A Modified Late Arrival Penalised User Equilibrium Model and Robustness in Data Perturbation

Manlan Li*and Huifu Xu[†]

January 2, 2024

Abstract

In a seminal paper [1], Watling proposes a stochastic variational inequality approach to model traffic flow equilibrium over a network where the transportation time is random and a path is selected by to transport if the user's expected utility of the transportation of the path is maximized over their paths. A key feature of Watling's model is that the user's utility function incorporates a penalty term for lateness and the resulting equilibrium is known as Late Arrival Penalised User Equilibrium (LAPUE). In this paper, we revisit the LAPUE model with a different focus: we begin by adopting a new penalty function which gives a smooth transition of the boundary between lateness and no lateness and demonstrate the LAPUE model based on the new penalty function has a unique equilibrium and is stable with respect to (w.r.t.) small perturbation of probability distribution under moderate conditions. We then move on to discuss statistical robustness of the modified LAPUE (MLAPUE) model by considering the case that the data to be used for fitting the density function may be perturbed in practice or there is a discrepancy between the probability distribution of the underlying uncertainty constructed with empirical data and the true probability distribution in future, we investigate how the data perturbation may affect the equilibrium. We undertake the analysis from two perspectives: (a) a few data are perturbed by outliers and (b) all data are potentially perturbed. In case (a), we use the well-known influence function to quantify the sensitivity of the equilibrium by the outliers and in case (b) we examine the difference between empirical distributions of the equilibrium based on perturbed data and the equilibrium based on unperturbed data. To examine the performance of the MLAPUE model and our theoretical analysis of statistical robustness, we carry out some numerical experiments, the preliminary results confirm the statistical robustness as desired.

Key words. Smooth penalty function for lateness, MLAPUE, distribution shift, data perturbation, statistical robustness

1 Introduction

Traffic assignment involves determining the flow patterns of arcs or paths in a traffic network, taking into account the network topology, origin-destination (OD) demands, and arc performance functions. Various models have been proposed for this, most of which are based on Wardrop's user equilibrium framework [2]. Wardrop states two principles in assigning vehicles into transportation network: (a) user equilibrium (UE); (b) system optimum (SO). The UE principle states that in a transportation network, individual travelers selfishly choose their routes to minimize their own travel costs. In other words, no traveler can decrease their travel time by unilaterally changing their route. This equilibrium ensures that no traveler has an incentive to switch to a different route, as it would increase their individual travel time. The SO principle, also known as the social optimum, aims to minimize the total travel time or cost for all travelers in the network. Unlike the UE, the SO does not consider individual behavior, rather it focuses on the overall efficiency of the transportation system. The SO condition is met when all travelers are assigned to routes that collectively minimize the total travel time or cost across the network. This may involve redistributing traffic from congested routes to less congested ones to improve the overall system performance. Beckmann et al [3] formulate UE as a mathematical program with symmetric arc costs while Smith [4] and Dafermos [5] cast it as a variational inequality (VI) problem with general asymmetric arc costs. In a more recent development, the UE model has been extended to encompass ride-hailing and ride-sharing services, see e.g. [6, 7, 8] and references therein.

The classic UE models assume that travelers make their choices based on fixed and known arc travel times, aiming to minimize their traffic times or costs. This assumption implies that travelers have complete information about the network and can accurately predict the travel times on each arc. In practice, travelers often face uncertainty and imperfect information about the actual travel times. To address the issue, Daganzo and Sheffi [9] propose a stochastic user equilibrium (SUE) model that takes into account the imperfect perceptions of travel times by travelers. Their model recognizes that travelers may have limited or inaccurate information about the actual travel conditions, and it incorporates these imperfect perceptions into the equilibrium framework. Lou et al [10] develop a mathematical model that incorporates travelers' bounded rationality and their decision-making process in response to congestion pricing strategies. They consider the uncertainties in travelers' route choices and develop a robust optimization approach to determine congestion pricing schemes that are resilient to the variations in travelers' behaviors and information. As Prakash et al mentioned in literature [11] that the traditional SUE models exhibit several drawbacks that limit their effectiveness. First, they do not adequately capture the risk preferences of users and the value of reliability in route choice, as empirical evidence suggests [12]. Second, while these models incorporate errors in users' perception of travel times, they treat actual travel times as deterministic [13]. Third, there is a lack of consistency in the assumptions made regarding the stochastic nature of different components of the traffic system within the equilibrium framework [14]. To address these limitations, Watling [13] introduces an extension to the standard SUE termed as Generalized SUE. This extension endogenously models the impact of flow variability on travel time variability, effectively addressing the latter two drawbacks mentioned above. Building upon this work, Nakayama and Watling [14] propose a comprehensive framework for formulating network equilibrium problems in stochastic networks. They present four model variants that differ in how stochastic flows are generated. While their framework provides a flexible and detailed characterization of equilibrium problems with stochastic flows, it does not explicitly consider the risk preferences of travelers.

Another stream of previous research acknowledges that traffic conditions inherently exhibit stochastic behavior, primarily due to uncertainties in both demand and supply factors. This line of investigation aims to develop more realistic models that capture how travelers behave in an uncertain traffic environment [15]. Multiple studies have focused on the reliability-based UE problem, which explicitly considers the risk preferences of travelers. In these studies, cost functions are employed that incorporate a measure of travel time reliability, allowing for a more comprehensive analysis of transportation network dynamics. A brief summary of each study is provided below, highlighting key model characteristics such as the reliability measure used, treatment of uncertainty, problem formulation, and solution algorithm. The proposed models encompass various behavioral assumptions regarding travelers' preference behaviors, including but not limited to models based on expected utility theory (e.g., [16]), the travel time budget models (e.g., [17]), the late arrival penalty model (e.g., [1]), the mean excess travel time model (e.g., [18]), the models based on cumulative prospect theory (e.g., [19, 15]) and the mean-risk model [20]. Regarding the treatment of uncertainty, existing models can be categorized based on how they handle uncertainty on the supply side [1], demand side [21, 22, 7], or both [23, 24]. For example, Lo, Luo, and Siu [17] develop a mathematical framework to capture the travel time budget of individual travelers, considering their risk preferences and the degradability of the transport network. The model allows for a more realistic representation of traveler behavior by accounting for the trade-off between travel time and the perceived risk associated with congestion.

Watling [1] proposes the late arrival penalty model and extends the UE to Late Arrival Penalized User Equilibrium (LAPUE). It incorporates the concept of late arrival penalties into the equilibrium condition to capture the preference of travelers for minimizing both travel time and the risk of arriving late to their destinations. LAPUE is a variation of the UE principle in transportation network modeling. In traditional UE travelers aim to minimize their travel time without explicitly considering the potential penalties associated with late arrival. However, in real-world scenarios, individuals often have time constraints or face penalties for arriving late, such as missing appointments, incurring financial costs, or experiencing inconvenience. The LAPUE principle addresses this by introducing penalties for late arrival. It assumes that travelers have a certain value or cost associated with arriving late, and they consider this penalty when making route choices. The objective for travelers in LAPUE is to minimize the total cost, which includes both travel time and the penalties for late arrival. Chen et al [21] introduce the α -reliable mean-excess traffic equilibrium model, which considers the stochastic nature of travel times and incorporates reliability considerations into the equilibrium framework. Nikolova and Stier-Moses [20] introduce a mean-risk traffic assignment model, which combines the mean travel time and a risk-aversion factor multiplied by the standard deviation of travel time along a path. This objective function allows users to incorporate their risk preferences into their route selection process. Ma et al [7] explore and address the challenges of modeling and solving the user equilibrium problem in stochastic ridesharing systems with elastic demand. For more descriptions of relevant aspects, we refer readers to the literature review section of [11] and the review [25].

In this paper, we revisit the LAPUE model but with some new focuses. First, we propose a parameterized penalty function for lateness which allows a smooth transition of the boundary between lateness and no lateness. Second, we demonstrate under some moderate conditions that the LAPUE based on the new penalty function approximates the LAPUE when the parameter is driven to 0. Third, we consider data perturbation in the modified LAPUE (MLAPUE) model. There are at least three types of perturbations which we believe may occur in practice: (a) the perceived data used for the construction of mathematical model are perturbed for various reasons such as measurement/recording errors; (b) there is a nominal distribution describing the probability distribution of the random parameters in a transportation network but the actual probability distribution of these uncertainty parameters might deviate from the nominal, e.g., due to unexpected closure of a road or prolonged duration of maintenance work; (c) the validation data (usually for future) may deviate from the current or past data that the model is developed. Under these circumstances, there is a need to investigate how the change of the data may affect the MLAPUE. We show under some moderate conditions that the MLAPUE based on the new penalty function is resilient to the exogenous data perturbation by exploiting classical techniques in robust statistics [26, 27] and recent developments on qualitative and quantitative statistical robustness analysis in risk management and operations research [28, 29, 30, 31, 32].

The rest of the paper is organized as follows. In Section 2, we recall the definition of the LAPUE model, introduce a MLAPUE model with a new penalty function for lateness and discuss existence and uniqueness of MLAPUE and its relation to LAPUE. We also propose sample average approximation of the MLAPUE model and discuss convergence of MLAPUE obtained with sample data converges to its true counterpart as the sample size goes to infinity. In Section 3, we discuss statistical robustness of MLAPUE when the sample data are perturbed. In Section 4, we report numerical test results of the statistical robustness of sample average approximated MLPAUE. Finally we conclude with some remarks in Section 5. All proofs of technical results are delegated to the appendix.

Throughout the paper, we use the following notation.

- G: directed graph representing the transportation network;
- \mathcal{N} : the set of nodes on G and $|\mathcal{N}| = n$ where $|\mathcal{N}|$ denotes cardinality of set \mathcal{N} ;
- \mathcal{A} : the set of arcs on G and $|\mathcal{A}| = A$;
- \mathcal{W} : the set of all original-destination pairs on G and $|\mathcal{W}| = W$;
- R_k : the set of paths connecting the OD pair $k = 1, \dots, W$;
- \mathcal{R} : collection of paths between all OD pairs $\mathcal{R} = \bigcup_{k=1}^{W} R_{K}$ and $|\mathcal{R}| = N$;
- q_k : demand between OD pair k;
- f_r : flow on path r;
- $\boldsymbol{f} \in \mathbb{R}^N$: vector of path flows with component variable f_r for $r \in \mathcal{R}$;

- v_a : flow on arc a;
- $\boldsymbol{v} \in \mathbb{R}^A$: vector of arc-flows with component variable v_a for $a \in \mathcal{A}$;
- δ_{ar} : arc-path indicator variable;
- Δ : arc-path incidence matrix;
- Π: OD-path incidence matrix;
- $\xi \in \mathbb{R}^k$: the vector of uncertain factors;
- $t_a^Q(\boldsymbol{v})$: mean travel time on arc $a \in A$ under the distribution Q of random vector ξ when the overall arc-flow distribution is \boldsymbol{v} ;
- $t^{Q}(v) \in \mathbb{R}^{A}$: vector of mean arc travel time under the distribution Q when the overall arc-flow distribution is v;
- $T(v,\xi) \in \mathbb{R}^A$: the vector of actual arc travel time which depends on the arc flow vector v and random vector ξ ;
- $C_r(f,\xi)$: random travel time along path $r \in \mathcal{R}$ when the overall path-flow distribution is f;
- $C(f,\xi)$: vector of path travel times when the overall path-flow distribution is f;
- $u_r(f,\xi)$: disutility of path $r \in \mathcal{R}$ when the overall path-flow distribution is f;
- $u(f,\xi)$: vector of path-disutility when the overall path-flow distribution is f;
- ${\rm I\!R}^N$ and ${\rm I\!R}^N_+ :$ $N\text{-dimensional Euclidean space and its nonnegetive subspace.$
- $\|\cdot\|$ denotes the Euclidean norm in a finite dimensional space unless specified otherwise.

2 Watling's LAPUE model and its variation

The transportation network of interest is represented by a directed graph $G(\mathcal{N}, \mathcal{A})$, where \mathcal{N} denotes the set of n nodes and \mathcal{A} represents the set of A directed arcs. The set of all origindestination (OD) pairs on the network G is denoted by \mathcal{W} , and the set of path connecting the OD pair k is given by R_k for $k = 1, \dots, \mathcal{W}$. The entire collection of paths between all the OD pairs is represented by $\mathcal{R} = \bigcup_{k=1}^W R_k$. The total number of paths is given by $N = |\mathcal{R}|$. Let $q \in \mathbb{R}^W$ be a vector of demands with components q_k representing the deterministic demand on the kth OD.

For a deterministic demand vector \boldsymbol{q} , an assignment of flows to all paths is denoted by a vector $\boldsymbol{f} \in \mathbb{R}^N$, where each component f_r represents the flow on path r. In order to be feasible for meeting the demand, we must have $\boldsymbol{f} \in D$ where

$$D = \left\{ \boldsymbol{f} \in \mathbb{R}^N_+ : \Pi \boldsymbol{f} = \boldsymbol{q} \right\},$$
(2.1)

and Π denotes the OD-pair incidence matrix with entries $\pi_{k,r} = 1$ if path r connects the kth OD, and $\pi_{k,r} = 0$ otherwise. While an assignment of flows to all arcs is denoted by $\boldsymbol{v} \in \mathbb{R}^A$ with components v_a representing the flow on arc a. The path flows are related to the arc flows by

$$\boldsymbol{v} = \Delta \boldsymbol{f},\tag{2.2}$$

where Δ is the arc-path incidence matrix with components $\delta_{ar} = 1$ if arc *a* is on path *r*, and $\delta_{ar} = 0$ otherwise. Based on relation in (2.2), we denote the set of demand-feasible arc flow vectors similarly by

$$\tilde{D} = \left\{ \boldsymbol{v} \in \mathbb{R}^A : \boldsymbol{v} = \Delta \boldsymbol{f} \text{ and } \boldsymbol{f} \in D \right\}.$$
(2.3)

2.1 LAPUE model

Watling [1] proposes a generalised UE model known as *late arrival penalised user equilibrium* (LAPUE) which reflects (a) a driver's valuation of path's expected attributes, such as distance, expected travel time, tolls, and more; and (b) the extent to which following the path is likely, in the light of travel time variability, to satisfy a traveller on that OD pair in achieving an "acceptable" arrival time at the destination.

Let T(v) denote the vector of arc travel times, where component $T_a(v)$ represents the actual travel time on arc *a* for $a = 1, \dots, A$. Since arc travel time is often random, the path travel time is also a random vector. We denote it by C(f), where the *r*th component C_r represents the travel time on path *r*, which is related to the random arc travel time vector by the transformation

$$\boldsymbol{C}(\boldsymbol{f}) = \boldsymbol{\Delta}^{\top} \boldsymbol{T}(\boldsymbol{v}). \tag{2.4}$$

For each OD pair $k \in \{1, \dots, W\}$, let τ_k be a longest acceptable travel time. Watling [1] uses a composite path disutility to incorporate both the standard "generalized travel time" and the travel time acceptability in the form of a lateness penalty:

$$u_r = \theta_0 d_r + \theta_1 C_r + \theta_2 \max(C_r - \tau_k, 0), \text{ for } r = 1, \cdots, N, \ k = 1, \cdots, W,$$
(2.5)

where d_r denotes the composite of attributes (such as distance) that are independent on time/flow and θ_0 is the value placed on these attributes, θ_1 is the value-of-time, and θ_2 reflects the value of being one time unit later than acceptable. This is indeed a key feature of the LAPUE model. By introducing ψ_r to represent the marginal density function of C_r , we can reformulate the expected disutility of path r as

$$\mathbb{E}[u_r] = \theta_1 \mathbb{E}[C_r] + \theta_2 \mathbb{E}[\max(C_r - \tau_k, 0)]$$

= $\theta_0 d_r + \theta_1 \mathbb{E}[C_r] + \theta_2 \int_{\tau_k}^{\infty} (c - \tau_k) \psi_r(c) dc$, for $r = 1, \cdots, N, \ k = 1, \cdots, W$, (2.6)

where $\mathbb{E}[\cdot]$ is the expectation taken w.r.t. the probability distribution of C_r .

In the forthcoming discussions, we will investigate UE in terms of path flow and arc flow. To this end, we need to represent the user's disutility in terms of f and v. We begin by rewriting the path travel time C and the arc travel time T in (2.2) and (2.4) respectively as $C(f,\xi)$ and $T(v,\xi)$ to indicate explicitly that both quantities depend on f, v and random vector ξ , where the latter is known as arc performance function in transportation network. The random vector ξ is used to describe various uncertain factors affecting the travel time on a path (or arc) and we assume that ξ takes values on a compact set $\Xi \subseteq \mathbb{R}^k$. Note that in the literature of transportation research, the sources of uncertainty behind travel time are not explicitly indicated, rather the capacity of arc are made random when the demand is deterministic. Here we adopt a new form of representation to separate the the decision vector f(v) from random vector ξ .

