as the carrier density decreases. This behavior contradicts with what is expected from the intrinsic AHC generated by the Weyl points, which is independent of carrier density as the Fermi level approaches the charge neutrality point. In contrast, the scaling relationship between AHC and longitudinal conductivity aligns with the characteristics of variable range hopping insulators. Our results suggest that EuCd_2As_2 is a magnetic semiconductor rather than a topological Weyl semimetal.

INTRODUCTION

Weyl semimetals have attracted significant attention due to their intriguing electronic properties arising from the presence of the Weyl points[5, 6]. Among them, the ideal magnetic Weyl semimetals, characterized by a single pair of Weyl points close to the Fermi level, are long sought for exploring the intrinsic topological effects associated with Weyl fermions free from interference by other trivial energy bands. In the past few years, the layered magnetic compound EuCd_2As_2 was proposed to be one of the leading candidates to realize ideal magnetic Weyl semimetal in its field-induced ferromagnetic (FM) state[1–3]. EuCd_2As_2 has a hexagonal unit cell with space group P-3m1 (No.164) (Fig. 1(a)). At temperature of 9.5 K, the localized magnetic moments of Eu develop a long-range magnetic order, with moments fer-

romagnetically coupled within layers and antiferromagnetically coupled between layers[7–9]. Application of a 2 Tesla magnetic field saturates all magnetic moments along the c -axis at the low temperature, stabilizing a field-induced FM state. Previous density functional theory (DFT) calculations suggested that Cd s and As p orbitals are inverted near the Γ point in the energy bands of EuCd_2As_2 [8, 10], leading to an antiferromagnetic (AFM) topological insulator. Once the moments are fully saturated along the c -axis in the FM state, the Zeeman splitting lifts the band degeneracy and gives rise to a single pair of Weyl points[1–3].

In previous works, high magnetic field quantum oscillation study has revealed a small Fermi surface with a light effective mass in the field-induced FM state of EuCd_2As_2 [1]; Hall resistivity study has presented a large anomalous Hall conductivity at low temperatures presumably related with topological state of EuCd_2As_2 [1, 11–13]; ARPES experiments observed the quasi-linear dispersion of the valence band in the AFM state and the band degeneracy splitting at temperature right above the Neel temperature due to the existence of strong spin fluctuations[3, 14, 15]. All of these observations seem to agree with the existence of Weyl semimetal phase. Nevertheless, the direct observation of Weyl crossings of EuCd_2As_2 is not possible because all the samples synthesized so far are p -type with Fermi level below the valence band top. In contrast, a recent study employing optical conductivity and pump-probe photoemission has suggested that EuCd_2As_2 is, in fact, a semiconductor with an electronic gap of 0.77 eV instead of a Weyl semimetal[4]. Furthermore, a systematic investigation on the DFT calculation of materials family EuCd_2X_2 (X=P, As, Sb, Bi) revealed that the topological states of materials in this family are sensitive to the choice of functional and the value of Hubbard U , hence the conduction and valence band might not even be inverted in EuCd_2As_2 [16].

A well known prediction for a type-I Weyl semimetal is that the anomalous Hall conductivity (AHC) is solely determined by the distance between the Weyl nodes in the momentum space when the Fermi level is exactly at the Weyl crossings[17, 18]. Therefore, the AHC is ex-

(c) Temperature dependence of magnetic susceptibility χ with 0.1 T magnetic field applied along the c -axis. The inset shows the inverse susceptibility versus temperature and the Curie-Weiss fitting. (d) Magnetization versus field at different temperatures. The saturated magnetization is $\sim 7 \mu_B$ per Eu atom at the base temperature 2 K. (e) Temperature dependence of the electrical resistivity $\rho(T)$ between 2-300 K. The inset shows $\ln \rho$ versus the inverse of temperature $1/T$ of the sample from 10Sn. The transport activation gap $\Delta_{\text{gap}} = 55.8 \text{ meV}$ is obtained by fitting $\ln \rho$ versus $1/T$ in the temperature range of 30-100 K.