Recall that $C(f,\xi) = \Delta^{\top} T(v,\xi)$ and $v = \Delta f$, where Δ is the arc-path incidence matrix with entries $\delta_{a,r} = 1$ if arc *a* is on the path *r*, and $\delta_{a,r} = 0$ otherwise. In some literature of transportation research with uncertain supply, the components of the arc travel time $T(v,\xi)$ are described by a so-called generalized Bureau of Public Roads (GBPR) function:

$$T_a(\boldsymbol{v},\xi) = t_a^0 \left(1 + b_a \left(\frac{v_a}{C_a(\xi)} \right)^{n_a} \right), \qquad (2.7)$$

where t_a^0, b_a and n_a are given parameters, t_a^0 denotes the arc free-flow travel time of arc a, $C_a(\xi)$ denotes the random capacity of arc a and v_a represents the flow of arc a, see e.g. [33, 24, 34]. Let $\boldsymbol{\tau} = (\boldsymbol{\tau}_1^\top, \cdots, \boldsymbol{\tau}_W^\top)^\top \in \mathbb{R}^N$ be a block vector, where the kth block $\boldsymbol{\tau}_k$ is a column vector with dimensions $|R_k|$ and each component takes the same value $\boldsymbol{\tau}_k$. Under the settings outlined above, we can write the disutility function of path as

$$\boldsymbol{u}(\boldsymbol{f}, \boldsymbol{C}(\boldsymbol{f}, \xi)) = \theta_0 \boldsymbol{d} + \theta_1 \boldsymbol{C}(\boldsymbol{f}, \xi) + \theta_2 \max\{\boldsymbol{C}(\boldsymbol{f}, \xi) - \boldsymbol{\tau}, 0\},$$
(2.8)

and the LAPUE model in [1] as the following stochastic variational inequality problem:

(SVIP-path)
$$0 \in \mathbb{E}_P[\boldsymbol{u}(\boldsymbol{f}, \boldsymbol{C}(\boldsymbol{f}, \xi))] + \mathcal{N}_D(\boldsymbol{f}),$$
 (2.9)

where $\boldsymbol{u}: \mathbb{R}^N \times \mathbb{R}^k \to \mathbb{R}^N$ is a continuous vector-valued function,

$$\mathcal{N}_D(\boldsymbol{f}) = \{ \boldsymbol{w} \in \mathrm{I\!R}^N : \boldsymbol{w}^T(\boldsymbol{g} - \boldsymbol{f}) \leq 0, \forall \boldsymbol{g} \in D \}$$

is the normal cone to the convex set D at $\mathbf{f}, \xi : \Omega \to \mathbb{R}^k$ is a random vector defined on a probability space $(\Omega, \mathcal{F}, \mathbb{P})$ with probability distribution $P \in \mathscr{P}(\Xi)$, which can be reflected on the uncertain factors, $\mathbb{E}_P[\cdot]$ is the expected value w.r.t. P and $\mathscr{P}(\Xi)$ denotes the set of all probability measures over Ξ . We call a solution to SVIP-path (2.9) an LAPUE and use $\mathcal{F}(P)$ to denote the set of all such solutions. Note that in the case when $\theta_2 = 0$, the LAPUE model collapses to UE model. Moreover, by the connection between $C(\mathbf{f}, \xi)$ and $T(\mathbf{v}, \xi)$ as well as path flow \mathbf{f} and arc flow \mathbf{v} , the SVP-path (2.9) can be equivalently presented as follows:

(SVIP-arc)
$$0 \in \mathbb{E}_P[\tilde{\boldsymbol{u}}(\boldsymbol{v}, \boldsymbol{T}(\boldsymbol{v}, \boldsymbol{\xi}))] + \mathcal{N}_{\tilde{D}}(\boldsymbol{v}),$$
 (2.10)

where

$$\tilde{\boldsymbol{u}}(\boldsymbol{v}, \boldsymbol{T}(\boldsymbol{v}, \xi)) = \theta_0 \boldsymbol{d} + \theta_1 \Delta^\top \boldsymbol{T}(\boldsymbol{v}, \xi) + \theta_2 \max\{\Delta^\top \boldsymbol{T}(\boldsymbol{v}, \xi) - \boldsymbol{\tau}, 0\},$$
(2.11)

and D is defined as in (2.3). We also call a solution to SVIP-arc (2.10) an LAPUE. In the rest of the paper, we use terminologies "LAPUE" and "solution to SVIP-arc" interchangeably. The difference between the two forms of LAPUE is that the former is presented in terms of path flow whereas the latter is in arc flow. The next theorem summarizes existence and uniqueness of LAPUE from Watling [1] in terms of the solutions to SVIP-path (2.9) and SVIP-arc (2.10). **Theorem 2.1 (Existence and uniqueness of LAPUE [1])** Consider the marginal path travel time density function for path r and write it as $\psi_r(c_r; \mu_r)$ to denote its (partial) parameterisation by the mean path travel time μ_r . Assume: (a) the functions

$$F_r(\mu_r) = \int_{\tau_k}^{\infty} (c - \tau_k) \psi_r(c; \mu_r) dc, \text{ for } r \in R_k, k = 1, \cdots, W$$

are well-defined, continuous and non-decreasing; (b) $\theta_1 > 0$ and $\theta_2 \ge 0$ in (2.6); (c) the mean arc travel time functions $t_a^P(\mathbf{v})$ are continuous and strictly monotone mapping. Then both SVIP-path (2.9) and SVIP-arc (2.10) have a solution, and SVIP-arc (2.10) has a unique solution.

Non-uniqueness of solution to SVIP-path (2.9) is due to the fact that the matrix Δ is not necessarily of full column rank. For the purposes of theoretical analysis, we make the following assumption for SVIP-path (2.9).

2.2 A new penalty function for lateness and the MLAPUE model

In this paper, our focus is not on Watling's original LAPUE model, rather it is on its modification and statistical robustness of the resulting UE against data perturbation. Specifically we propose to adopt a different penalty function for lateness as follows:

$$h(z,t) = \begin{cases} z, & \text{for } t < z, \\ \frac{1}{4t}(z^2 + 2zt + t^2), & \text{for } -t \le z \le t, \\ 0, & \text{for } z < -t, \end{cases}$$
(2.12)

where t > 0 is a small positive number.

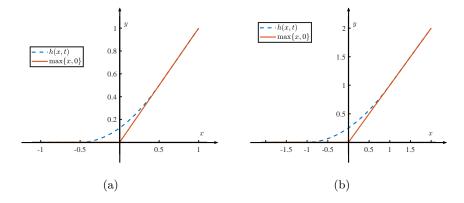

Figure 1: (Color online) (a)-(b) Parameterized penalty function with parameter t = 0.5 and t = 1.

Compared to the max penalty function $\max\{z, 0\}$, h(z, t) is parameterized by a positive number t, which means that when the lateness exceeds -t, there is a penalty and this penalty increases gradually as z increases. The new penalty function gives a smooth transition of the boundary between lateness and no lateness. In practice, we can interpret this as driver/traveller becoming increasingly worried when the travel time approaches the longest acceptable travel time τ_k . When z exceeds t, the penalty is back up to the Watling's maximum penalty. The new penalty function gives us some flexibility to model a driver/traveller's risk preference on lateness by setting a different value of t. Mathematically, the new penalty function enjoys nicer property because it is continuously differentiable at z = 0 and it approximates the maximum penalty function when $t \to 0$. The continuous differentiability allows use to undertake robustness/resilient of the resulting LAPUE againt data perturbation, and this is indeed another major reason why we adopt the new penalty. Note that it is possible to adopt other parametric penalty functions with similar properties, here we concentrate on (2.12) as it is the simplest.

Let

$$\hat{\boldsymbol{u}}(\boldsymbol{f}, \boldsymbol{C}(\boldsymbol{f}, \boldsymbol{\xi}), t) := \boldsymbol{g}(\boldsymbol{f}, \boldsymbol{C}(\boldsymbol{f}, \boldsymbol{\xi})) + \boldsymbol{h}(\boldsymbol{f}, \boldsymbol{C}(\boldsymbol{f}, \boldsymbol{\xi}), t),$$
(2.13)

where $\boldsymbol{g}(\boldsymbol{f}, \boldsymbol{C}(\boldsymbol{f}, \xi)) = \theta_0 \boldsymbol{d} + \theta_1 \boldsymbol{C}(\boldsymbol{f}, \xi), \ \boldsymbol{h}(\boldsymbol{f}, \boldsymbol{C}(\boldsymbol{f}, \xi), t) := \theta_2 \boldsymbol{h}(\boldsymbol{C}(\boldsymbol{f}, \xi) - \boldsymbol{\tau}, t)$ and the penalty function \boldsymbol{h} acts componentwise. The modified LAPUE model can be written as the following modified SVIP

(MSVIP)
$$0 \in \mathbb{E}_P[\hat{\boldsymbol{u}}(\boldsymbol{f}, \boldsymbol{C}(\boldsymbol{f}, \boldsymbol{\xi}), t)] + \mathcal{N}_D(\boldsymbol{f}).$$
 (2.14)

We call a solution to the MSVIP a modified LAPUE (MLAPUE) and use $\mathcal{F}_t(P)$ to denote the set of all such solutions. We indicate in the notation explicitly the dependence on t and P because we will consider variation of t later in this section and the case when P is perturbed from Section 3. The next proposition states existence and uniqueness of an MLAPUE.

Proposition 2.1 (Existence and uniqueness of MLAPUE) Assume: (a) the conditions of Theorem 2.1 (b-c) hold, (b) the functions

$$F_r(\mu_r, t) = \int_{\tau_k - t}^{\infty} h(c - \tau_k, t) \psi_r(c; \mu_r) dc, \text{ for } r \in R_k, k = 1, \cdots, W$$

are well-defined, continuous and non-decreasing for fixed t > 0, where $h(\cdot, t)$ is defined as in (2.12) $\psi_r(c_r; \mu_r)$ is defined as in Theorem 2.1. Then MSVIP has a solution, and the associated MLAPUE in terms of arc flow is unique.

We skip the proof because the only difference between Proposition 2.1 and Theorem 2.1 is that $F_r(\mu_r)$ is replaced by $F_r(\mu_r, t)$. The replacement does not affect the key properties of the disutility function u in the proof of Theorem 2.1, which means the proof of Theorem 2.1 is applicable to that of Proposition 2.1.

Next, we investigate the relationship between MLAPUE and LAPUE. We do so by showing $\mathbb{D}(\mathcal{F}_t(P), \mathcal{F}(P)) \to 0$ as $t \to 0$, where $\mathbb{D}(A, B)$ denotes the deviation distance $\mathbb{D}(A, B) = \sup_{x \in A} d(x, B)$, in other words, we can interpret MLAPUE as an approximation of LAPUE as t is sufficiently small. To this end, we need to make some technical assumptions.

Assumption 2.1 For fixed t > 0, there exists a convex compact set $\mathbb{F}_t \subset \mathbb{R}^N$ which contains $\mathcal{F}_t(P) + b\mathcal{B}$ for some positive number b, where \mathcal{B} is a unit ball in \mathbb{R}^N . Let $\mathbb{V}_t := \{ v = \Delta f | f \in \mathbb{F}_t \} \subseteq \mathbb{R}^A$.

The assumption virtually requires $\mathcal{F}_t(P)$ to be bounded. We introduce set \mathbb{F}_t containing an open neighborhood of $\mathcal{F}_t(P)$ purely for the convenience of theoretical analysis in the forthcoming discussions in Section 3. The next assumption requires the travel time function to be continuous differentiable and Lipschitz continuous with respect to arc flow, and integrably boundedness both of which are needed in the forthcoming theoretical analysis in this section and the next section.

Assumption 2.2 For the probability distribution $P \in \mathscr{P}(\Xi)$,

- (a) $T(\cdot,\xi)$ is continuously differentiable for every $\xi \in \Xi$;
- (b) there exists some measurable function $\Phi_1(\xi)$ such that $\sup_{v \in \mathbb{V}_t} \|T(v,\xi)\| \leq \Phi_1(\xi)$ and $\mathbb{E}_P[\Phi_1(\xi)] < \infty;$
- (c) there exists a positive measurable function $\Phi_2(\xi)$ such that $\mathbb{E}_P[\Phi_2(\xi)] < \infty$ and

$$\|T(v,\xi) - T(v',\xi)\| \le \Phi_2(\xi) \|v - v'\|_{2}$$

for all $v, v' \in \mathbb{V}_t$, and $\xi \in \Xi$, where \mathbb{V}_t is defined as in Assumption 2.1.

Assumption 2.2 is satisfied when each component of $T(v, \xi)$ is BPR function defined as in (2.7). We will come back to this in Section 3.3. Let

$$\hat{\mathscr{P}} := \{ Q \in \mathscr{P}(\Xi) : \mathbb{E}_Q[\Phi_1(\xi)] < \infty, \mathbb{E}_Q[\Phi_2(\xi)] < \infty \}.$$
(2.15)

The next proposition states some important properties of user's disutility function under the new penalty function (2.12).

Proposition 2.2 (Properties of the new disutility function) Under Assumption 2.2, the following assertions hold for the parametric disutility function $\hat{u}(f, C(f, \xi), t)$.

- (i) $\hat{\boldsymbol{u}}(\cdot, \boldsymbol{C}(\cdot, \xi), t)$ is continuously differentiable for every $\xi \in \Xi$ and t > 0;
- (ii) There exists some measurable function $\tilde{\Phi}_1(\xi, t)$ such that $\sup_{\boldsymbol{f}\in\mathbb{F}_t} \|\hat{\boldsymbol{u}}(\boldsymbol{f}, \boldsymbol{C}(\boldsymbol{f}, \xi), t)\| \leq \tilde{\Phi}_1(\xi, t)$ and $\mathbb{E}_P[\tilde{\Phi}_1(\xi, t)] < \infty$ for any fixed t > 0.
- (iii) There exists a positive measurable function $\Phi_2(\xi)$ such that $\mathbb{E}_P[\Phi_2(\xi)] < \infty$ and for every $\xi \in \Xi$ and t > 0,

$$\|\hat{\boldsymbol{u}}(\boldsymbol{f},\boldsymbol{C}(\boldsymbol{f},\boldsymbol{\xi}),t)-\hat{\boldsymbol{u}}(\boldsymbol{f}',\boldsymbol{C}(\boldsymbol{f}',\boldsymbol{\xi}),t)\| \leq \eta_{\Delta^{\top}}\eta_{\Delta}(\theta_1+\theta_2)\Phi_2(\boldsymbol{\xi})\|\boldsymbol{f}-\boldsymbol{f}'\|, \ \forall \boldsymbol{f},\boldsymbol{f}'\in\mathbb{F}_t,$$

where \mathbb{F}_t is defined as in Assumption 2.1 and $\tilde{\Phi}_1(\xi, t) = \eta_{\Delta^{\top}}(\theta_1 + \theta_2)\Phi_1(\xi) + \theta_0 \|\boldsymbol{d}\| + \theta_2 \|\boldsymbol{\tau}\| + t$.

Proposition 2.2 (ii) implies that $\mathbb{E}_P[\hat{\boldsymbol{u}}(\boldsymbol{f}, \boldsymbol{C}(\boldsymbol{f}, \xi), t)]$ is well-defined for each fixed $t \geq 0, \boldsymbol{f} \in \mathbb{F}$ and $P \in \hat{\mathscr{P}}$, where $\hat{\mathscr{P}}$ is defined as (2.15). Together with (i) and (iii), $\mathbb{E}_P[\hat{\boldsymbol{u}}(\boldsymbol{f}, \boldsymbol{C}(\boldsymbol{f}, \xi), t)]$ is continuously differentiable in \boldsymbol{f} , this is, $\nabla_{\boldsymbol{f}} \mathbb{E}_P[\hat{\boldsymbol{u}}(\boldsymbol{f}, \boldsymbol{C}(\boldsymbol{f}, \xi), t)] = \mathbb{E}_P[\nabla_{\boldsymbol{f}} \hat{\boldsymbol{u}}(\boldsymbol{f}, \boldsymbol{C}(\boldsymbol{f}, \xi), t)]$ for each $\boldsymbol{f} \in \mathbb{F}$, fixed t > 0 and $P \in \hat{\mathscr{P}}$, where $\nabla_{\boldsymbol{f}} \hat{\boldsymbol{u}}(\boldsymbol{f}, \boldsymbol{C}(\boldsymbol{f}, \xi), t)$ denotes the Jacobian of $\hat{\boldsymbol{u}}$ in \boldsymbol{f} . Next, we need to introduce a notion of so-called strong regularity of a generalized equation. This is because we will use generalized equation as a mathematical framework for undertaking the desired theoretical analysis of MLAPUE defined by MSVIP, a special generalized equation.

Definition 2.1 (Strong regularity) Let Z and W be Banach spaces, $\phi : Z \to W$ be a continuously differentiable mapping, $\mathcal{N} : Z \rightrightarrows W$ be a set-valued mapping. Consider the generalized equation: find $z \in Z$ such that

$$0 \in \phi(z) + \mathcal{N}(z). \tag{2.16}$$

A solution z_0 is said to be strongly regular if there exist neighborhoods \mathcal{V}_Z and \mathcal{V}_W of $z_0 \in Z$ and $0 \in W$, respectively, such that for every $\delta \in \mathcal{V}_W$, the linearized abstract generalized equation

$$\delta \in \phi(z_0) + D\phi(z_0)(z - z_0) + \mathcal{N}(z)$$

has a unique solution in \mathcal{V}_Z , denoted by $\zeta(\delta)$, and the mapping $\zeta : \mathcal{V}_W \to \mathcal{V}_Z$ is Lipschitz continuous with constant c.

In the case that $\mathcal{N}(z) = 0$, the strong regularity conditions is equivalent to the case that $D\phi(z_0)$ is one-to-one and onto mapping. With the proposition and the notion of strong regularity, we are now ready to state our main result in this section.

Theorem 2.2 (Approximation of MLAPUE to LAPUE) Under the conditions of Proposition 2.1 and Assumption 2.2, the following assertions hold.

(i) If there exists an integral function $\varphi(\cdot)$ such that each component of $\hat{u}(f, C(f, \xi), t)$ is bounded by $\varphi(\xi)$, then

$$\limsup_{t\downarrow 0} \mathcal{F}_t(P) \subset \mathcal{F}(P), \tag{2.17}$$

where $\limsup_{t\downarrow 0} \mathcal{F}_t(P)$ denotes the outer limit of $\mathcal{F}_t(P)$ at point 0 (see Definition A.1 in the appendix).

(ii) Let $f(P) \in \mathcal{F}(P)$. If $\Upsilon(f) := \phi(f, P) + \mathcal{N}_D(f)$ is metrically regular (see Definition A.3) at f(P) for 0 with regularity modulus α , then there exist a closed neighborhood $\mathcal{V}_{f(P)}$ of f(P) and a sufficiently small constant $t_0 > 0$ such that

$$d(\boldsymbol{f}_t(P), \boldsymbol{\mathcal{F}}(P)) \le \alpha \sup_{\boldsymbol{f} \in \mathcal{V}_{\boldsymbol{f}(P)}} \| \hat{\phi}_t(\boldsymbol{f}, P) - \phi(\boldsymbol{f}, P) \|$$
(2.18)

for all $f_t(P) \in \mathcal{F}_t(P) \cap \mathcal{V}_{f(P)}$ and $t \in (0, t_0]$, where

$$\hat{\phi}_t(\boldsymbol{f}, P) := \mathbb{E}_P[\hat{\boldsymbol{u}}(\boldsymbol{f}, \boldsymbol{C}(\boldsymbol{f}, \xi), t)] \text{ and } \phi(\boldsymbol{f}, P) := \mathbb{E}_P[\boldsymbol{u}(\boldsymbol{f}, \boldsymbol{C}(\boldsymbol{f}, \xi))], \qquad (2.19)$$

 $\|\cdot\|$ denotes the Euclidean norm on \mathbb{R}^N and d(b, B) denotes the distance from a point b to a set B; if Υ is strongly metrically regular at $\mathbf{f}(P)$ for 0 with same regularity modulus, then there exist a unique $\mathbf{f}_t(P) \in \mathcal{F}_t(P) \cap \mathcal{V}_{\mathbf{f}(P)}$ such that

$$\|\boldsymbol{f}_t(P) - \boldsymbol{f}(P)\| \le \alpha \sup_{\boldsymbol{f} \in \mathcal{V}_{\boldsymbol{f}(P)}} \|\hat{\phi}_t(\boldsymbol{f}, P) - \phi(\boldsymbol{f}, P)\|$$
(2.20)

for all $t \in (0, t_0]$, where $\Upsilon^{-1}(0) := \{ \boldsymbol{f} \in \mathbb{R}^N : 0 \in \Upsilon(\boldsymbol{f}) \} = \boldsymbol{\mathcal{F}}(P).$

Theorem 2.2 (i) guarantees the convergence of MLAPUE to LAPUE as t is driven to 0. Theorem 2.2 (ii) is an implicit function theorem, where (2.20) gives a bound for the difference of $f_t(P)$ and f(P) in terms of the uniform difference of $\hat{\phi}_t(f, P)$ and $\phi(f, P)$. Metric regularity is a generalization of Jacobian nonsingularity of a vector-valued function to a set-valued mapping [35]. It is virtually about Lipschitz continuity of the inverse of a set-valued mapping, that is, $\Upsilon(f) := \phi(f, P) + \mathcal{N}_D(f)$ in our context. Strong regularity requires the inverse of the set-valued mapping to be single-valued in the considered neighborhoods.