pected to approach a finite and constant value as carrier density decreases to zero, which serves as a direct evidence to distinguish Weyl semimetals from other trivial electronic states. In this work, we successfully synthesized EuCd_2As_2 single crystals with carrier density ranging from 10^{15} to 10^{16} cm^{-3} in the field induced FM state and conducted a systematic study of the transport behaviors of these samples. We found that the temperature dependence of resistivity of all samples show an insulating behavior, and the resistivity dramatically decreases by several orders of magnitude as Eu moments are fully saturated by a c -axis magnetic field. We found the AHC decreases by several orders of magnitude as the carrier density decreases, far below the value expected from previous DFT calculations that predicted Weyl semimetal phase in this system. In contrary, scaling analysis shows good agreement with the AHC in the variable range hopping regime. The optical transmittance measurement further confirms a finite optical gap of 0.7 eV, consistent with previous study. *Ab initio* calculation to compute the Hubbard U parameter of EuCd_2As_2 was also performed in this work, which reveals that previous calculations significantly underestimate the value of Hubbard U , highlighting the importance of correlation when determining the topological phase of magnetic semiconductors.

RESULTS

A. Transport and Magnetic Characterization

EuCd_2As_2 single crystals were synthesized via the Sn flux method[19]. We discovered that the residual carrier density of crystals is sensitive to the Sn flux ratio. The stoichiometric Eu pieces, Cd and As shots with 10 to 25 times atomic mass Sn shots yield EuCd_2As_2 crystals with hole carrier density spanning from 10^{15} to 10^{16} cm^{-3} . While it is unclear how the Sn flux ratio alters the defect density, the wide range of carrier density offers us a convenient knob to tune the transport properties of EuCd_2As_2 .

Figure 1(b) shows the powder X-ray diffraction of EuCd_2As_2 samples from batches using 10, 15, 20, and 25 Sn flux ratio (labeled as 10Sn, 15Sn, 20Sn, and 25Sn). All diffraction patterns and extracted lattice constants are identical to the previous report[19], indicating that the change of Sn flux ratio has minimal effect on structural properties. Similarly, the magnetic properties of samples from different batches show no measurable difference and agree with previous studies[3]. The representative data of a sample from 10Sn is summarized in Fig. 1. As shown in Fig. 1(c), the temperature dependence of c -axis magnetic susceptibility χ follows the Curie-Weiss temperature dependence, with a kink at 9.5 K indicating the onset of AFM order. Fitting the high temperature

FIG. 2. **Colossal Magnetoresistance.** (a) Temperature dependence of resistivity, $\rho(T)$, under different magnetic fields applied along the c -axis. (b) Resistivity ρ_{xx} versus magnetic field at temperatures between 2-200 K.

susceptibility with the Curie-Weiss law yields a Weiss temperature of -9.8 K and effective magnetic moment of $8.28 \mu_B$. Figure 1(d) shows the magnetization \mathbf{M} as a function of the field measured at different temperatures. At the base temperature 2 K, \mathbf{M} increases linearly before reaching the saturated value of $\sim 7 \mu_B$ per Eu atom, in agreement with the magnetic moment of a divalent Eu with half-filled $4f$ orbitals.

Unlike the structural and magnetic properties, the electrical transport of EuCd_2As_2 is very sensitive to the Sn flux ratio. Figure 1(e) shows the temperature dependence of in-plane resistivity $\rho(T)$ for samples selected from different batches. All samples show an insulating behavior below 100 K, where resistivity increases by three to seven orders of magnitude as the temperature decreases. This is very different from the semimetal behavior reported in previous literatures[1, 11, 12], with the exception of the most recent work[4]. The kink of resistivity at 9.5 K is consistent with the AFM transition determined from the magnetic susceptibility. Below 9.5 K the resistivity of the sample from 10Sn continuously increases, while samples from 15Sn, 20Sn, and 25Sn initially decrease before increasing again as the temperature cools further down to 2 K. The inset of Fig. 1(e) shows $\ln \rho$ versus $1/T$ of the sample from 10Sn. The black solid line denotes the linear fit of the $\ln \rho$ versus $1/T$ in the temperature range between 30 to 100 K, which allows us to extract the activation energy $\Delta_{gap} \sim 55.8$ meV using the relationship $\ln \rho = \frac{\Delta_{gap}}{2k_B T}$. We note that in a disordered semiconductor the activation energy extracted from resistivity is often related to the energy of impurity levels, which is much lower than the bandgap.

B. Colossal Magnetoresistance

The insulating resistivity of EuCd_2As_2 can be strongly modulated by the application of magnetic fields. The magnetoresistance of the sample from 10Sn is summarized in Fig. 2. The results are qualitatively similar to samples from other batches. Figure 2(a) shows the temperature dependence of the resistivity $\rho(T)$ under different magnetic fields from 0 to 7 T. The exponential increase of resistivity is suppressed by the external magnetic field, resulting in a dramatic decrease of resistivity by almost five orders of magnitude. As the magnetic field increases, the kink at Neel temperature is smeared, and a bump-like feature at ~ 20 K emerges for 1 T magnetic field and then shifts to the higher temperatures. For temperatures higher than 100 K, where resistivity is no longer following the thermally activated temperature dependence, the magnetoresistance becomes negligible.

Figure 2(b) shows the magneto-resistivity ρ_{xx} as a function of field at a fixed temperature between 2-200 K. It can be seen that at low temperatures resistivity abruptly drops by several orders of magnitude as magnetic field increases, followed by a kink at the saturation field, above which the resistivity increases again when magnetic moments are fully aligned with the field. As temperature increases, the drop of resistivity becomes more gradual and the kink is smeared out, which is highly correlated with the field dependence of magnetization at higher temperatures (Fig. 1(d)). This is consistent with the decrease of bandgap induced by the saturation of magnetization reported in Ref.[4]. The $\text{MR} = 100\% \times (\rho_{xx}(9\text{T}) - \rho_{xx}(0\text{T}))/\rho_{xx}(0\text{T})$ reaches negative 90% at $T < 50$ K. Such a colossal negative MR was also observed in several Eu-based semiconducting materials, a property that might be of interests for spintronics

applications[20, 21].

C. Anomalous Hall Effect

The Hall resistivity ρ_{xy} are shown in Fig. 3(a) for samples from 10Sn, 15Sn and 20Sn. Similar to the longitudinal resistivity ρ_{xx} , ρ_{xy} is also strongly affected by the magnetism. As temperature decreases, the field dependence of ρ_{xy} becomes highly non-linear and resembles that of the magnetization, a clear sign of anomalous Hall effect (AHE). For temperatures below 10 K, ρ_{xx} becomes too large (\sim M Ω cm) for magnetic fields below 2 T so that anti-symmetrization becomes too difficult to extract ρ_{xy} , and hence only data above 2 T is presented. To quantitatively understand the temperature and carrier density dependence of AHE, we extract the anomalous Hall resistivity, ρ_{xy}^A , and the ordinary Hall effect, $R_0\mu_0H$, from the linear fit of ρ_{xy} in the field range of 3 to 9 T using the expression $\rho_{xy} = R_0\mu_0H + \rho_{xy}^A$. The ordinary Hall coefficient, R_0 , allows us to calculate the carrier density n . The anomalous Hall resistivity ρ_{xy}^A is converted to AHC σ_{xy}^A via the expression $\sigma_{xy}^A = \rho_{xy}^A / (\rho_{xy}^A{}^2 + \rho_{xx}^2)$, where the values of ρ_{xx} is taken at 9 T, at which the magnetic moments are most aligned along the c -axis. Using ρ_{xx} at different fields results in minor changes of the absolute values AHC, but does not change its dependence on carrier density or longitudinal conductivity. Figures 3(b) and 3(c) show the temperature dependence of carrier density n and AHC σ_{xy}^A between 2 and 100 K. Intriguingly, the carrier densities of all three samples show a non-monotonic temperature dependence, which is in contrast to the thermally activated behavior where carrier density decreases monotonically with temperature. This is likely due to the interplay between the thermal activation of carriers and the change of magnetic configurations at elevated temperatures due to moment fluctuations. Regardless of the origin, the carrier density and the AHC measured across three samples show a substantial variation for $T < T_N$, providing us an opportunity to systematically investigate the carrier density dependence of AHC of EuCd₂As₂ in the field induced FM state.

In a Weyl semimetal, the Weyl nodes are the source and sink of Berry curvature flux in the momentum space. In an ideal time-reversal symmetry breaking Weyl semimetal, the single pair of Weyl nodes form a Berry curvature dipole gives rise to an intrinsic AHE solely depending on the separation of the Weyl nodes, $\sigma_{xy}^A = (e^2/2\pi h\Delta k)$. This σ_{xy}^A is topological and independent of the Fermi level position, hence we should expect a constant AHC even if the carrier density approaches zero. Here, we compiled the data of σ_{xy}^A and n extracted below 10 K in the field range of 3-9 T, where EuCd₂As₂ is in the field induced FM state, from Figs. 3(b) and 3(c), and plotted in Fig. 4(a) in a log-log scale. In addition to the data collected in this work (blue squares), the AHC mea-