2.3 Sample average approximation and perturbation of distribution

In practice, we may use empirical data to solve MSVIP problem (2.14), that is, use empirical travel time dataset to approximate the probability distribution of true travel time. For example, when the travel time function $T_a(\boldsymbol{v},\xi)$ is the BPR function given in (2.7), we can use the empirical data of $T_a(\boldsymbol{v},\xi)$ to derive the empirical data of random capacity $C_a(\xi)$. To facilitate theoretical analysis, we assume that ξ^1, \dots, ξ^M are the corresponding samples and they are generated by the true probability distribution P of ξ . We consider the sample average approximation of MSVIP

(SAA-MSVIP)
$$0 \in \frac{1}{M} \sum_{i=1}^{M} \hat{\boldsymbol{u}}(\boldsymbol{f}, \boldsymbol{C}(\boldsymbol{f}, \xi^{i}), t) + \mathcal{N}_{D}(\boldsymbol{f}).$$
 (2.21)

Let $P_M := \frac{1}{M} \sum_{i=1}^M \delta_{\xi^i}$ be an empirical distribution of ξ^1, \dots, ξ^M , where δ_{ξ^i} denotes the Dirac measure at ξ^i . We use $\mathcal{F}_t(P_M)$ to denote the set of solutions to (2.21). In practice, we often obtain only one solution instead of multiple solutions of (2.21). Since the solution is based on sample data, we call it a statistical estimator of some $f_t(P) \in \mathcal{F}_t(P)$. The next theorem states existence of a solution to (2.21) and convergence of the solution as the sample size goes to infinity.

Theorem 2.3 Let $f_t(P)$ be a strongly regular solution to MSVIP problem (2.14), i.e., there exist neighborhoods \mathcal{V}_0 and $\mathcal{V}_{f_t(P)}$ of $0 \in \mathbb{R}^N$ and $f_t(P)$, respectively, such that for $\delta \in \mathcal{V}_0$, the following generalized equation

$$\delta \in \mathbb{E}_P[\hat{\boldsymbol{u}}(\boldsymbol{f}_t(P), C(\boldsymbol{f}_t(P), \xi), t)] + \nabla_{\boldsymbol{f}} \mathbb{E}_P[\hat{\boldsymbol{u}}(\boldsymbol{f}_t(P), \boldsymbol{C}(\boldsymbol{f}_t(P), \xi), t)](\boldsymbol{f} - \boldsymbol{f}_t(P)) + \mathcal{N}_D(\boldsymbol{f}) \quad (2.22)$$

has a unique solution $\mathbf{f}_t(\delta)$ in $\mathcal{V}_{\mathbf{f}_t(P)}$ which is Lipschitz continuous in δ over $\mathcal{V}_{\mathbf{f}_t(P)}$. Let $\hat{\phi}_t(\mathbf{f}, P_M) = \frac{1}{M} \sum_{i=1}^M \hat{\mathbf{u}}(\mathbf{f}, \mathbf{C}(\mathbf{f}, \xi^i), t)$. If, in addition, both $\hat{\phi}_t(\mathbf{f}, P)$ and $\hat{\phi}_t(\mathbf{f}, P_M)$ are continuously differentiable in a neighborhood of $\mathbf{f}_t(P)$ and $\|\hat{\phi}_t(\mathbf{f}, P_M) - \hat{\phi}_t(\mathbf{f}, P)\|_{1,\mathcal{V}_{\mathbf{f}_t(P)}} \to 0$ with probability 1 (w.p.1) as $M \to \infty$, where $\|\cdot\|_{1,\mathcal{V}_{\mathbf{f}_t(P)}}$ is a norm defined as in (A.6), then w.p.1 for M large enough the SAA-MSVIP problem (2.21) possesses a unique solution $\mathbf{f}_t(P_M)$ in a neighborhood of $\mathbf{f}_t(P)$ and $\mathbf{f}_t(P_M) \to \mathbf{f}_t(P)$ w.p.1 as $M \to \infty$.

The theorem follows directly from Proposition 21 in [36]. It requires strong regularity condition which is essentially about coherent orientation of the Jacobian matrix $\nabla_{\mathbf{f}} \mathbb{E}_P[\hat{u}(\mathbf{f}, \mathbf{C}(\mathbf{f}, \xi), t)]$, we refer readers to Robinson [37] and Gürkan et al [38] for sufficient conditions. In this context, the condition depends on the topological structure of the transportation network (i.e. the structure of Δ matrix) and the properties of the arc performance function $\mathbf{T}(\mathbf{v}, \xi)$.

In the SAA problem (2.21), we assume that ξ^1, \dots, ξ^M are generated by the true probability distribution P of ξ . In practice, P is usually unknown and the samples are obtained via empirical data which contain noise for various reasons such measurement/recording errors. We call the former real data and the latter perceived data denoted by $\tilde{\xi}^1, \dots, \tilde{\xi}^M$. In other words, the perceived data may be generated by another distribution of Q which deviates from P. The shift from P to Q may also be interpreted as follows: P is the nominal distribution of ξ which we are familiar with based on experience whereas Q is a mixture distribution of P and H, i.e., $Q = (1 - \epsilon)P + \epsilon H$, where H captures random shocks such as unexpected road accidents and/or maintenance work which have significant effect on traffic flows on some arcs. Another way to interpret the data shift or distribution shift is that P is the probability distribution of ξ corresponding to the past or present data whereas Q is the probability distribution for the future, which means that the traffic equilibrium in future might be different from the one obtained based on the past or present data. Our main objective in this paper is to derive qualitative and quantitative statistical analysis on the difference between the equilibrium based on the sample data of Q and the one based on the sample data of P. If the difference is small, then the equilibrium obtained from past or present available data might provide a viable forecast of equilibrium in the future. In the case that the deviation is caused by measurement errors of data, we may interpret the equilibrium based on the samples of Q as model equilibrium whereas the one based on the samples of P as the true equilibrium. A small difference between the two equilibria means that the true equilibrium is stable, resilient or insensitive against perturbation of the underlying random data. Figure 2 summarizes this.

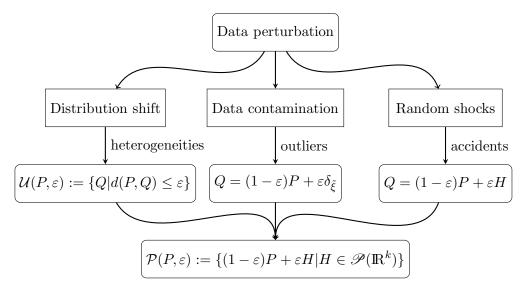

Figure 2: Data perturbations

3 Statistical robustness of MLAPUE

We proceed our analysis of impact of data perturbation on MLAPUE in two cases: (a) a few data are perturbed such as outliers and (b) all data are potentially perturbed. To this end, we

write the perturbed MSVIP (2.9) as:

(MSVIP-ptb)
$$0 \in \mathbb{E}_Q[\hat{\boldsymbol{u}}(\boldsymbol{f}, \boldsymbol{C}(\boldsymbol{f}, \boldsymbol{\xi}), t)] + \mathcal{N}_D(\boldsymbol{f}),$$
 (3.1)

where $Q \in \mathscr{P}(\mathbb{R}^k)$ is the underlying probability distribution of the perceived data and $\mathscr{P}(\mathbb{R}^k)$ denotes the set of all probability measures over \mathbb{R}^k . In case (a), we may represent Q as a mixture distribution $Q = (1 - \varepsilon)P + \varepsilon H$ where P is the true probability distribution, H is the distribution generating the perturbed data and ε is a small positive number. In this case, the perturbed data are generated by H with probability ε .

3.1 Single data perturbation

We begin with single data perturbation, that is, $Q = (1 - \varepsilon)P + \varepsilon \delta_{\tilde{\xi}}$, where $\delta_{\tilde{\xi}}$ denotes the Dirac measure at $\tilde{\xi}$ and $\tilde{\xi}$ is an outlier which is located outside the support set of ξ under distribution P. In this case, MSVIP-ptb (3.1) can be written as

$$0 \in \mathbb{E}_{(1-\varepsilon)P+\varepsilon\delta_{\tilde{\varepsilon}}}[\hat{\boldsymbol{u}}(\boldsymbol{f}, \boldsymbol{C}(\boldsymbol{f}, \xi), t)] + \mathcal{N}_{D}(\boldsymbol{f}).$$
(3.2)

Under the conditions of Proposition 2.1 (a) and (b), we can show (3.2) has a solution provided that $\mathbb{E}_{(1-\varepsilon)P+\varepsilon\delta_{\xi}}[\hat{u}(\boldsymbol{f}, \boldsymbol{C}(\boldsymbol{f}, \xi), t)]$ is bounded. As we discussed earlier, (3.2) has multiple solutions because it concerns path flow equilibrium. Let $\mathcal{F}_t((1-\varepsilon)P+\varepsilon\delta_{\xi})$ denote the set of solutions to problem (3.2). We investigate the impact of the perturbation of the probability distribution on the set of solutions by so called *generalized influence function* of $\mathcal{F}_t(\cdot)$. Let

$$\Psi_{\tilde{\xi},P,t}(\boldsymbol{f},\varepsilon) := \mathbb{E}_{(1-\varepsilon)P+\varepsilon\delta_{\tilde{\xi}}}[\hat{\boldsymbol{u}}(\boldsymbol{f},\boldsymbol{C}(\boldsymbol{f},\xi),t)] = \hat{\phi}_t(\boldsymbol{f},P) + \varepsilon \left(\hat{\boldsymbol{u}}(\boldsymbol{f},\boldsymbol{C}(\boldsymbol{f},\tilde{\xi}),t) - \hat{\phi}_t(\boldsymbol{f},P)\right)$$

where $\hat{\phi}_t(\boldsymbol{f}, P) = \mathbb{E}_P[\hat{\boldsymbol{u}}(\boldsymbol{f}, \boldsymbol{C}(\boldsymbol{f}, \xi), t)]$, and

$$\tilde{\boldsymbol{\mathcal{F}}}_{\tilde{\xi},P,t}(\varepsilon) := \boldsymbol{\mathcal{F}}_t\left((1-\varepsilon)P + \varepsilon\delta_{\tilde{\xi}}\right) = \left\{\boldsymbol{f} \in \mathbb{R}^N \left| 0 \in \Psi_{\tilde{\xi},P,t}(\boldsymbol{f},\varepsilon) + \mathcal{N}_D(\boldsymbol{f}) \right.\right\}.$$
(3.3)

In line with influence function approach in robust statistics [27], we want to investigate the derivative of $\tilde{\mathcal{F}}_{\xi,P,t}(\varepsilon)$ in ε at 0, or in other words, the directional derivative of $\mathcal{F}_t\left((1-\varepsilon)P+\varepsilon\delta_{\tilde{\xi}}\right) = \mathcal{F}_t\left(P+\varepsilon(\delta_{\tilde{\xi}}-P)\right)$ at P along the "direction" $\delta_{\tilde{\xi}}-P$. Unfortunately $\tilde{\mathcal{F}}_{\tilde{\xi},P,t}(\varepsilon)$ is a set-valued mapping. This requires us to exploit the notion of so-called proto-derivative, see Definition A.2 in the appendix. Observe that $\tilde{\mathcal{F}}_{\tilde{\xi},P,t}(0) = \mathcal{F}_t(P)$ and the proto-derivative of $\tilde{\mathcal{F}}_{\tilde{\xi},P,t}(\varepsilon)$ at 0 for $f_t(P) \in \tilde{\mathcal{F}}_{\tilde{\xi},P,t}(0)$ can be written as

$$\tilde{\boldsymbol{\mathcal{F}}}_{\tilde{\boldsymbol{\xi}},P,t;0,\boldsymbol{f}_{t}(P)}^{\prime}(1) = \limsup_{\epsilon \downarrow 0} \sup_{s \to 1} \frac{\tilde{\boldsymbol{\mathcal{F}}}_{\tilde{\boldsymbol{\xi}},P,t}(\epsilon s) - \boldsymbol{f}_{t}(P)}{\epsilon} = \limsup_{\epsilon \downarrow 0} \sup_{s \to 1} \frac{\boldsymbol{\mathcal{F}}_{t}((1-\epsilon s)P + \epsilon s\delta_{\tilde{\boldsymbol{\xi}}}) - \boldsymbol{f}_{t}(P)}{\epsilon}.$$
 (3.4)

Following [39, Definition 2], we call $\tilde{\mathcal{F}}'_{\tilde{\xi},P,t;0,\boldsymbol{f}_t(P)}(1)$ generalized influence function and denote it by $\operatorname{GIF}(\tilde{\xi}; \mathcal{F}_t(\cdot), P, \boldsymbol{f}_t(P))$.

The generalized influence function evaluates the influence of an infinitesimal amount of perturbation on the distribution P, which extends the classical definition of influence function introduced by Hampel [26]. In general, we are unable to obtain a closed form of $\mathcal{F}_t(\cdot)$. However, we may derive an upper bound for $\operatorname{GIF}(\tilde{\xi}, \mathcal{F}_t(P), P)$ by employing the implicit function theorem.

Since $\hat{\boldsymbol{u}}(\boldsymbol{f}, \boldsymbol{C}(\boldsymbol{f}, \xi), t)$ is continuously differentiable in \boldsymbol{f} for almost every $\xi \in \Xi$, by exploiting proto-derivative of the normal cone $\mathcal{N}_D(\boldsymbol{f})$, we can represent $\operatorname{GIF}(\tilde{\xi}; \boldsymbol{\mathcal{F}}_t(\cdot), P, \boldsymbol{f}_t(P))$ as a set of solutions of the following equation:

$$-\hat{\boldsymbol{u}}(\boldsymbol{f}_t^*, \boldsymbol{C}(\boldsymbol{f}_t^*, \tilde{\xi}), t) + \hat{\phi}_t(\boldsymbol{f}_t^*, P) - \mathbb{E}[\nabla_{\boldsymbol{f}} \hat{\boldsymbol{u}}(\boldsymbol{f}_t^*, \boldsymbol{C}(\boldsymbol{f}_t^*, \tilde{\xi}), t)] \boldsymbol{f} \in (\mathcal{N}_D)'_{\boldsymbol{f}_t^*, \hat{\boldsymbol{u}}_t^*}(\boldsymbol{f}),$$

where $\mathbf{f}_t^* = \mathbf{f}_t(P)$ and $\hat{\mathbf{u}}_t^* = -\hat{\phi}_t(\mathbf{f}_t^*, P)$. Proposition C.1 in the appendix states the details about this. Define

$$\left\|\operatorname{GIF}(\tilde{\xi}; \boldsymbol{\mathcal{F}}_t(\cdot), P, \boldsymbol{f}_t^*)\right\| := \min\left\{\nu : \|\eta\| \le \nu, \forall \eta \in \operatorname{GIF}(\tilde{\xi}; \boldsymbol{\mathcal{F}}_t(\cdot), P, \boldsymbol{f}_t^*)\right\}$$

The next theorem states a sufficient condition for the boundedness of $\operatorname{GIF}(\tilde{\xi}; \mathcal{F}_t(\cdot), P, f_t^*)$.

Theorem 3.1 Assume that the generated equations

$$0 \in \mathbb{E}_P\left[\nabla_{\boldsymbol{f}} \hat{\boldsymbol{u}}(\boldsymbol{f}_t^*, \boldsymbol{C}(\boldsymbol{f}_t^*, \boldsymbol{\xi}), t)\right] \boldsymbol{f} + (\mathcal{N}_D)'_{\boldsymbol{f}_t^*, \hat{\boldsymbol{u}}^*}(\boldsymbol{f})$$

has a unique solution 0. Then the following assertions hold.

- (i) GIF $(\tilde{\xi}; \mathcal{F}_t(\cdot), P, f_t^*)$ is bounded for every $\tilde{\xi} \in \mathbb{R}^k$.
- (ii) If, in addition, $\Upsilon_t(\mathbf{f}) = \hat{\phi}_t(\mathbf{f}, P) + \mathcal{N}_D(\mathbf{f})$ is strongly metrically regular at \mathbf{f}_t^* for 0 with regular modulus γ , then

$$\sup_{\tilde{\xi}\in\mathbb{R}^{k}}\left\|\operatorname{GIF}(\tilde{\xi};\boldsymbol{\mathcal{F}}_{t}(\cdot),P,\boldsymbol{f}_{t}^{*})\right\| \leq \gamma \sup_{\boldsymbol{f}\in\mathbb{F}_{t},\tilde{\xi}\in\mathbb{R}^{k}}\left\|\hat{\phi}_{t}(\boldsymbol{f},P)-\hat{\boldsymbol{u}}(\boldsymbol{f},\boldsymbol{C}(\boldsymbol{f},\tilde{\xi}),t)\right\|,\tag{3.5}$$

where \mathbb{F}_t is defined as in Assumption 2.1.

To see how the generalized influence function may be calculated, we use a simple example to illustrate.

Example 3.1 The MSVIP (2.14) can be reformulated as a complementarity problem:

$$oldsymbol{0} \leq egin{pmatrix} oldsymbol{f} \ ilde{oldsymbol{z}} \end{pmatrix} oldsymbol{oldsymbol{\perp}} egin{pmatrix} \hat{\phi}_t(oldsymbol{f},P) - \Pi^ op oldsymbol{ ilde{oldsymbol{z}}} \ \Pioldsymbol{f} - oldsymbol{q} \end{pmatrix} \geq oldsymbol{0},$$

where $\tilde{\boldsymbol{z}} \in \mathbb{R}^W$ is a vector of minimum OD disutilities corresponding to \boldsymbol{f} , $\hat{\phi}(\boldsymbol{f}, P)$ is defined as in (2.19) and Π is the OD-path incidence matrix. Let $\boldsymbol{f}_t^* \in \boldsymbol{\mathcal{F}}_t(P)$ be a solution to MSVIP problem (2.14), $\hat{\boldsymbol{u}}_t^* = -\mathbb{E}_P[\hat{\boldsymbol{u}}(\boldsymbol{f}_t^*, \boldsymbol{C}(\boldsymbol{f}_t^*, \boldsymbol{\xi}), t)]$ and $\tilde{\boldsymbol{z}} = \min_{1 \leq r \leq N} \{-\hat{\boldsymbol{u}}_{t,r}^*\}$, where $\hat{\boldsymbol{u}}_{t,r}^*$ represents the rth component of vector $\hat{\boldsymbol{u}}_t^*$. Let

$$\begin{split} \mathcal{I}_{+} &:= \left\{ r \in \{1, \cdots, N\} | f_{t,r}^{*} > 0, -\hat{u}_{t,r}^{*} - [\Pi^{\top}]_{r} \tilde{z} = 0 \right\}, \\ \mathcal{I}_{0} &:= \left\{ r \in \{1, \cdots, N\} | f_{t,r}^{*} = 0, -\hat{u}_{t,r}^{*} - [\Pi^{\top}]_{r} \tilde{z} = 0 \right\}, \\ \mathcal{I}_{-} &:= \left\{ r \in \{1, \cdots, N\} | f_{t,r}^{*} = 0, -\hat{u}_{t,r}^{*} - [\Pi^{\top}]_{r} \tilde{z} < 0 \right\}, \end{split}$$

where $f_{t,r}^*$ denotes the rth component of vector \mathbf{f}_t^* and $[\Pi^\top]_r$ denotes the rth row vector of matrix Π^\top . Since

$$\begin{aligned} \operatorname{gph}(\mathcal{N}_{D})'_{\boldsymbol{f}_{t}^{*},\hat{\boldsymbol{u}}_{t}^{*}} &= \operatorname{gph}(\mathcal{N}_{\mathbb{R}_{+}^{N}})'_{\boldsymbol{f}_{t}^{*},\hat{\boldsymbol{u}}_{t}^{*}+\Pi^{\top}\tilde{z}} = \operatorname{gph}D\mathcal{N}_{\mathbb{R}_{+}^{N}}(\boldsymbol{f}_{t}^{*}|\hat{\boldsymbol{u}}_{t}^{*}+\Pi^{\top}\tilde{z}) \\ &= \mathcal{T}_{\operatorname{gph}\mathcal{N}_{\mathbb{R}_{+}^{N}}}(\boldsymbol{f}_{t}^{*},\hat{\boldsymbol{u}}_{t}^{*}+\Pi^{\top}\tilde{z}) \\ &= \left\{ \left(\boldsymbol{f}_{t},\hat{\boldsymbol{u}}_{t}\right) \in \mathbb{R}^{N} \times \mathbb{R}^{N} \middle| \begin{array}{l} \hat{\boldsymbol{u}}_{t,r}+\Pi^{\top}\tilde{z}=0(r\in\mathcal{I}_{+}), f_{t,r}=0(r\in\mathcal{I}_{-}) \\ f_{t,r}=0,\hat{\boldsymbol{u}}_{t,r}+\Pi^{\top}\tilde{z}=0 \text{ or } \\ f_{t,r}=0,\hat{\boldsymbol{u}}_{t,r}+\Pi^{\top}\tilde{z}\leq 0(r\in\mathcal{I}_{0}) \end{array} \right\}, \end{aligned}$$

where $\operatorname{gph}(\mathcal{N}_D)'_{f_t^*,\hat{u}_t^*}$ denotes the graph of proto-derivative $(\mathcal{N}_D)'_{f_t^*,\hat{u}_t^*}$, $\operatorname{gph}\mathcal{D}\mathcal{N}_{\mathbb{R}^N_+}(\boldsymbol{a}|\boldsymbol{b})$ denotes the graph of graphical derivative $\mathcal{D}\mathcal{N}_{\mathbb{R}^N_+}(\boldsymbol{a}|\boldsymbol{b})$ and $\mathcal{T}_{\operatorname{gph}\mathcal{N}_{\mathbb{R}^N_+}}(\boldsymbol{a},\boldsymbol{b})$ denotes the tangent cone of $\operatorname{gph}\mathcal{N}_{\mathbb{R}^N_+}$ at point $(\boldsymbol{a},\boldsymbol{b})$ (see Definition A.2 in the appendix). Let

$$\boldsymbol{g}(\boldsymbol{f},t) := -\hat{\boldsymbol{u}}(\boldsymbol{f}_t^*, \boldsymbol{C}(\boldsymbol{f}_t^*, \tilde{\boldsymbol{\xi}}), t) - \hat{\phi}_t(\boldsymbol{f}_t^*, P) - \mathbb{E}_P[\nabla_{\boldsymbol{f}} \hat{\boldsymbol{u}}(\boldsymbol{f}_t^*, \boldsymbol{C}(\boldsymbol{f}_t^*, \boldsymbol{\xi}), t)]\boldsymbol{f} + \boldsymbol{\Pi}^\top \tilde{\boldsymbol{z}}.$$

By Proposition C.1 in the appendix,

$$\operatorname{GIF}(\tilde{\xi}; \boldsymbol{\mathcal{F}}_t(\cdot), P, \boldsymbol{f}_t^*) = \left\{ \boldsymbol{f} \in \mathbb{R}^N \middle| \begin{array}{l} g_r(\boldsymbol{f}, t) = 0 \text{ (for } r \in \mathcal{I}_+), f_r = 0 \text{ (for } r \in \mathcal{I}_-) \\ f_r = 0, g_r(\boldsymbol{f}, t) = 0 \text{ or } f_r = 0, g_r(\boldsymbol{f}, t) \le 0 \text{ (for } r \in \mathcal{I}_0) \end{array} \right\}.$$

The rhs is a complementary problem which can be easily solved by an existing code [40].

3.2 Breakdown point analysis

We now turn to discuss the case that the data set has multiple outliers instead of a single outlier and how the number of outliers may affect the quality of MLAPUE by using the notion of breakdown point introduced by Hampel [26]. Let P_M denote the empirical distribution based on unperturbed samples and $P_{M,m}$ is the one where m of the samples are outliers. Let $\hat{f}_t(P_M) \in \hat{\mathcal{F}}_t(P_M)$ and $\hat{f}_t(P_{M,m}) \in \hat{\mathcal{F}}_t(P_{M,m})$ denote the solution obtained from solving SAA-MSVIP problem (2.21) with P_M and $P_{M,m}$. Following [27], we define the finite-sample breakdown point for estimator \hat{f}_t as

$$\epsilon^*(\hat{\boldsymbol{f}}_t, P_M) := \max_m \left\{ \frac{m}{M} \left| \sup_{\tilde{P}_{M,m}} \| \hat{\boldsymbol{f}}_t(P_M) - \hat{\boldsymbol{f}}_t(\tilde{P}_{M,m}) \| < \infty \right\},\tag{3.6}$$

where the supremum is taken because outliers are not identifiable and the maximum is taken w.r.t. the number of outliers. $\epsilon^*(\hat{f}_t, P_M)$ represents the maximum proportion of outliers within the entire dataset such that the deviation between the estimator based on the mixed data (containing both outliers and unperturbed data) and the estimator based solely on unperturbed data remains bounded.

In the case when the data are generated by a mixture distribution $(1 - \varepsilon)P + \varepsilon H$ where P is the nominal distribution generating good data and H is the distribution generating outliers, we may define the breakdown point as

$$\epsilon^*(\hat{f}_t, P) := \min_{\varepsilon \in [0,1]} \left\{ \varepsilon : \sup_{P' \in \mathcal{P}(P,\varepsilon)} \| \hat{f}_t(P) - \hat{f}_t(P') \| = \infty \right\},$$
(3.7)

where

$$\mathcal{P}(P,\varepsilon) := \{ (1-\varepsilon)P + \varepsilon H | H \in \mathscr{H} \subset \mathscr{P}(\mathbb{R}^k) \}$$
(3.8)

for $\varepsilon \in [0,1]$ and \mathscr{H} is a subset of distributions generating the outliers. In this formulation, the information about the true probability distribution H generating outliers is incomplete. Consequently, we consider the worst-case distribution from \mathscr{H} .

3.3 All data perturbation

The influence function and breakdown point approaches are concerned with the cases that perceived sample data can be divided into two categories: good data which are not perturbed and bad data which are outliers. In some cases, all data could be potentially perturbed but they are not necessarily outliers. Let $\tilde{\xi}^1, \dots, \tilde{\xi}^M$ denote the perceived data and $Q_M := \frac{1}{M} \sum_{i=1}^M \delta_{\tilde{\xi}^i}$. Assume that $\tilde{\xi}^1, \dots, \tilde{\xi}^M$ are i.i.d copies of $\tilde{\xi}$ with distribution Q, where Q be regarded as a perturbation of P. Differing from (2.21), we consider sample average approximation of the MSVIP based perceived data:

$$0 \in \frac{1}{M} \sum_{i=1}^{M} \hat{\boldsymbol{u}}(\boldsymbol{f}, \boldsymbol{C}(\boldsymbol{f}, \tilde{\xi}^{i}), t)] + \mathcal{N}_{D}(\boldsymbol{f}), \qquad (3.9)$$

which may be viewed as the sample average approximation of MSVIP-ptb problem (3.1). Let $\mathcal{F}_t(Q_M)$ denote the set of solutions to problem (3.9) and $f_t(Q_M) \in \mathcal{F}_t(Q_M)$. We use $f_t(Q_M)$ as an estimator of a solution to MSVIP (2.14). Unfortunately $f_t(Q_M)$ converges to $f_t(Q)$ instead of $f_t(P)$ (a solution to MSVIP (2.14)) whereas $f_t(P_M)$ converges to $f_t(P)$ as $M \to \infty$ under some moderate conditions. In what follows, we derive conditions under which the distributions of $f_t(Q_M)$ and $f_t(P_M)$ are close under some metric. By then, we will be able to use $f_t(Q_M)$ as an estimator of $f_t(P)$. To this end, we need additional conditions on $T(v,\xi)$ and $\hat{u}(f, C(f,\xi), t)$.

Assumption 3.1 For the actual arc travel time function $T(v,\xi)$, we assume that there exists a constant L > such that

$$\|\boldsymbol{T}(\boldsymbol{v},\boldsymbol{\xi}) - \boldsymbol{T}(\boldsymbol{v},\boldsymbol{\xi}')\| \le L \|\boldsymbol{\xi} - \boldsymbol{\xi}'\| \text{ and } \|\nabla_{\boldsymbol{v}}\boldsymbol{T}(\boldsymbol{v},\boldsymbol{\xi}) - \nabla_{\boldsymbol{v}}\boldsymbol{T}(\boldsymbol{v},\boldsymbol{\xi}')\| \le L \|\boldsymbol{\xi} - \boldsymbol{\xi}'\|$$
(3.10)

for all $v \in \mathbb{V}_t$, $\xi, \xi' \in \Xi$, where \mathbb{V}_t is defined as in Assumption 2.1 and $\Xi \subset \mathbb{R}^k$.

To justify Assumption 3.1 as well as Assumption 2.2 in Section 2, we consider the case that each component of $T(v,\xi)$ is the common BPR function (see (2.7)). It is obvious that $T(v,\xi)$ is continuously differentiable in v for any fixed $t_a^0, b_a, n_a > 0$. Moreover, it is not hard to prove that $T(v,\xi)$ satisfies Assumption 2.2 (b) and (c) if $C_a(\xi)$ is continuous in ξ . This verifies Assumption 2.2. To see how Assumption 3.1 may be fulfilled, we note that

$$\boldsymbol{T}(\boldsymbol{v},\xi) = \{T_a(\boldsymbol{v},\xi)\}_{a=1}^A = \left\{ t_a^0 \left(1 + b_a \left(\frac{v_a}{C_a(\xi)} \right)^{n_a} \right) \right\}_{a=1}^A,$$
(3.11)

we can obtain that

for all ξ, ξ

$$\nabla_{\boldsymbol{v}}\boldsymbol{T}(\boldsymbol{v},\xi) = \left\{ \frac{t_a^0 n_a}{C_a(\xi)} \left(1 + b_a \left(\frac{v_a}{C_a(\xi)} \right)^{n_a - 1} \right) \cdot e_a \right\}_{a=1}^A,$$

where e_a denotes the unit vector whose *a*th component is 1 and all the other components are 0. Thus

$$\begin{split} \|\nabla_{\boldsymbol{v}}\boldsymbol{T}(\boldsymbol{v},\xi) - \nabla_{\boldsymbol{v}}\boldsymbol{T}(\boldsymbol{v},\xi')\| \\ &= \max_{a \in \{1,\cdots,A\}} \left| \frac{t_a^0 n_a}{C_a(\xi)} \left(1 + b_a \left(\frac{v_a}{C_a(\xi)} \right)^{n_a - 1} \right) - \frac{t_a^0 n_a}{C_a(\xi')} \left(1 + b_a \left(\frac{v_a}{C_a(\xi')} \right)^{n_a - 1} \right) \right| \\ &= \left| \frac{t_{a^*}^0 n_{a^*}}{C_{a^*}(\xi)} - \frac{t_{a^*}^0 n_{a^*}}{C_{a^*}(\xi')} + \left(\frac{t_{a^*}^0 n_{a^*} b_{a^*} v_{a^*}^{n_a - 1}}{C_{a^*}^{n_a *}(\xi)} - \frac{t_{a^*}^0 n_a b_{a^*} v_{a^*}^{n_a - 1}}{C_{a^*}^{n_a *}(\xi')} \right) \right|. \end{split}$$

The discussions above show that $T(v,\xi)$ satisfy Assumptions 3.1 (a) and (b) when $C_a(\xi)$ is Lipschitz continuous w.r.t. ξ , $|C_{a^*}^{n_{a^*}}(\xi)|$ is lower bounded by a positive constant and Ξ is a compact set.

Proposition 3.1 For the disutility function $\hat{\boldsymbol{u}}(\boldsymbol{f}, \boldsymbol{C}(\boldsymbol{f}, \xi), t)$, the following assertions hold.

(i) There exists a constant L > 0 such that

$$\|\hat{\boldsymbol{u}}(\boldsymbol{f}, \boldsymbol{C}(\boldsymbol{f}, \boldsymbol{\xi}), t) - \hat{\boldsymbol{u}}(\boldsymbol{f}, \boldsymbol{C}(\boldsymbol{f}, \boldsymbol{\xi}'), t)\| \leq L\eta_{\Delta^{\top}}(\theta_1 + \theta_2) \|\boldsymbol{\xi} - \boldsymbol{\xi}'\|.$$
(3.12)
$$\boldsymbol{\xi}' \in \boldsymbol{\Xi}, \boldsymbol{f} \in \mathbb{F}_t \text{ and } t \geq 0.$$

(ii) There exist a constant $\hat{C}(t)$ dependent on t such that

$$\|\nabla_{\boldsymbol{f}} \hat{\boldsymbol{u}}(\boldsymbol{f}, \boldsymbol{C}(\boldsymbol{f}, \boldsymbol{\xi}), t) - \nabla_{\boldsymbol{f}} \hat{\boldsymbol{u}}(\boldsymbol{f}, \boldsymbol{C}(\boldsymbol{f}, \boldsymbol{\xi}'), t)\| \leq L\eta_{\Delta^{\top}} \left(\theta_1 \eta_{\Delta} + \theta_2 \eta_{\Delta} + \theta_2 \hat{\boldsymbol{C}}(t)\right) \|\boldsymbol{\xi} - \boldsymbol{\xi}'\|,$$
(3.13)

for all $\xi, \xi' \in \Xi, \mathbf{f} \in \mathbb{F}_t$ and t > 0, where \mathbb{F}_t is defined as in Assumption 2.1, $\hat{C}(t) = \frac{C'_0}{2t}$, $C'_0 = \sup_{\mathbf{f} \in \mathbb{F}_t, \xi \in \Xi} \|\nabla_{\mathbf{f}} \mathbf{C}(\mathbf{f}, \xi)\|$ and $\eta_{\Delta} = \|\Delta\|$ for matrix $\Delta \in \mathbb{R}^{A \times N}$.

The proposition above implies that $\hat{\boldsymbol{u}}(\boldsymbol{f}, \boldsymbol{C}(\boldsymbol{f}, \xi), t)$ is locally Lipschitz continuous in ξ and its Jacobian $\nabla_{\boldsymbol{f}} \hat{\boldsymbol{u}}(\boldsymbol{f}, \boldsymbol{C}(\boldsymbol{f}, \xi), t)$ is locally Lipschitz continuous with the modulus related to parameter t. The explicit form of the Jacobian matrix of $\hat{\boldsymbol{u}}(\boldsymbol{f}, \boldsymbol{C}(\boldsymbol{f}, \xi), t)$ can be obtained. Observe that $\nabla_{\boldsymbol{f}} \boldsymbol{g}(\boldsymbol{f}, \boldsymbol{C}(\boldsymbol{f}, \xi)) = \theta_1 \Delta^\top \nabla_{\boldsymbol{v}} \boldsymbol{T}(\Delta \boldsymbol{f}, \xi) \Delta$ and

$$\left[\nabla_{\boldsymbol{f}}\hat{\boldsymbol{h}}(\boldsymbol{f},\boldsymbol{C},t)\right]_{r} = \begin{cases} \theta_{2}[\Delta^{\top}]_{r}\nabla_{\boldsymbol{v}}\boldsymbol{T}(\Delta\boldsymbol{f},\xi)\Delta, & \text{for } t < C_{r} - \tau_{k}, \\ \frac{\theta_{2}(C_{r}(\boldsymbol{f},\xi) + t - \tau_{k})}{2t}[\Delta^{\top}]_{r}\nabla_{\boldsymbol{v}}\boldsymbol{T}(\Delta\boldsymbol{f},\xi)\Delta, & \text{for } -t \leq C_{r} - \tau_{k} \leq t, \\ 0 \in \mathbb{R}^{1 \times N}, & \text{for } C_{r} - \tau_{k} < -t, \end{cases}$$
(3.14)

for $r = 1, \dots, N$ and $k = 1, \dots, W$, where $[A]_r$ denotes the rth row vector of matrix A. Thus

$$\left[\nabla_{\boldsymbol{f}}\hat{\boldsymbol{u}}(\boldsymbol{f},\boldsymbol{C},t)\right]_{r} = \begin{cases} \left(\theta_{1}+\theta_{2}\right)[\Delta^{\top}]_{r}\nabla_{\boldsymbol{v}}\boldsymbol{T}(\Delta\boldsymbol{f},\xi)\Delta, & \text{for } t < C_{r}-\tau_{k}, \\ \left(\theta_{1}+\frac{\theta_{2}(C_{r}(\boldsymbol{f},\xi)+t-\tau_{k})}{2t}\right)[\Delta^{\top}]_{r}\nabla_{\boldsymbol{v}}\boldsymbol{T}(\Delta\boldsymbol{f},\xi)\Delta, & \text{for } -t \leq C_{r}-\tau_{k} \leq t, \\ \theta_{1}[\Delta^{\top}]_{r}\nabla_{\boldsymbol{v}}\boldsymbol{T}(\Delta\boldsymbol{f},\xi)\Delta, & \text{for } C_{r}-\tau_{k} < -t. \end{cases}$$

$$(3.15)$$

Notice that $\nabla_{\boldsymbol{f}} \hat{\boldsymbol{u}}(\boldsymbol{f}, \boldsymbol{C}, t)$ can be written as $\operatorname{diag}(b_1, \cdots, b_N) \Delta^\top \nabla_{\boldsymbol{v}} T(\Delta \boldsymbol{f}, \xi) \Delta$, where b_r is either $(\theta_1 + \theta_2)$ or $\left(\theta_1 + \frac{\theta_2(C_r(\boldsymbol{f}, \xi) + t - \tau_k)}{2t}\right)$ or θ_1 for $r = 1, \cdots, N$.