sured from higher carrier density samples in the previous works are also included[1, 11–13]. The horizontal black dash line indicates the value of the intrinsic AHC, \sim 30 $\Omega^{-1}\text{cm}^{-1}$, from a single pair of Weyl points separated by 0.52 nm⁻¹ in ferromagnetic EuCd₂As₂ predicted by previous DFT calculations[1, 2]. As shown in Fig. 4(a), the observed σ_{xy}^A has a strong dependence of carrier density n and decreases dramatically as n decreases. As the carrier density approaches \sim 10¹⁵ cm⁻³, the AHC reaches a value that is five orders of magnitude smaller than the AHC expected for an ideal Weyl semimetal.

To gain insight into the underlying mechanism of the AHE in EuCd₂As₂, the σ_{xy}^A versus σ_{xx} ($\sigma_{xx} = \rho_{xx} / (\rho_{xy}^2 + \rho_{xx}^2)$) are plotted in Fig. 4(b). Note that we use the value of resistivity tensors at $\mu_0H = 9$ T for all conversions since both longitudinal and Hall resistivities depend strongly on the magnetic fields. As shown in the figure, all longitudinal conductivity σ_{xx} fall below the value of 1 $\Omega^{-1}\text{cm}^{-1}$, which belongs to the insulating regime, where conduction and AHE are governed by the variable range hopping or activated hopping process. Moreover, the AHC versus longitudinal conductivity can be well fitted by a power law relation, $\sigma_{xy}^A \propto \sigma_{xx}^\alpha$, with $\alpha = 1.6$ (black dash line). This is consistent with the previous experimental results and theoretical models of AHE in the insulating regime[22]. Thus, the observed AHC is fully consistent with EuCd₂As₂ being a magnetic semiconductor.

D. Optical Transmittance

As a final confirmation, the optical transmittance spectrum of sample 10Sn was measured by the Fourier Transform Infrared spectroscopy (FTIR) technique at room temperature. As shown in Fig. 5. EuCd₂As₂ remains transparent up to a wavenumber of 6000 cm⁻¹ (equivalent to \sim 0.74 eV), followed by a sharp drop of transmittance at higher wavenumber. This is consistent with the presence of a \sim 0.74 eV bandgap, which is in agreement with the optical study reported in Ref.[4].

DISCUSSION

The comprehensive anomalous Hall effect and optical transmittance measurements presented above clearly support the conclusion that EuCd₂As₂ is a magnetic semiconductor. A remaining question is why most of the previous first-principles calculations identify ferromagnetic EuCd₂As₂ as a Weyl semimetal. We note that recent calculations by Cuono *et al.*[23] have shown that electron correlation effects can significantly alter the electronic and topological behaviors of EuCd₂As₂. In particular, within the standard generalized gradient approximation (GGA) functional, antiferromagnetic

(AFM) EuCd_2As_2 can exhibit a vanishing electronic band gap and nontrivial band topology only when Eu's on-site Hubbard repulsion U is less than $\sim 6\text{eV}$ [16]. Previous theoretical and experimental studies have considered U values in the range of $\sim 3\text{-}5\text{eV}$ [3, 8, 10, 15, 24], which could tend to conclude that EuCd_2As_2 is topologically nontrivial. Since the Hubbard repulsion plays a

critical role, it is important to more accurately estimate the U value.

Here, we employ the linear response ansatz by Coccioni and de Gironcoli to determine the Hubbard U from first principles[23]. In this approach, the U value is derived by measuring the change in Eu f orbital occupation as a response to external perturbation of an on-

FIG. 5. **Transmittance spectrum.** Transmittance versus incident light wavenumber of sample 10Sn measured by FTIR at room temperature. The incident lights with wavenumber larger than 6000 cm^{-1} are fully absorbed, consistent with a bandgap of 0.74 eV .

site potential. Specifically, after an initial DFT ground state calculation, self-consistent response χ and non-self-consistent response χ_0 are constructed by computing the orbital occupation change respectively with and without DFT charge density updates. Afterwards, \mathbf{U} is determined by subtracting the inverse of the self-consistent response from the non-self-consistent one: $\mathbf{U} = \chi^{-1} - \chi_0^{-1}$. Figure 6(a) shows the corresponding calculation on a five-atom EuCd_2As_2 unit cell, in the external potential range -0.20 eV to 0.20 eV . When the perturbation is small, both response functions show a linear trend, so χ^{-1} and χ_0^{-1} can be obtained directly from the linear slopes. With a larger perturbation, the response functions may exist a non-linear behavior. In this case, the linear response approach can still be applied, by using a non-linear fit and then taking derivative near the zero potential[25]. The result is essentially equivalent to that of a linear fit in a smaller perturbation regime.