Under the proposition above and Lemma A.1 in the appendix, we are able to derive the main stability result about an isolated MLAPUE solution to (2.14).

Theorem 3.2 (Stability of MLAPUE) Let $f_t(P) \in \mathcal{F}_t(P)$ be a strongly regular solution to MSVIP (2.14) and $\mathcal{O}_t \subset \mathbb{F}_t$ be an open neighborhood of $f_t(P)$, where \mathbb{F}_t is defined as in Assumption 2.1. Let

$$\mathcal{M}_{k}^{1} := \left\{ \boldsymbol{Q} \in \mathscr{P}(\Xi) : \int_{\Xi} \|\xi\| \boldsymbol{Q}(d\xi) < \infty \right\}.$$
(3.16)

The following assertion hold.

(i) Under Assumption 3.1, there exist a unique vector-valued function $f_t(\cdot)$ defined in a neighborhood of P and positive constants δ and κ such that

$$\|\boldsymbol{f}_t(Q_1) - \boldsymbol{f}_t(Q_2)\| \le L\eta_{\Delta^{\top}}\kappa \left(\theta_1 + \theta_2 + \theta_1\eta_{\Delta} + \theta_2\eta_{\Delta} + \theta_2\hat{C}(t)\right) \mathsf{d}_K(Q_1, Q_2)$$
(3.17)

for any $Q_1, Q_2 \in \mathcal{M}_k^1$ satisfying $\mathsf{dl}_K(Q_1, P) \leq \delta$ and $\mathsf{dl}_K(Q_2, P) \leq \delta$, where \mathcal{M}_k^1 is defined as in (3.16), $\hat{C}(t)$ is defined as in Proposition 3.1 and $\mathsf{dl}_K(Q_1, Q_2)$ denotes the Kantorovich metric between Q_1 and Q_2 , defined as in (A.4) in the appendix.

(ii) Let

$$\mathcal{M}_{k,M_0}^{\gamma} := \left\{ Q \in \mathscr{P}(\mathbb{R}^k) : \int_{\mathbb{R}^k} \|\xi\|^{\gamma} Q(d\xi) \le M_0 \right\}$$
(3.18)

for some constants $\gamma > 1$ and $M_0 > 0$. If, in addition, there is a continuous solution $\mathbf{f}_t(\cdot) : \mathcal{M}_{k,M_0}^{\gamma} \to \mathbb{R}^N$ such that the strongly regular condition holds at $\mathbf{f}_t(P')$ for every $P' \in \mathcal{M}_{k,M_0}^{\gamma}$, then there exists a constant \tilde{C} such that

$$\|\boldsymbol{f}_t(Q_1) - \boldsymbol{f}_t(Q_2)\| \le L\tilde{C}\eta_{\Delta^{\top}} \left(\theta_1 + \theta_2 + \theta_1\eta_{\Delta} + \theta_2\eta_{\Delta} + \theta_2\hat{C}(t)\right) \mathsf{d}\mathsf{I}_K(Q_1, Q_2), \quad (3.19)$$

for all $Q_1, Q_2 \in \mathcal{M}_{k, M_0}^{\gamma}$.

Part (i) of the theorem is an implicit function theorem for MSVIP-ptb (3.1) in the space of probability measures \mathcal{M}_k^1 . Part (ii) is about global Lipschitz continuity of MLAPUE solution mapping over the $\mathcal{M}_{k,M_0}^{\gamma}$. In the case that when the support set of ξ is a compact set, $\mathcal{M}_{k,M_0}^{\gamma}$ coincides with $\mathscr{P}(\Xi)$. With Theorem 3.2, we are ready to state the main quantitative statistical robustness of an estimator of MLAPUE $f_t(\cdot)$. The assumption on the continuous solution $f_t(\cdot)$ over $\mathcal{M}_{k,M_0}^{\gamma}$ is strong and theoretical in general. It may be fulfilled under some circumstance when MSVIP (2.14) has a unique solution for all $P \in \mathscr{P}(\Xi)$. Again, this depends on the problem structure including the structure of the network and the properties of $T(v, \xi)$.

With Theorem 3.2, we are ready to state robustness of statistical estimator of MLAPUE in the next theorem.

Theorem 3.3 (Statistical robustness of MLAPUE estimator) Assume the conditions of Theorem 3.2 (iii) hold. Let $\hat{f}_{M,t} = f_t(Q_M)$ be a statistical estimator of $f_t(Q)$, where $f_t(\cdot)$ is defined as in Theorem 3.2. If the support of ξ , denoted by Ξ , is a compact set, then

$$\mathsf{dI}_{K}\left(P^{\otimes M}\circ\hat{f}_{M,t}^{-1},Q^{\otimes M}\circ\hat{f}_{M,t}^{-1}\right) \leq L\tilde{C}\eta_{\Delta^{\top}}\left(\theta_{1}+\theta_{2}+\theta_{1}\eta_{\Delta}+\theta_{2}\eta_{\Delta}+\theta_{2}\hat{C}(t)\right)\mathsf{dI}_{K}(P,Q) \quad (3.20)$$

for all M and $P, Q \in \mathscr{P}(\Xi)$, where $\hat{C}(t)$ is defined as in Proposition 3.1, \tilde{C} is defined as in Theorem 3.2 and $P^{\otimes M}$ denotes the Cartesian product of $\underbrace{P \times \cdots \times P}_{M}$.

The lhs of (3.20) is the difference between the empirical distribution $P^{\otimes M} \circ \hat{f}_{M,t}^{-1}$ based on unperturbed samples and the empirical distribution $Q^{\otimes M} \circ \hat{f}_{M,t}^{-1}$ based on perturbed samples under the Kantorovich metric. The rhs provides a bound for the lhs in terms of the difference between the original probability distributions generating the unperturbed and perturbed samples (P and Q) under the Kantorovich metric. The constant at the rhs depends on t. As t goes to 0, the constant goes to infinity, which means the quantitative statistical robustness result is not applicable to the LAPUE. Since the inequality is derived under some sufficient conditions rather than necessary conditions, it does not mean that the LAPUE is not statistically robust – it is simply because we are unable to establish the result under the current framework of analysis.

The theoretical result is useful in at least two cases: (a) P and Q are known but in actual calculations, only empirical data of Q are used. This is either because errors occur in the process of data generation, processing and recording, or the distribution of validation data (for the future) is shifted from the distribution of training data (in the past); (b) the difference between Q and P is known in the sense that the shift/perturbation of the distribution is within a controllable range. In the case only when perceived data (the sample data of Q) are known, we will not be able to say much about the quality of MLAPUE. Since the result is built on Theorem 3.2, it might be desirable to relax some of the conditions imposed on Theorem 3.2 such as strong regularity to extend the applicability of Theorem 3.3.

4 Numerical tests

We have carried out some numerical experiments on the MLAPUE model. In this section, we report the test results. For the vector of arc travel time functions $T(v,\xi)$, we set each of its components $T_a(v,\xi)$ to be a GBPR function,

$$T_a(\boldsymbol{v},\boldsymbol{\xi}) = t_a^0 \left(1 + b_a \left(\frac{v_a}{C_a(\boldsymbol{\xi})} \right)^{n_a} \right), \tag{4.1}$$

where t_a^0, b_a and n_a are given parameters, $C_a(\xi)$ denotes the random capacity of arc *a* in scenario ξ and v_a is flow at arc *a*.

4.1 Example 1: a simple 2-OD network

To examine the effect of the perturbation of probability distribution on arc travel time, we first consider a 2-OD pairs network varied from [41], see Figure 3. For network 1, we let the path

from node 1 to node 2 be the 1-OD pair with demand $q_1 = 3500$ and from node 1 to node 3 be the 2-OD pair with demand $q_2 = 4000$. In this case, we set the GBPR function as

$$T_{a}(\boldsymbol{v},\xi) = t_{a}^{0} \left(1 + 0.15 \left(\frac{v_{a}}{C_{a}(\xi)} \right)^{4} \right).$$
(4.2)

Detail of other parameters are given in Table 1. Following [41], we assume that $C_a(\xi)$ follows a normal distribution $C_a(\xi) \sim N(\mu_a, \sigma_a)$ and denote its CDF by $F(x; \mu_a, \sigma_a)$ for $a = 1, \dots, 6$. It is easy to verify that the arc-path incidence matrix of network 1 is of full column rank, and that the Jacobian matrix of travel time function $T(v, \xi)$ is a diagonal matrix with full rank for $v \neq 0$. Thus corresponding MSVIP problem (2.14) satisfies strong regularity condition and has a unique MLAPUE.

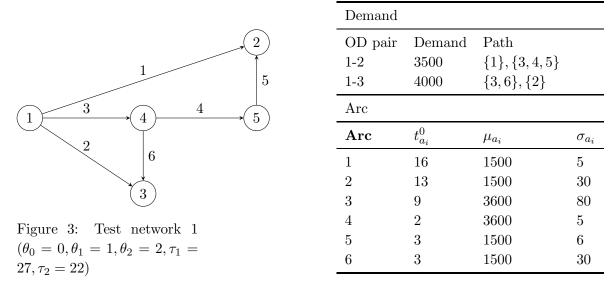

Table 1: Details for network 1

The UE path flows are (2182, 1318, 850, 3150) with corresponding disutility values (26.75, 26.79, 21.52, 21.54). For parameter t = 0.01, the MLAPUE path flow are (2193, 1306, 860, 3139) with corresponding disutility values (27.10, 27.08, 21.67, 21.71). We can see that the flow patterns are similar, the disutility values are larger in the MLAPUE model because of addition of the penalty of lateness.

Next, we investigate the effect of perturbation of the probability distribution on MLAPUE. We consider the case that only the distribution of the capacity at arc a = 1 is perturbed. Let P_a denote the distribution of the capacity at arc a and $F(x; \mu_a, \sigma_a)$ its CDF. Let Q_a be the perturbed distribution with CDF

$$F_{Q_a}(x) = \begin{cases} F(x; \mu_a, \sigma_a), & \text{for } x \le x_0, \\ q + \beta(x - x_0), & \text{for } x_0 \le x \le x_1, \\ 1, & \text{for } x > x_1, \end{cases}$$
(4.3)

where $x_0 = F^{-1}(q; \mu_a, \sigma_a)$, $x_1 = x_0 + \frac{1}{\beta}(1-q)$, β and $q \in (0, 1)$ are fixed positive constants. Figure 4a depicts the difference of the two CDFs. We use the CDFs to generate independent and identically distributed samples C_a^j and \tilde{C}_a^j for $j = 1, \dots, M$ respectively. Let $P_M = \frac{1}{M} \sum_{j=1}^M \delta_{C_a^j}$ and $Q_M = \frac{1}{M} \sum_{j=1}^M \delta_{\tilde{C}_a^j}$. Denote the MLAPUE obtained from solving (3.9) by $f_t(Q_M)$. We use the CDFs of Q_a and P_a to generate L groups of samples with size M = 1000. We calculate the MLAPUE $f_t(Q_M)$ and $f_t(P_M)$ for each group of samples with corresponding arc flows $v(Q_M) = \Delta f_t(Q_M)$ and $v(P_M) = \Delta f_t(P_M)$. We can use each of the L data points to construct empirical CDFs. Figure 4b depicts the CDFs of $v_1(P_M)$ and $v_1(Q_M)$ when t = 0.1. We can see that the flow on arc 1 is mainly distributed within the range [2192, 2195] and the blue dashed line approximates the red ones very well. Figure 5 simulates the empirical distribution of $v_1(P_M)$ and $v_1(Q_M)$ when L = 10 and L = 30.

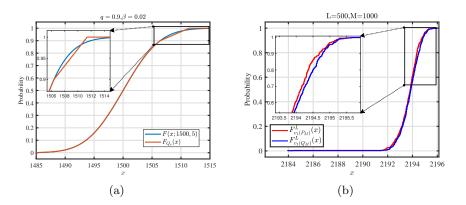

Figure 4: (Color online) (a) $F_{Q_a}(x)$ and F(x; 1500, 5). (b) Empirical distributions of $v_1(P_M)$ and $v_1(Q_M)$ based on L = 500 simulations with parameter t = 0.01.

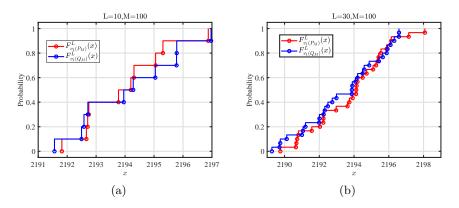

Figure 5: (Color online) (a)-(b) Empirical distributions of $v_1(P_M)$ and $v_1(Q_M)$ based on L = 10and L = 30 simulations with parameter t = 0.01.

To examine the difference between the flows $v_1(P_M)$ and $v_1(Q_M)$ at arc 1, we use the Kantorovich metric to quantify the difference between the CDFs of $v_1(P_M)$ and $v_1(Q_M)$ relative to the Kantorovich metric on the difference between the CDFs of the input data generated by F_{P_a} and $F_{Q_a}(x)$. Let $\Delta_2 = \mathsf{dl}_K(P_a, Q_a)$, and

$$\Delta_1^L = \mathsf{dl}_K(F_{v_1(P_M)}^L, F_{v_1(Q_M)}^L),$$

where $F_{v_1(P_M)}^L$ is the empirical distribution of random variable $v_1(P_M)$ using L samples. Figures 6a and 6b display convergence of the ratio $\frac{\Delta_1^L}{\Delta_2}$ as L varies from 20 to 200 as t = 0.01 and t = 0.1, which implies that the ratio converges when L increases. The ratio $\frac{\Delta_1^L}{\Delta_2}$ provides some insight for the constant at the rhs of (3.20) in Theorem 3.3.

We have also conducted tests to evaluate the effect of parameter t on MLAPUE. Figure 6c depicts the trend of flows on path 1 (which is also the flow of arc 1) as t varies from 0.2 to 2.2. The graph demonstrates that the flow exhibits an upward trend as parameter t increases. Figure 7 displays change of the influence function of $f_1(\cdot)$ when t = 0.01 and t = 0.1. We can see that the influence function IF $(\tilde{C}_1, f_1(\cdot), P_1)$ takes negative value. This occurs because, for path 1, the outlier scenario arises when the capacity of arc 1 is degraded (due to road incidents). To minimize user disutility, the flow on path 1 is reduced accordingly.

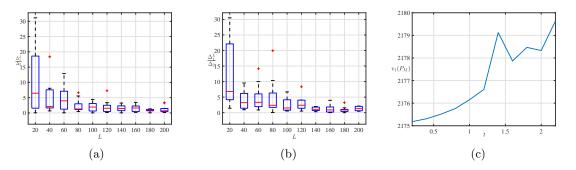

Figure 6: (Color online) (a)-(b) $\frac{\Delta_1^L}{\Delta_2}$ by L simulations as L varies from 20 to 200 when t = 0.01 and t = 0.1. (c) $v_1(P_M)$ when t varies from 0.2 to 2.2.

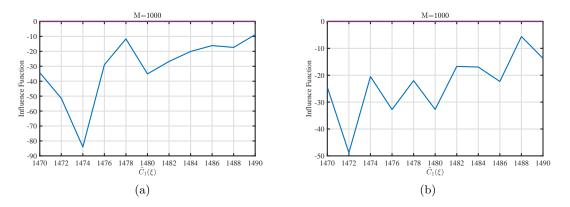

Figure 7: (Color online) (a)-(b) The influence function $IF(\tilde{C}_1(\xi), f_1(\cdot), P_1)$ when \tilde{C}_1 changes from 1470 to 1490 with parameter t = 0.01 and t = 0.1.

Finally, we investigate the case that the breakdown occurs on arc 1 by replacing m of the original M samples drown from the true normal distribution with m outliers. We calculate the MLAPUE and the corresponding minimum OD disutility for 10 cases where m takes values of 10, 20, \cdots , 100 and M is 1000. The results are depicted in Figures 8, 9 and 10. Figure 8a shows

that as the number of outliers increases, path flow on arc 1 (path 1) decreases gradually at the MLAPUE, whereas the flow on the other path under the same 1-2 OD pair increases gradually. Since the OD pair 1-2 and the OD pair 1-3 share arc 3, the MLAPUE path flows over the OD pair 1-3 changes accordingly: the flow over path 3 gradually decreases, whereas the flow on the other path gradually increases. Moreover, Figure 8b describes that the minimum OD disutility of each OD pair increases with increase of the number of outliers. Furthermore, Figures 9 and 10 manifest the facts that the MLAPUE solutions and the corresponding minimum OD disutilities deviate gradually from those under the true normal distribution as the number of outliers increases.

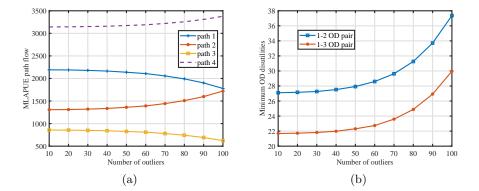

Figure 8: (Color online) MLAPUE path flows and minimum OD disutilities for network 1 as the number of outliers varies from 10 to 100.