As seen in Fig. 6(a), the Hubbard \mathbf{U} for a five-atom EuCd_2As_2 unit cell is calculated to be 6.77 eV . Since the \mathbf{U} value is largely affected by charge screening, it is necessary to examine the convergence in larger DFT supercells. We have performed corresponding linear-response \mathbf{U} calculations up to a unit cell of 40 atoms, where the \mathbf{U} value is found to converge to $\sim 8 \text{ eV}$, as shown in Fig. 6(b). We also performed the calculations using different DFT ground states – including paramagnetic and AFM – and found that the resulting \mathbf{U} values only differ by less than $\sim 0.1 \text{ eV}$. Unlike the empirical values of $\mathbf{U} \sim 3\text{-}5 \text{ eV}$ considered in the literatures[3, 8, 10, 15, 24], the strong Hubbard repulsion $\mathbf{U} \sim 8 \text{ eV}$ discovered in our *ab initio* calculations thereby suggests a finite energy gap and only trivial band topology in EuCd_2As_2 . We also note that a meta-GGA or hybrid DFT functional would

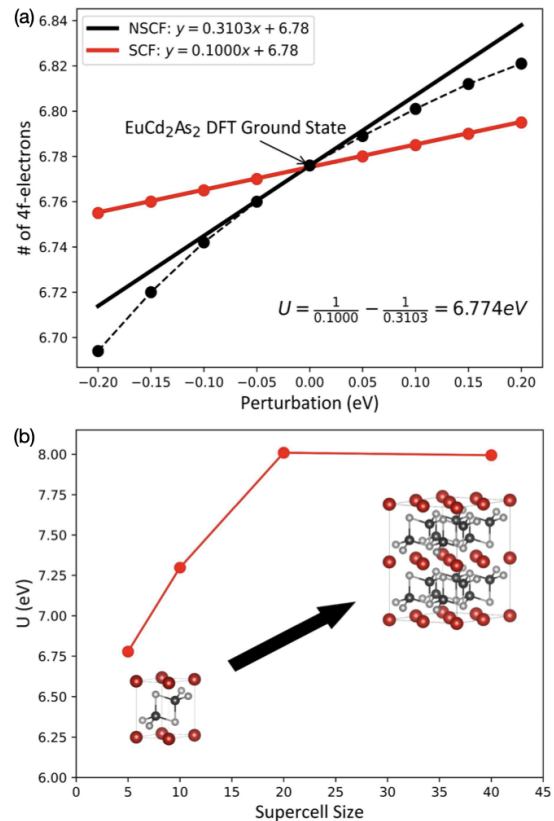

FIG. 6. **First-principle linear response calculations for the Hubbard \mathbf{U} of Eu atoms in EuCd_2As_2 .** (a) Fitted charge self-consistent (solid red line) and non-self-consistent (solid black line) linear response functions for a 5-atom EuCd_2As_2 unit cell. The inverse slopes of the response functions in the linear regime can be utilized to determine the \mathbf{U} value. (b) Convergence test of the calculated Hubbard \mathbf{U} parameter with respect to the supercell size. The results converge to $\mathbf{U} \sim 8 \text{ eV}$ in a 40-atom EuCd_2As_2 unit cell. Such a strong $\mathbf{U} \sim 8 \text{ eV}$ would lead to a finite energy gap and suppression of the topological behavior in EuCd_2As_2 .

lead to an ever larger energy gap that further suppresses the topological behavior[16]. Therefore, in accord with our carrier-control transport experiments, the theoretical results also indicate that EuCd_2As_2 is likely to be a topologically trivial magnetic semiconductor.