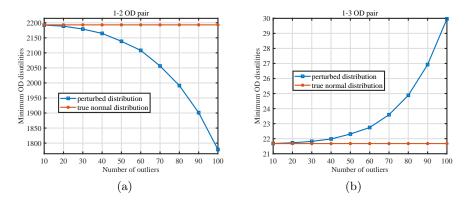

Figure 9: (Color online) Impact of perturbed distribution of arc travel time for arc 1 on minimum OD disutilities for network 1.

4.2 Example 2: the Nguyen and Dupuis network

We also consider the Nguyen and Dupuis network shown in Figure 11a, which includes 13 nodes, 19 directed arcs and 4 OD pairs $1 \rightarrow 2$, $1 \rightarrow 3$, $4 \rightarrow 2$ and $4 \rightarrow 3$. The free-flow arc travel time t_a^0 and the mean of arc capacity $\mathbb{E}_P[C_a(\xi)]$ of the network are the same as those used by Yin et

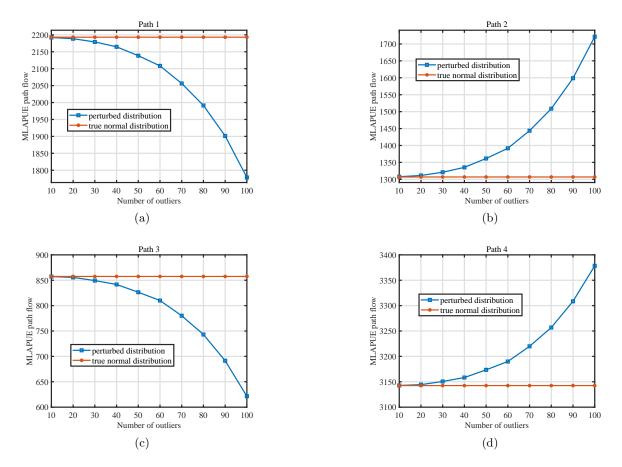

Figure 10: (Color online) Impact of perturbed distribution of arc travel time for arc 1 on MLAPUE solutions for network 1 with parameter t = 0.1.

al. [33, Table 1]. The demands of all OD pairs are shown as Figure 11b. Note that in this case, the arc-path incidence matrix is a 19×25 matrix with column rank 10. So the metric regularity condition is not satisfied and indeed the MLAPUE is not unique. We record the computational results for traffic assignment pattern $f_{\rm UE}$, $f_{\rm MLAPUE}$, $f_{\rm MLAPUE-ptb}$ and the corresponding minimum OD disutilities in Table 2, where $f_{\rm MLAPUE-ptb}$ is the result for the case that only the distribution of the capacity at arc a = 2 is perturbed. From the results, we can see that the flows of the path through arc 2 under the MLAPUE-ptb pattern either decrease or remains 0 compared with the flows in the MLAPUE model.

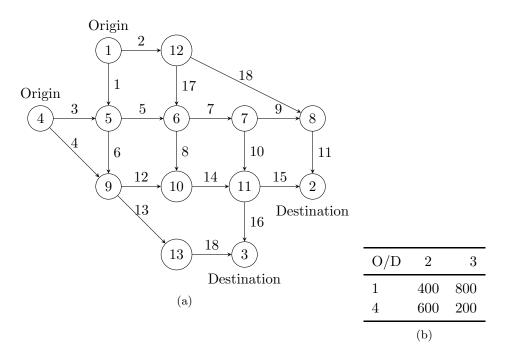

Figure 11: Nguyen and Dupuis network and OD pair demands.

5 Concluding remarks

In this paper, we propose a modification of the well-known LAPUE model by adopting a new parameterized penalty function for user's lateness. Under the same conditions as for the LAPUE model, we demonstrate existence and uniqueness of LAPUE under the new penalty function and show that it approximates Watling's LAPUE when the parameter is driven to zero. While the new penalty function offers flexibility to describe a user's preference of riskiness in lateness, it has a main advantage that the resulting LAPUE based on perturbed data is statistically robust which means that they are not very sensitive to the data perturbation. The result may provide a mathematical framework for analysing LAPUE in data driven problems. As far as we are concerned, this kind of analysis is new in the literature of transportation user equilibrium. We are unable to show whether the original LAPUE based on the max penalty function for user's lateness is statistically robust when all sample data are potentially perturbed because the error bound in (3.19) goes to infinity when t is driven to zero. It does not necessarily mean that the

Table 2: Optimal path flow and minimum OD disutilities

LAPUE is not quantitatively statistically robust, rather it is because our current mathematical framework of analysis does not enable us to establish the result. We leave this interested readers to explore.

Another important point that we would like to bring readers to attend is that differing from the main stream research in this area, the sample average approximation problem in this paper is based on the samples of the underlying uncertainty factors behind random travel time rather than samples of travel time. This is because travel time depends not only the uncertainty factors but also volume of arc flow/path flow which are decision variables in the model. We will not be able to undertake the statistical robustness analysis if we mix up the decision variables and the uncertainty parameters in the empirical data. To address this discrepancy between the theoretical model (SAA) and the practical availability of the sample data, we may use regression models to derive samples of uncertain parameters from samples of travel time via (2.7).

Appendix

A Perliminaries

Definition A.1 (Outer limit [42]) For a sequence \mathcal{F}_t of subsets of \mathbb{R}^N , the outer limit is the set

$$\limsup_{t\downarrow 0} \boldsymbol{\mathcal{F}}_t := \left\{ \boldsymbol{f} \mid \exists t_k \to 0, \ \exists \boldsymbol{f}_{t_k} \in \boldsymbol{\mathcal{F}}_{t_k} \text{ with } \boldsymbol{f}_{t_k} \to \boldsymbol{f} \right\}.$$
(A.1)

Definition A.2 (Proto-derivative [43]) A set-valued mapping $\Gamma : \mathbb{R}^N \Rightarrow \mathbb{R}^N$ is protodifferentiable at a point z and for a particular element $u \in \Gamma(z)$ if the set-valued mappings

$$\Delta_{z,u,\varepsilon}: d \to \frac{\Gamma(z+\varepsilon d) - u}{\varepsilon}$$

regarded as a family indexed by $\varepsilon > 0$, graph-converge as $\varepsilon \downarrow 0$. The limit, if exists, is denoted by $\Gamma'_{z,u}$ and called the *proto-derivative* of Γ at z for u.

In the case that the proto-derivative exists,

$$\Gamma'_{z,u}(d) = \limsup_{\varepsilon \downarrow 0, d' \to d} \frac{\Gamma(z + \varepsilon d') - u}{\varepsilon}$$

for every $d \in \mathbb{R}^N$ via [43, Proposition 2.3]. The graphical outer limit of the set-valued mappings $\{\Delta_{z,u,\varepsilon(\cdot):\varepsilon>0}\}$ is called *graphical derivative*, denoted by $D\Gamma(z|u)$, this is,

$$\mathrm{ghp}D\Gamma(z|u) := \limsup_{\varepsilon \downarrow 0} \mathrm{ghp}\Delta_{z,u,\varepsilon} = \limsup_{\varepsilon \downarrow 0} \frac{\mathrm{ghp}\Gamma - (z,u)}{\varepsilon}.$$

The graphical derivative always exists and its graph is the tangent cone of gph Γ at point (z, u). In the case the proto-derivative exists, the proto-derivative and the graphical derivative are equal.

Definition A.3 (Metric regularity) Let $\Upsilon : \mathbb{R}^N \Rightarrow \mathbb{R}^N$ be a closed set-valued mapping. For $\bar{f}, \bar{g} \in \mathbb{R}^N$, Υ is said to be metrically regular at \bar{f} for \bar{g} if there exist a constant $\alpha > 0$, neighborhoods $\mathcal{V}_{\bar{f}}$ and $\mathcal{V}_{\bar{g}}$ of \bar{f} and \bar{g} such that

$$d(\boldsymbol{f}, \Upsilon^{-1}(\boldsymbol{g})) \leq \alpha d(\boldsymbol{g}, \Upsilon(\boldsymbol{f})), \ \forall \boldsymbol{f} \in \mathcal{V}_{\bar{\boldsymbol{f}}}, \boldsymbol{g} \in \mathcal{V}_{\bar{\boldsymbol{g}}}.$$

Here the inverse mapping is defined as $\Upsilon^{-1}(\boldsymbol{g}) := \{\boldsymbol{f} : \boldsymbol{g} \in \Upsilon(\boldsymbol{f})\}$. Υ is said to be strongly metrically regular at $\bar{\boldsymbol{f}}$ for $\bar{\boldsymbol{g}}$ if it is metrically regular and there exist neighborhoods $\mathcal{V}_{\bar{\boldsymbol{f}}}$ and $\mathcal{V}_{\bar{\boldsymbol{g}}}$ such that for $\boldsymbol{g} \in \mathcal{V}_{\bar{\boldsymbol{g}}}$ there is only one $\boldsymbol{f} \in \mathcal{V}_{\bar{\boldsymbol{f}}} \cap \Upsilon^{-1}(\boldsymbol{g})$.

Definition A.4 (Fortet-Mourier metric) Let

$$\mathcal{F}_p(\mathbb{R}^k) := \left\{ \phi : \mathbb{R}^k \to \mathbb{R} : |\phi(\xi) - \phi(\tilde{\xi})| \le L_p(\xi, \tilde{\xi}) \|\xi - \tilde{\xi}\|, \forall \xi, \tilde{\xi} \in \mathbb{R}^k \right\}$$
(A.2)

where $L_p(\xi, \tilde{\xi}) := \max\{1, \|\xi\|, \|\tilde{\xi}\|\}^{p-1}$ for $p \ge 1$. The pth order Fortet-Mourier metric over $\mathscr{P}(\mathbb{R}^k)$ is defined by

$$\mathsf{dI}_{\mathrm{FM}}(P,Q) := \sup_{\phi \in \mathcal{F}_p(\mathbb{R}^k)} \left| \int_{\mathbb{R}^k} \phi(\xi) P(d\xi) - \int_{\mathbb{R}^k} \phi(\xi) Q(d\xi) \right|.$$
(A.3)

It is well-known that the Fortet-Mourier distance metricizes weak convergence on \mathcal{M}_k^p , see [44, Theorem 6.2.1]. In the case when p = 1, it reduces to the *Kantorovich metric*

$$\mathsf{dI}_{\mathrm{K}}(P,Q) := \sup_{\phi \in \mathcal{F}_1(\mathbb{R}^k)} \left| \int_{\mathbb{R}^k} \phi(\xi) P(d\xi) - \int_{\mathbb{R}^k} \phi(\xi) Q(d\xi) \right|,\tag{A.4}$$

see also [45].

Let \mathbb{F}_t be the set defined as in Assumption 2.1, $\tilde{\mathscr{G}} := \{ \boldsymbol{g}(\cdot) = \hat{\boldsymbol{u}}(\boldsymbol{f}, \boldsymbol{C}(\boldsymbol{f}, \cdot), t) : \boldsymbol{f} \in \mathbb{F}_t, t > 0 \}.$ For $P, Q \in \hat{\mathscr{P}}$, define

$$\mathscr{D}(P,Q) := \sup_{\boldsymbol{g} \in \mathscr{G}} \|\mathbb{E}_P[\boldsymbol{g}(\xi)] - \mathbb{E}_Q[\boldsymbol{g}(\xi)]\|.$$
(A.5)

According to Proposition 2.2 (i), $\mathscr{D}(P,Q)$ is well-defined for any $P,Q \in \hat{\mathscr{P}}$. Then $\mathscr{D}(P,Q)$ is a kind of pseudo-metric in the space of probability measures $\hat{\mathscr{P}}$ in the sense that $\mathscr{D}(P,Q) = 0$ implies $\mathbb{E}_P[\mathbf{g}(\xi)] - \mathbb{E}_Q[\mathbf{g}(\xi)]$ for all $\mathbf{g} \in \mathscr{G}$ but not necessarily Q = P. Note that this definition is slightly different from the classical definition of pseudo-metric in the literature [46] where \mathbf{g} is often restricted to real-valued functions.

Lemma A.1 Let V be an open neighborhood of z_0 and consider the Banach space $U := C^1(V, W)$ of continuously differentiable mapping $\psi : V \to W$ having finite norm

$$\|\psi\|_{1,V} := \sup_{z \in V} \|\psi(z)\| + \sup_{z \in V} \|D\psi(z)\|.$$
(A.6)

If z_0 is a strongly regular solution of the abstract generalized equation (2.16), then for all $\tilde{\phi}$ in a neighborhood of ϕ w.r.t. the norm $\|\cdot\|_1$, the generalized equation

$$0 \in \tilde{\phi}(z) + N(z)$$

has a Lipschitz continuous and unique solution $\bar{z}(\tilde{\phi})$ in a neighborhood of z_0 .

B Proof of section 2

B.1 Proof of Proposition 2.2

Proof. Part (i). Since for any t > 0, $\hat{\boldsymbol{u}}(\boldsymbol{f}, \boldsymbol{C}(\boldsymbol{f}, \xi), t)$ is continuously differentiable w.r.t. \boldsymbol{C} , which implies that $\hat{\boldsymbol{u}}(\cdot, \boldsymbol{C}(\cdot, \xi), t)$ is continuously differentiable w.r.t. \boldsymbol{f} via Assumption 2.2 and $\boldsymbol{C}(\boldsymbol{f}, \xi) = \Delta \boldsymbol{T}(\Delta \boldsymbol{f}, \xi)$.

Part (ii). By Assumption 2.2(b), we have

$$\sup_{\boldsymbol{f}\in\mathbb{F}} \|\boldsymbol{C}(\boldsymbol{f},\xi)\| = \sup_{\boldsymbol{v}\in\mathbb{V}_t} \|\Delta^\top \boldsymbol{T}(\boldsymbol{v},\xi)\| \le \eta_{\Delta^\top} \sup_{\boldsymbol{v}\in\mathbb{V}} \|\boldsymbol{T}(\boldsymbol{v},\xi)\| \le \eta_{\Delta^\top} \Phi_1(\xi).$$

Moreover,

$$\begin{split} \sup_{\boldsymbol{f}\in\mathbb{F}_{t}} \|\hat{\boldsymbol{u}}(\boldsymbol{f},\boldsymbol{C}(\boldsymbol{f},\xi),t)\| &= \sup_{\boldsymbol{f}\in\mathbb{F}_{t}} \|\theta_{0}\boldsymbol{d} + \theta_{1}\boldsymbol{C}(\boldsymbol{f},\xi) + \theta_{2}\hat{\boldsymbol{h}}(\boldsymbol{f},\boldsymbol{C}(\boldsymbol{f},\xi),t)\| \\ &\leq \theta_{0}\|\boldsymbol{d}\| + \sup_{\boldsymbol{f}\in\mathbb{F}_{t}} \|\theta_{1}\boldsymbol{C}(\boldsymbol{f},\xi)\| + \sup_{\boldsymbol{f}\in\mathbb{F}_{t}} \theta_{2}\|\hat{\boldsymbol{h}}(\boldsymbol{f},\boldsymbol{C}(\boldsymbol{f},\xi),t)\| \\ &\leq \theta_{0}\|\boldsymbol{d}\| + \theta_{1}\eta_{\Delta^{\top}}\Phi_{1}(\xi) + \theta_{2}\sup_{\boldsymbol{f}\in\mathbb{F}_{t}} \|\boldsymbol{C}(\boldsymbol{f},\xi) - \boldsymbol{\tau} + \boldsymbol{t}\|, \\ &\leq \eta_{\Delta^{\top}}(\theta_{1} + \theta_{2})\Phi_{1}(\xi) + \theta_{0}\|\boldsymbol{d}\| + \theta_{2}\|\boldsymbol{\tau}\| + t, \end{split}$$

Let $\tilde{\Phi}_1(\xi, t) = \eta_{\Delta^{\top}}(\theta_1 + \theta_2)\Phi_1(\xi) + \theta_0 \|\boldsymbol{d}\| + \theta_2 \|\boldsymbol{\tau}\| + t$. Since $\mathbb{E}_P[\Phi_1(\xi)] < \infty$, then we can easily obtain $\mathbb{E}_P[\tilde{\Psi}_1(\xi, t)] < \infty$ for any fixed t > 0.

Part (iii). Since

$$\begin{split} &\|\hat{\boldsymbol{u}}(\boldsymbol{f},\boldsymbol{C}(\boldsymbol{f},\xi),t)-\hat{\boldsymbol{u}}(\boldsymbol{f}',\boldsymbol{C}(\boldsymbol{f}',\xi),t)\|\\ &= \|\theta_1(\boldsymbol{C}(\boldsymbol{f},\xi)-\boldsymbol{C}(\boldsymbol{f}',\xi))+\hat{\boldsymbol{h}}(\boldsymbol{f},\boldsymbol{C}(\boldsymbol{f},\xi),t)-\hat{\boldsymbol{h}}(\boldsymbol{f}',\boldsymbol{C}(\boldsymbol{f}',\xi),t)\|\\ &\leq (\theta_1+\theta_2)\|\Delta^\top\|\|\boldsymbol{T}(\boldsymbol{v},\xi)-\boldsymbol{T}(\boldsymbol{v}',\xi)\|\\ &\leq (\theta_1+\theta_2\eta_{\Delta^\top}\Phi_2(\xi)\|\Delta\|\|\|\boldsymbol{f}-\boldsymbol{f}'\|\\ &\leq \eta_{\Delta^\top}\eta_{\Delta}(\theta_1+\theta_2)\Phi_2(\xi)\|\boldsymbol{f}-\boldsymbol{f}'\|, \quad \forall \boldsymbol{f},\boldsymbol{f}'\in\mathbb{F}_t,t>0. \end{split}$$

The first inequality holds is due to the fact that each component of $\hat{h}(f, C(f, \xi), t)$ is Lipschitz continuous in $C(f, \xi)$ with modulus θ_2 for any t > 0 and $C(f, \xi) = \Delta^{\top} T(v, \xi)$. The proof is completed.

B.2 Proof of Theorem 2.2

Proof. Observe firs that by Proposition 2.1, $\mathcal{F}_t(P) \neq \emptyset$.