CONCLUSION

Our study revealed that the carrier density dependence of the anomalous Hall conductivity (AHC) in EuCd_2As_2 does not align with the expected behavior of an ideal Weyl semimetal. Instead, the scaling relationship between AHC and longitudinal conductivity is in good agreement with the characteristics of insulating hopping transport. These observations, coupled with the substantial electronic gap revealed in optical transmittance measurement, unambiguously establish that EuCd_2As_2 is

a magnetic semiconductor instead of a Weyl semimetal. We further performed *ab initio* calculations and discovered that the underestimation of Hubbard U could play a key role in previous misidentification of the topological phase in this material system. Despite being topological trivial, the resistivity of EuCd_2As_2 is extremely sensitive to the magnetic configuration of Eu-ordered moments, leading to a colossal magnetoresistance effect, indicative of a strong coupling between the electronic band gap and the magnetic orders. This unusual property may be useful for applications in spintronics and magneto-optoelectronics.

METHODS

Crystal synthesis. EuCd_2As_2 single crystals were synthesized via the Sn flux method[19]. To avoid oxidation, the start materials were weighed, mixed, and loaded in the glovebox filled with argon, and the ball valve was used to keep input materials from air when taking it out of the glovebox. This process yields ultra-clean single crystals with sizes up to a few millimeters. We discovered that the residual carrier density of crystals is highly sensitive to the ratio of Sn flux to start materials. The stoichiometric Eu pieces, Cd and As shots with 10, 15, 20, and 25 times atomic mass Sn shots yield EuCd_2As_2 with hole carrier density spanning from 10^{15} cm^{-3} to 10^{16} cm^{-3} , which allows us to use various carrier density as a convenient knob to study the electronic band structure of EuCd_2As_2 .

Materials characterization. The composition of all batches of crystals was determined by elemental analysis on a clean crystalline surface using a Sirion XL30 scanning electron microscope. All batches of crystals exhibited nearly perfect stoichiometric composition. A subset of crystals was crushed into fine powder and characterized by powder X-ray diffraction using Rigaku MiniFlex at room temperature. The obtained crystal structure and lattice constants of all batches of crystals are identical to previous reports[9].

Transport measurement. For transport measurements, the sample was cut into a rectangular plate using the wire saw and then made into a standard six-probe contact configuration with the current direction in-plane and the magnetic field out-of-plane (c -axis). The contact resistance of samples was limited to few hundreds Ω , which was achieved by sputtering gold pads on sample surface and adhering gold wires with sliver paste. The magneto-transport measurements were carried out in a 9T Physical Property Measurement System (PPMS). We utilized a Keithley2450 as the current source and voltmeter for measuring the $G\Omega$ level resistance benefiting from the high impedance resistance of Keithley2450.

Even though, the current source and measured voltage range should be adjusted accordingly to get a better signal as the resistivity changes a few orders of magnitude as temperature decreases in a short time. To eliminate any effects from contact misalignment, the magneto- and Hall resistance were symmetrized and anti-symmetrized respectively. Magnetization measurements were made using the vibrating sample magnetometry option of the PPMS.

Optical measurement. Fourier-transform infrared (FTIR) spectroscopy was conducted using the Hyperion 2000 system from Bruker Inc. The measurement was performed in the transmission mode, employing an infrared (IR) global source and a Liquid Nitrogen-cooled Mercury Cadmium Telluride (MCT) detector. To ensure optimal signal transmission, a thin crystal with the flat and clean surface was utilized. Additionally, a reference measurement was taken by passing the IR through a Si-wafer aside.

DFT calculation. Density functional theory (DFT) calculations were performed based on the plane-wave pseudopotential software VASP (the Vienna Ab initio Simulation Package)[26, 27]. The calculations utilized the Perdew-Burke-Ernzerhof generalized gradient approximation (PBE-GGA) functional[28] and the projector augmented wave (PAW) basis[29, 30]. Spin-orbit coupling (SOC) was also included. A theoretically relaxed EuCd_2As_2 crystal structure was considered, with the lattice parameters $a = 4.45 \text{ \AA}$ and $c = 7.35 \text{ \AA}$, which are within 1% errors compared to the experimental cell[31, 32]. Convergence tests with respect to the plane-wave cutoff energy and k-grid size were conducted. The calculations were converged with a cutoff energy of 600 eV, using the global break condition of 10^{-6} eV in the electronic self-consistent loops. For the largest 40-atom unit cell under study, a $9 \times 9 \times 5$ k-grid was adopted, which corresponds to a fine KPPRA (k-points per reciprocal atom) of 16,200. The DFT ground states provide the input charge densities and wavefunctions for subsequent *ab initio* linear-response U calculations[23] to determine the Hubbard U value on Eu atoms.