Part (i). Let $f_t(P) \in \mathcal{F}_t(P)$. Since $\mathcal{F}_t(P)$ is bounded, we show that any cluster point of the sequence is a solution of (2.9). By taking a subsequence if necessary, we may assume for the simplicity of notation that

$$\lim_{t \to 0} \boldsymbol{f}_t(P) = \boldsymbol{f}(P). \tag{B.1}$$

Since $\hat{\boldsymbol{u}}(\boldsymbol{f}_t(P), \boldsymbol{C}(\boldsymbol{f}_t(P), \xi), t)$ is a approximation of $\boldsymbol{u}(\boldsymbol{f}(P), \boldsymbol{C}(\boldsymbol{f}(P), \xi))$, we have by the continuity of \boldsymbol{C} w.r.t. \boldsymbol{f} ,

$$\lim_{t \downarrow 0} \hat{\boldsymbol{u}}(\boldsymbol{f}_t(P), \boldsymbol{C}(\boldsymbol{f}_t(P), \boldsymbol{\xi}), t) = \boldsymbol{u}(\boldsymbol{f}(P), \boldsymbol{C}(\boldsymbol{f}(P), \boldsymbol{\xi})).$$
(B.2)

Moreover, by Proposition 2.2, $\hat{u}(f_t(P), C(f_t(P), \xi), t)$ is integrally bounded. Consequently, we have by Lebesgue's dominated convergence theorem

$$\begin{split} \lim_{t \downarrow 0} \hat{\phi}_t(\boldsymbol{f}_t(P), P) &= \lim_{t \downarrow 0} \mathbb{E}_P \left[\hat{\boldsymbol{u}}(\boldsymbol{f}_t(P), \boldsymbol{C}(\boldsymbol{f}_t(P), \xi), t) \right] \\ &= \mathbb{E}_P \left[\lim_{t \downarrow 0} \hat{\boldsymbol{u}}(\boldsymbol{f}_t(P), \boldsymbol{C}(\boldsymbol{f}_t(P), \xi), t) \right] \\ &= \mathbb{E}_P [\boldsymbol{u}(\boldsymbol{f}(P), \boldsymbol{C}(\boldsymbol{f}(P), \xi))] = \phi(\boldsymbol{f}(P), P). \end{split}$$

The conclusion follows immediately from this and the fact that the normal cone is upper semicontinuous.

Part (ii). Let $\mathbf{f}(P) \in \mathcal{F}(P)$. It is easy to prove that there exist a sufficiently small constant $t_0 > 0$ and closed neighborhood $\mathcal{V}_{\mathbf{f}(P)}$ of $\mathbf{f}(P)$ such that $\{\mathbf{f}_t(P) \in \mathcal{F}_t(P) : \lim_{t \downarrow 0} \mathbf{f}_t(P) = \mathbf{f}(P), t \in (0, t_0]\} \subseteq \mathcal{V}_{\mathbf{f}(P)}$ by virtue of (i). Let \mathcal{B} be a unit ball in \mathbb{R}^N and s be a constant such that

$$s > \max_{\boldsymbol{f} \in \mathcal{V}_{\boldsymbol{f}(P)} \cap D, t \in (0, t_0]} \{ \| \hat{\phi}_t(\boldsymbol{f}, P) \|, \| \phi(\boldsymbol{f}, P) \| \}.$$

Then for any $\boldsymbol{f} \in \mathcal{V}_{\boldsymbol{f}(P)} \cap D$,

$$0 \in \phi(\boldsymbol{f}, P) + \mathcal{N}_D(\boldsymbol{f}) \cap s\mathcal{B},$$

where \mathcal{B} is a unit ball in \mathbb{R}^N . Likewise, for $f \in \{f_t(P) : t \in (0, t_0]\},\$

$$0 \in \hat{\phi}_t(\boldsymbol{f}, P) + \mathcal{N}_D(\boldsymbol{f}) \cap s\mathcal{B}.$$
(B.3)

On the other hand, the metric regularity of $\Upsilon(\mathbf{f})$ at $\mathbf{f}(P)$ for 0 with regularity modulus α implies that there exists a neighborhood $\mathcal{V}_{\mathbf{f}(P)}$ of $\mathbf{f}(P)$ such that

$$d(\boldsymbol{f}_t(P), \boldsymbol{\mathcal{F}}(P)) \le \alpha d(0, \Upsilon(\boldsymbol{f}_t(P)))$$
(B.4)

for all $f_t(P) \in \mathcal{F}_t(P) \cap \mathcal{V}_{f(P)}$ and $t \in (0, t_0]$. Since

$$\Upsilon(oldsymbol{f}) = \phi(oldsymbol{f},P) + \mathcal{N}_D(oldsymbol{f}) \supset \phi(oldsymbol{f},P) + \mathcal{N}_D(oldsymbol{f}) \cap s\mathcal{B}_{s}$$

then

$$d(0, \Upsilon(\boldsymbol{f})) \leq d(0, \phi(\boldsymbol{f}, P) + \mathcal{N}_D(\boldsymbol{f}) \cap s\mathcal{B}).$$

Moreover, since $f_t(P)$ satisfies (B.3), then

$$\begin{aligned} d(\boldsymbol{f}_{t}(P), \boldsymbol{\mathcal{F}}(P)) &\leq & \alpha d(0, \phi(\boldsymbol{f}_{t}(P), P) + \mathcal{N}_{D}(\boldsymbol{f}_{t}(P)) \cap s\mathcal{B}) \\ &\leq & \alpha \mathbb{D}(\hat{\phi}_{t}(\boldsymbol{f}_{t}(P), P) + \mathcal{N}_{D}(\boldsymbol{f}_{t}(P)) \cap s\mathcal{B}, \phi(\boldsymbol{f}_{t}(P), P) + \mathcal{N}_{D}(\boldsymbol{f}_{t}(P)) \cap s\mathcal{B}) \\ &\leq & \alpha \|\hat{\phi}_{t}(\boldsymbol{f}_{t}(P), P) - \phi(\boldsymbol{f}_{t}(P), P)\| \\ &\leq & \alpha \sup_{\boldsymbol{f} \in \mathcal{V}_{\boldsymbol{f}(P)}} \|\hat{\phi}_{t}(\boldsymbol{f}, P) - \phi(\boldsymbol{f}, P)\| \end{aligned}$$

for all $f_t(P) \in \mathcal{F}_t(P) \cap \mathcal{V}_{f(P)}$ and $t \in (0, t_0]$. Therefore, we obtain (2.18). Inequality (2.20) follows straight-forwardly from (2.18) and strong mertic regularity.

C Proof of Section 3

C.1 Proof of Proposition C.1

Proposition C.1 For fixed t, let f_t^* be a solution of (2.14) and $\hat{u}_t^* = -\mathbb{E}_P[\hat{u}(f_t^*, C(f_t^*, \xi), t)]$. Then the generalized influence function $\text{GIF}(\tilde{\xi}, f_t(\cdot), P)$ exists and has the following formula:

$$GIF(\tilde{\xi}; \boldsymbol{\mathcal{F}}_t(\cdot), P, \boldsymbol{f}_t^*) = \{\boldsymbol{f} \in \mathbb{R}^N | - \hat{\boldsymbol{u}}(\boldsymbol{f}_t^*, \boldsymbol{C}(\boldsymbol{f}_t^*, \tilde{\xi}), t) + \hat{\phi}_t(\boldsymbol{f}_t^*, P) \\ - \mathbb{E}_P[\nabla_{\boldsymbol{f}} \hat{\boldsymbol{u}}(\boldsymbol{f}_t^*, \boldsymbol{C}(\boldsymbol{f}_t^*, \xi), t)] \boldsymbol{f} \in \mathcal{N}_{\boldsymbol{f}_t^*, \hat{\boldsymbol{u}}_t^*}(\boldsymbol{f}) \}.$$
(C.1)

Proof. By [47, Definition 3.1], the directional derivative of $\Psi_{\tilde{\xi},P,t}(\cdot,\cdot)$ at $(f_t^*,0)$ in the direction (f,1) can be written as

$$\begin{split} & \Psi'_{\tilde{\xi},P,t;\boldsymbol{f}_{t}^{*},0}(\boldsymbol{f},1) \\ = & \lim_{\epsilon \downarrow 0,(\boldsymbol{f}',s) \to (\boldsymbol{f},1)} \frac{\Psi_{\tilde{\xi},P,t}(\boldsymbol{f}_{t}^{*} + \epsilon \boldsymbol{f}',\epsilon s) - \Psi_{\tilde{\xi},P,t}(\boldsymbol{f}_{t}^{*},0)}{\epsilon} \\ = & \lim_{\epsilon \downarrow 0,(\boldsymbol{f}',s) \to (\boldsymbol{f},1)} \left\{ \frac{\hat{\phi}_{t}(\boldsymbol{f}_{t}^{*} + \epsilon \boldsymbol{f}',P) - \hat{\phi}_{t}(\boldsymbol{f}_{t}^{*},P)}{\epsilon} \\ & + \frac{\epsilon s \left(\hat{\boldsymbol{u}}(\boldsymbol{f}_{t}^{*} + \epsilon \boldsymbol{f}',\boldsymbol{C}(\boldsymbol{f}_{t}^{*} + \epsilon \boldsymbol{f}',\tilde{\xi}),t) - \hat{\phi}_{t}(\boldsymbol{f}_{t}^{*} + \epsilon \boldsymbol{f}',P) \right)}{\epsilon} \right\} \\ = & \hat{\boldsymbol{u}}(\boldsymbol{f}_{t}^{*},\boldsymbol{C}(\boldsymbol{f}_{t}^{*},\tilde{\xi}),t) - \hat{\phi}_{t}(\boldsymbol{f}_{t}^{*},P) + \nabla_{\boldsymbol{f}}\hat{\phi}_{t}(\boldsymbol{f}_{t}^{*},P)\boldsymbol{f}. \end{split}$$

Thus, by the continuous differentiability of $\hat{u}(\cdot, C(\cdot, \xi), t)$ and [47, Theorem 4.1], we conclude (C.1).

C.2 Proof of Theorem 3.1

Proof. Part (i). By the condition,

$$\tilde{\boldsymbol{\mathcal{F}}}_{\tilde{\boldsymbol{\xi}},P,t;0,\boldsymbol{f}_{t}^{*}}^{\prime}(0) = \left\{ \boldsymbol{f} \in \mathbb{R}^{N} | 0 \in \mathbb{E}_{P}\left[\nabla_{\boldsymbol{f}} \hat{\boldsymbol{u}}(\boldsymbol{f}_{t}^{*},\boldsymbol{C}(\boldsymbol{f}_{t}^{*},\boldsymbol{\xi}),t)\right] \boldsymbol{f} + \mathcal{N}_{\boldsymbol{f}_{t}^{*},\hat{\boldsymbol{u}}^{*}}^{\prime}(\boldsymbol{f}) \right\} = \{0\},$$

then by [43, Theorem 4.1], there exist constants α_0 , ρ and $\beta \in (0, 1)$ depending on $\tilde{\xi}$ such that

$$\tilde{\boldsymbol{\mathcal{F}}}_{\tilde{\boldsymbol{\xi}},P,t}(\varepsilon) \cap (\boldsymbol{f}_t^* + \alpha_0 \boldsymbol{\mathcal{B}}) \subset \boldsymbol{f}_t^* + \rho \varepsilon \boldsymbol{\mathcal{B}}$$

for all $\varepsilon \in (0, \beta)$, where \mathcal{B} denotes a unit ball in \mathbb{R}^N . In addition,

$$\frac{\boldsymbol{\mathcal{F}}_{\tilde{\xi},P,t}(\epsilon s) - \boldsymbol{f}_t^*}{\epsilon} \cap \frac{\alpha_0}{\epsilon} \boldsymbol{\mathcal{B}} \subset \rho s \boldsymbol{\mathcal{B}}$$

for all $\epsilon s \in (0, \beta)$. Therefor

$$\operatorname{GIF}(\tilde{\xi}; \boldsymbol{\mathcal{F}}_t(\cdot), P, \boldsymbol{f}_t^*) = \limsup_{\epsilon \downarrow 0, s \to 1} \frac{\tilde{\boldsymbol{\mathcal{F}}}_{\tilde{\xi}, P, t}(\epsilon s) - \boldsymbol{f}_t^*}{\epsilon} \in \rho \mathcal{B},$$

which implies

$$\|\operatorname{GIF}(\tilde{\xi}; \boldsymbol{\mathcal{F}}_t(\cdot), P, \boldsymbol{f}_t^*)\| \leq \rho.$$

Part (ii). Similar to the proof of Theorem 2.2 (ii), under the strong regularity condition, we can obtain that

$$\|\boldsymbol{f}_t(Q), \boldsymbol{f}_t^*\| \le \gamma \|\hat{\phi}_t(\boldsymbol{f}_t(Q), P) - \hat{\phi}_t(\boldsymbol{f}_t(Q), Q)\|$$
(C.2)

for all $f_t(Q) \in \mathcal{F}_t(Q) \cap \mathcal{V}_{f_t^*}$ and $Q \in \mathscr{P}(\Xi)$. Let $Q = (1 - \varepsilon)P + \varepsilon \delta_{\tilde{\xi}}$ and $\epsilon_0 > 0$ such that $\mathcal{F}_t(Q) \cap \mathcal{V}_{f_t^*, \epsilon_0} \neq \emptyset$. We have

$$\begin{aligned} \boldsymbol{\mathcal{F}}_{t}(Q) \cap \boldsymbol{\mathcal{V}}_{\boldsymbol{f}_{t}^{*},\epsilon_{0}} &\subset \boldsymbol{f}_{t}^{*} + \gamma \| \hat{\phi}_{t}(\boldsymbol{f}_{t}(Q),P) - \hat{\phi}_{t}(\boldsymbol{f}_{t}(Q),Q) \| \boldsymbol{\mathcal{B}} \\ &\subset \boldsymbol{f}_{t}^{*} + \gamma \sup_{\boldsymbol{f} \in \mathbb{F}_{t}} \| \hat{\phi}_{t}(\boldsymbol{f},P) - \hat{\phi}_{t}(\boldsymbol{f},Q) \| \boldsymbol{\mathcal{B}} \\ &= \boldsymbol{f}_{t}^{*} + \gamma \varepsilon \sup_{\boldsymbol{f} \in \mathbb{F}_{t}} \| \hat{\phi}_{t}(\boldsymbol{f},P) - \hat{\boldsymbol{u}}(\boldsymbol{f},\boldsymbol{C}(\boldsymbol{f},\tilde{\xi}),t) \| \boldsymbol{\mathcal{B}} \end{aligned}$$
(C.3)

via (C.2), where $\mathcal{V}_{\boldsymbol{f}_t^*,\epsilon_0}$ denotes a ϵ_0 -neighborhood of \boldsymbol{f}_t^* and \mathbb{F}_t is defined as in Assumption 2.1. Note that $\mathcal{F}_t(Q) = \tilde{\mathcal{F}}_{\tilde{\xi},P,t}(\varepsilon)$, then (C.3) implies that

$$\frac{\hat{\boldsymbol{\mathcal{F}}}_{\tilde{\xi},P,t}(\epsilon s) - \boldsymbol{f}_{t}^{*}}{\epsilon} \cap \frac{\epsilon_{0}}{\epsilon} \boldsymbol{\mathcal{B}} \subset \gamma s \sup_{\boldsymbol{f} \in \mathbb{F}_{t}} \|\hat{\phi}_{t}(\boldsymbol{f},P) - \hat{\boldsymbol{u}}(\boldsymbol{f},\boldsymbol{C}(\boldsymbol{f},\tilde{\xi}),t)\|\boldsymbol{\mathcal{B}}$$

for $\gamma s \in (0, 1)$. Thus

$$GIF(\tilde{\xi}; \mathcal{F}_{t}(\cdot), P, \mathbf{f}_{t}^{*}) = \limsup_{\epsilon \downarrow 0, s \to 1} \frac{\tilde{\mathcal{F}}_{\tilde{\xi}, P, t}(\epsilon s) - \mathbf{f}_{t}^{*}}{\epsilon} \in \rho \mathcal{B},$$
$$\subset \sup_{\mathbf{f} \in \mathbb{F}_{t}} \|\hat{\phi}_{t}(\mathbf{f}, P) - \hat{u}(\mathbf{f}, \mathbf{C}(\mathbf{f}, \tilde{\xi}), t)\|\mathcal{B}_{t}^{*}$$

which implies

$$\|\operatorname{GIF}(\tilde{\xi}; \boldsymbol{\mathcal{F}}_t(\cdot), P, \boldsymbol{f}_t^*)\| \leq \gamma \sup_{\boldsymbol{f} \in \mathbb{F}_t} \|\hat{\phi}_t(\boldsymbol{f}, P) - \hat{\boldsymbol{u}}(\boldsymbol{f}, \boldsymbol{C}(\boldsymbol{f}, \tilde{\xi}), t)\|.$$

for all $\tilde{\xi} \in \mathbb{R}^k$. By taking the supremum w.r.t. $\tilde{\xi} \in \mathbb{R}^k$, we derive (3.5). The proof is completed.

C.3 Proof of Proposition 3.1

Proof. Part (i). Since \hat{h} is globally Lipschitz continuous in the second argument uniformly w.r.t. the first and the third arguments with modulus θ_2 , then

$$\begin{split} &\|\hat{\bm{u}}(\bm{f},\bm{C}(\bm{f},\xi),t)-\hat{\bm{u}}(\bm{f},\bm{C}(\bm{f},\xi'),t)\|\\ &= \|\bm{g}(\bm{f},\bm{C}(\bm{f},\xi))-\bm{g}(\bm{f},\bm{C}(\bm{f},\xi'))+\hat{\bm{h}}(\bm{f},\bm{C}(\bm{f},\xi),t)-\hat{\bm{h}}(\bm{f},\bm{C}(\bm{f},\xi'),t)\|\\ &\leq \|\bm{g}(\bm{f},\bm{C}(\bm{f},\xi))-\bm{g}(\bm{f},\bm{C}(\bm{f},\xi'))\|+\|\hat{\bm{h}}(\bm{f},\bm{C}(\bm{f},\xi),t)-\hat{\bm{h}}(\bm{f},\bm{C}(\bm{f},\xi'),t)\|\\ &\leq (\theta_1+\theta_2)\|\bm{C}(\bm{f},\xi))-\bm{C}(\bm{f},\xi'))\|\\ &\leq L\eta_{\Delta^{\top}}(\theta_1+\theta_2)\|\xi-\xi'\|. \end{split}$$

Part (ii). Since,

$$\begin{split} \|\nabla_{\boldsymbol{f}} \hat{\boldsymbol{u}}(\boldsymbol{f}, \boldsymbol{C}(\boldsymbol{f}, \boldsymbol{\xi}), t) - \nabla_{\boldsymbol{f}} \hat{\boldsymbol{u}}(\boldsymbol{f}, \boldsymbol{C}(\boldsymbol{f}, \boldsymbol{\xi}'), t)\| \\ &= \|\nabla_{\boldsymbol{f}} \boldsymbol{g}(\boldsymbol{f}, \boldsymbol{C}(\boldsymbol{f}, \boldsymbol{\xi})) - \nabla_{\boldsymbol{f}} \boldsymbol{g}(\boldsymbol{f}, \boldsymbol{C}(\boldsymbol{f}, \boldsymbol{\xi}')) + \nabla_{\boldsymbol{f}} \hat{\boldsymbol{h}}(\boldsymbol{f}, \boldsymbol{C}(\boldsymbol{f}, \boldsymbol{\xi}), t) - \nabla_{\boldsymbol{f}} \hat{\boldsymbol{h}}(\boldsymbol{f}, \boldsymbol{C}(\boldsymbol{f}, \boldsymbol{\xi}'), t)\| \\ &\leq \|\nabla_{\boldsymbol{f}} \boldsymbol{g}(\boldsymbol{f}, \boldsymbol{C}(\boldsymbol{f}, \boldsymbol{\xi})) - \nabla_{\boldsymbol{f}} \boldsymbol{g}(\boldsymbol{f}, \boldsymbol{C}(\boldsymbol{f}, \boldsymbol{\xi}'))\| + \|\nabla_{\boldsymbol{f}} \hat{\boldsymbol{h}}(\boldsymbol{f}, \boldsymbol{C}(\boldsymbol{f}, \boldsymbol{\xi}), t) - \nabla_{\boldsymbol{f}} \hat{\boldsymbol{h}}(\boldsymbol{f}, \boldsymbol{C}(\boldsymbol{f}, \boldsymbol{\xi}'), t)\| \\ &\leq \theta_1 \|\Delta^\top\| \|\nabla_{\boldsymbol{v}} \boldsymbol{T}(\Delta \boldsymbol{f}, \boldsymbol{\xi}) - \nabla_{\boldsymbol{v}} \boldsymbol{T}(\Delta \boldsymbol{f}, \boldsymbol{\xi}')\| \|\Delta\| + \|\nabla_{\boldsymbol{f}} \hat{\boldsymbol{h}}(\boldsymbol{f}, \boldsymbol{C}(\boldsymbol{f}, \boldsymbol{\xi}), t) - \nabla_{\boldsymbol{f}} \hat{\boldsymbol{h}}(\boldsymbol{f}, \boldsymbol{C}(\boldsymbol{f}, \boldsymbol{\xi}'), t)\| \end{split}$$

Moreover, since for the case that $C_r(\mathbf{f}, \xi)$ and $C_r(\mathbf{f}, \xi')$ are in the same segment interval, we have

where $C_r = C_r(\boldsymbol{f}, \xi)$ and $C'_r = C_r(\boldsymbol{f}, \xi')$. Then, it is not hard to obtain that

$$\|\nabla_{\boldsymbol{f}} \hat{\boldsymbol{h}}(\boldsymbol{f}, \boldsymbol{C}(\boldsymbol{f}, \boldsymbol{\xi}), t) - \nabla_{\boldsymbol{f}} \hat{\boldsymbol{h}}(\boldsymbol{f}, \boldsymbol{C}(\boldsymbol{f}, \boldsymbol{\xi}'), t)\| \leq L\theta_2 \eta_{\Delta^{\top}} \left(\eta_{\Delta} + \frac{C'_0}{2t}\right) \|\boldsymbol{\xi} - \boldsymbol{\xi}'\|,$$

where $C'_0 = \sup_{\boldsymbol{f} \in D, \xi \in \Xi} \|\nabla_{\boldsymbol{f}} \boldsymbol{C}(\boldsymbol{f}, \xi)\|$. Since $\boldsymbol{C}(\boldsymbol{f}, \xi)$ is continuously differentiable w.r.t. \boldsymbol{f} and continuous w.r.t. ξ and Ξ and \mathbb{F} are compact sets, then $C'_0 < \infty$. Therefore, it follows that

$$\|\nabla_{\boldsymbol{f}} \hat{\boldsymbol{u}}(\boldsymbol{f}, \boldsymbol{C}(\boldsymbol{f}, \boldsymbol{\xi}), t) - \nabla_{\boldsymbol{f}} \hat{\boldsymbol{u}}(\boldsymbol{f}, \boldsymbol{C}(\boldsymbol{f}, \boldsymbol{\xi}'), t)\| \leq L\eta_{\Delta^{\top}} \left(\theta_1 \eta_{\Delta} + \theta_2 \eta_{\Delta} + \theta_2 \hat{C}(t)\right) \|\boldsymbol{\xi} - \boldsymbol{\xi}'\|$$

for $t > 0$, where $\hat{C}(t) = \frac{C'_0}{2t}$.

C.4 Proof of Theorem 3.2

Proof. Part (i). It follows by Lemma A.1, there exist a unique vector-valued function $f_t(\cdot)$ and positive constants κ and δ such that

$$\|\boldsymbol{f}_{t}(Q_{1}) - \boldsymbol{f}_{t}(Q_{2})\| \leq \kappa \|\hat{\phi}_{t}(\cdot, Q_{1}) - \hat{\phi}_{t}(\cdot, Q_{2})\|_{1,\mathcal{O}_{t}}$$
(C.4)

for any $Q_1, Q_2 \in \mathcal{M}^1_k$ satisfying $\mathsf{dl}_K(Q_1, P) \leq \delta$ and $\mathsf{dl}_K(Q_2, P) \leq \delta$. By the definition of $\|\cdot\|_{1,\mathcal{O}_t}$,

$$\begin{split} \|\hat{\phi}_{t}(\cdot,Q_{1}) - \hat{\phi}_{t}(\cdot,Q_{2})\|_{1,\mathcal{O}_{t}} \\ &= \sup_{\boldsymbol{f}\in\mathcal{O}_{t}} \|\hat{\phi}_{t}(\boldsymbol{f},Q_{1}) - \hat{\phi}_{t}(\boldsymbol{f},Q_{2})\| + \sup_{\boldsymbol{f}\in\mathcal{O}_{t}} \|\nabla_{\boldsymbol{f}}\hat{\phi}_{t}(\boldsymbol{f},Q_{1}) - \nabla_{\boldsymbol{f}}\hat{\phi}_{t}(\boldsymbol{f},Q_{2})\| \\ &= \sup_{\boldsymbol{f}\in\mathcal{O}_{t},\|\boldsymbol{\eta}\|\leq 1} \left|\boldsymbol{\eta}^{\top}\hat{\phi}_{t}(\boldsymbol{f},Q_{1}) - \boldsymbol{\eta}^{\top}\hat{\phi}_{t}(\boldsymbol{f},Q_{2})\right| \\ &+ \sup_{\boldsymbol{f}\in\mathcal{O}(t),\|\boldsymbol{\eta}\|\leq 1,\|\boldsymbol{\nu}\|\leq 1} \left|\boldsymbol{\eta}^{\top}\nabla_{\boldsymbol{f}}\hat{\phi}_{t}(\boldsymbol{f},Q_{1})\boldsymbol{\nu}| - \boldsymbol{\eta}^{\top}\nabla_{\boldsymbol{f}}\hat{\phi}_{t}(\boldsymbol{f},Q_{2})\boldsymbol{\nu}\right| \\ &\leq L\eta_{\Delta^{\top}}(\theta_{1}+\theta_{2})\mathrm{dI}_{K}(Q_{1},Q_{2}) + L\eta_{\Delta^{\top}}\left(\theta_{1}\eta_{\Delta}+\theta_{2}\eta_{\Delta}+\theta_{2}\hat{C}(t)\right)\mathrm{dI}_{K}(Q_{1},Q_{2}) \\ &= L\eta_{\Delta^{\top}}\left(\theta_{1}+\theta_{2}+\theta_{1}\eta_{\Delta}+\theta_{2}\eta_{\Delta}+\theta_{2}\hat{C}(t)\right)\mathrm{dI}_{K}(Q_{1},Q_{2}), \end{split}$$

where $\hat{\phi}_t(\boldsymbol{f}, Q) = \mathbb{E}_Q[\hat{\boldsymbol{u}}(\boldsymbol{f}, \boldsymbol{C}(\boldsymbol{f}, \xi), t)]$. The first inequality holds due to $\frac{\boldsymbol{\eta}^{\top} \hat{\boldsymbol{u}}(\boldsymbol{f}, \boldsymbol{C}(\boldsymbol{f}, \xi), t)}{L\eta_{\Delta^{\top}}(\theta_1 + \theta_2)}$ and $\frac{\boldsymbol{\eta}^{\top} \nabla_{\boldsymbol{f}} \hat{\boldsymbol{u}}(\boldsymbol{f}, \boldsymbol{C}(\boldsymbol{f}, \xi), t)\boldsymbol{\nu}}{L\eta_{\Delta^{\top}}(\theta_1 \eta_{\Delta} + \theta_2 \eta_{\Delta} + \theta_2 \hat{\boldsymbol{C}}(t))} \in \mathcal{F}_1(\mathbb{R}^k)$ via Proposition 3.1, where $\mathcal{F}_1(\mathbb{R}^k)$ is defined as in (A.4).

Part (ii). Since \mathcal{M}_k^{γ} is relatively compact under $\|\cdot\|$ -weak topology when $\gamma > 1$ (see [48, Lemma 2.69]) and dl_K metrizes the $\|\cdot\|$ -topology (see [44, Theorem 6.3.1]), thus by Prokhorov's theorem [49], we can construct a ϵ -net $\mathcal{Q}_J := \{Q_1, \cdots, Q_J\}$ in the closure of \mathcal{M}_{k,M_0}^1 under the metric dl_K such that $\mathcal{M}_{k,M_0}^1 \subset \bigcup_{j=1}^J \mathcal{B}(Q_j, \epsilon)$, where $\mathcal{B}(Q_j, \epsilon)$ represents a closed ball centered at Q_j with radius ϵ under the metric dl_K . Since $f_t(\cdot)$ is continuous over $\mathcal{M}_{k,M_0}^{\gamma}$ and the strong regularity condition holds at $f_t(Q)$ for $Q \in \mathcal{M}_{k,M_0}^{\gamma}$ by the conditions in (iii), then we can set ϵ sufficiently small such that $f_t(Q)$ for $Q \in \mathcal{B}(Q_j, \epsilon)$, is the unique solution to (3.1) in a neighborhood of $f_t(Q_j)$ containing $\{f_t(Q) : Q \in \mathcal{B}(Q_j, \epsilon)\}$ for $j = 1, \cdots, J$. Following a similar argument to Part (ii), we can obtain that there exists a constant $\kappa_j > 0$ such that

$$\|\boldsymbol{f}_t(Q') - \boldsymbol{f}_t(Q'')\| \le L\eta_{\Delta^{\top}}\kappa_j \left(\theta_1 + \theta_2 + \theta_1\eta_{\Delta} + \theta_2\eta_{\Delta} + \theta_2\hat{C}(t)\right) \mathsf{d}_K(Q',Q'') \tag{C.5}$$

for any $Q', Q'' \in \mathcal{B}(Q_j, \epsilon)$.

For any $Q', Q'' \in \mathcal{M}_{k,M_0}^{\gamma}$ and $\beta \in (0,1)$, define $Q(\beta) = (1-\beta)Q' + \beta Q''$. Let $\hat{Q}_1 \in \mathcal{Q}_J$ be such that $Q' \in \mathcal{B}(\hat{Q}_1, \epsilon)$ and β_1 be the smallest value in (0,1) such that $Q(\beta_1)$ lies at the boundary of $\mathcal{B}(\hat{Q}_1, \epsilon)$ and in the next ball $\mathcal{B}(\hat{Q}_2, \epsilon)$, where $\hat{Q}_2 \in \mathcal{Q}_J$. Next, we let β_2 be the smallest value in $[\beta_1, 1)$ such that $Q(\beta_2)$ lies at the boundary of $\mathcal{B}(\hat{Q}_2, \epsilon)$ and in the next ball $\mathcal{B}(\hat{Q}_3, \epsilon)$, where $\hat{Q}_3 \in \mathcal{Q}_J$. Continuing the process, we let β_{J-1} be the smallest value in $[\beta_{J-2}, 1)$ such that $Q(\beta_{J-1})$ lies at the boundary of $\mathcal{B}(\hat{Q}_{J-1}, \epsilon)$ and in the next ball $\mathcal{B}(\hat{Q}_J, \epsilon)$, where $\hat{Q}_J \in \mathcal{Q}_J$ and $Q'' \in \mathcal{B}(\hat{Q}_J, \epsilon)$. Consequently, we have

$$\begin{split} \|f_{t}(Q') - f_{t}(Q'')\| &\leq \|f_{t}(Q') - f_{t}(Q(\beta_{1}))\| + \sum_{j=1}^{J-2} \|f_{t}(Q(\beta_{j})) - f_{t}(Q(\beta_{j+1}))\| \\ &+ \|f_{t}(Q(\beta_{J-1})) - f_{t}(Q'')\| \\ &\leq L\eta_{\Delta^{\top}} \left(\theta_{1} + \theta_{2} + \theta_{1}\eta_{\Delta} + \theta_{2}\eta_{\Delta} + \theta_{2}\hat{C}(t)\right) \left[\kappa_{1} \mathrm{dI}_{K} \left(Q', Q(\beta_{1})\right) \\ &+ \sum_{j=1}^{J-2} \kappa_{j+1} \mathrm{dI}_{K} \left(Q(\beta_{j}), Q(\beta_{j+1})\right) + \kappa_{J} \mathrm{dI}_{K} \left(Q(\beta_{J}), Q''\right)\right] \\ &\leq \tilde{C}L\eta_{\Delta^{\top}} \left(\theta_{1} + \theta_{2} + \theta_{1}\eta_{\Delta} + \theta_{2}\eta_{\Delta} + \theta_{2}\hat{C}(t)\right) \left[\beta_{1} \mathrm{dI}_{K} \left(Q', Q''\right) + \sum_{j=1}^{J-2} (\beta_{j+1} - \beta_{j}) \\ &\quad \mathrm{dI}_{K} \left(Q', Q''\right) + (1 - \beta_{j}) \mathrm{dI}_{K} \left(Q', Q''\right)\right] \\ &= \tilde{C}L\eta_{\Delta^{\top}} \left(\theta_{1} + \theta_{2} + \theta_{1}\eta_{\Delta} + \theta_{2}\eta_{\Delta} + \theta_{2}\hat{C}(t)\right) \mathrm{dI}_{K}(Q', Q''), \end{split}$$

where $\tilde{C} = \max_{1 \le j \le J} \kappa_j$. The proof is complete.

C.5 Proof of Theorem 3.3

Proof. By definition

$$\mathsf{dI}_{K}(Q_{M}, P_{M}) = \sup_{g \in \mathcal{F}_{1}(\mathbb{R}^{k})} \left| \frac{1}{M} \sum_{i=1}^{M} g(\tilde{\xi}^{i}) - \frac{1}{M} \sum_{i=1}^{M} g(\xi^{i}) \right| \le \frac{1}{M} \sum_{i=1}^{M} \|\tilde{\xi}^{i} - \xi^{i}\|,$$

where $\mathcal{F}_1(\mathbb{R}^k)$ is defined as in (A.4) and the last inequality is due to the fact that g is Lipschitz continuous with modulus being 1. By rewriting $\hat{f}_{M,t}(\tilde{\xi}^1, \dots, \tilde{\xi}^M)$ and $\hat{f}_{M,t}(\xi^1, \dots, \xi^M)$ respectively for $f_t(Q_M)$ and $f_t(P_M)$, we have

$$\begin{aligned} \|\hat{f}_{M,t}(\tilde{\xi}^{1},\cdots,\tilde{\xi}^{M}) - \hat{f}_{M,t}(\xi^{1},\cdots,\xi^{M})\| &= \|f_{t}(Q_{M}) - f_{t}(P_{M})\| \\ &\leq L\tilde{C}\eta_{\Delta^{\top}} \left(\theta_{1} + \theta_{2} + \theta_{1}\eta_{\Delta} + \theta_{2}\eta_{\Delta} + \theta_{2}\hat{C}(t)\right) \mathsf{d}|_{K}(Q_{M},P_{M}) \\ &\leq \frac{L\tilde{C}\eta_{\Delta^{\top}} \left(\theta_{1} + \theta_{2} + \theta_{1}\eta_{\Delta} + \theta_{2}\eta_{\Delta} + \theta_{2}\hat{C}(t)\right)}{M} \sum_{i=1}^{M} \|\tilde{\xi}^{i} - \xi^{i}\|, \end{aligned}$$

where the first inequality holds due to Theorem 3.2 (iii) and the fact that $\mathscr{P}(\Xi)$ is a weakly compact set according to the compactness of Ξ . Moreover, by [31, Lemma 1],

$$\begin{aligned} \mathsf{dI}_{K}(P^{\otimes M} \circ \hat{\boldsymbol{f}}_{M,t}^{-1}, Q^{\otimes M} \circ \hat{\boldsymbol{f}}_{M,t}^{-1}) \\ &= \sup_{g \in \mathcal{F}_{1}(\mathbb{R}^{k})} \left| \int_{\mathbb{R}} g(s) P^{\otimes M} \circ \hat{\boldsymbol{f}}_{M,t}^{-1}(ds) - \int_{\mathbb{R}} g(s) Q^{\otimes M} \circ \hat{\boldsymbol{f}}_{M,t}^{-1}(ds) \right| \\ &= \sup_{g \in \mathcal{F}_{1}(\mathbb{R}^{k})} \left| \int_{\mathbb{R}} g(\hat{\boldsymbol{f}}_{M,t}(\vec{\xi}^{M})) P^{\otimes M}(d\vec{\xi}^{M}) - \int_{\mathbb{R}} g(\hat{\boldsymbol{f}}_{M,t}(\vec{\xi}^{M})) Q^{\otimes M}(d\vec{\xi}^{M}) \right| \\ &= \mathsf{dI}_{\psi}(P^{\otimes M}, Q^{\otimes M}) \leq L\tilde{C}\eta_{\Delta^{\top}} \left(\theta_{1} + \theta_{2} + \theta_{1}\eta_{\Delta} + \theta_{2}\eta_{\Delta} + \theta_{2}\hat{C}(t) \right) \mathsf{dI}_{K}(P,Q) \end{aligned}$$

for all M, where $\vec{\xi}^M = (\xi^1, \cdots, \xi^M)$ and $\vec{\xi}^M = (\tilde{\xi}^1, \cdots, \tilde{\xi}^M)$. The proof is completed.
