# On SAT information content, its polynomial-time solvability and fixed code algorithms

M.Drozdowski

Institute of Computing Science, Poznań University of Technology, Piotrowo 2, 60-965 Poznań, Poland

#### Abstract

The amount of information in satisfiability problem (SAT) is considered. SAT can be polynomial-time solvable when the solving algorithm holds an exponential amount of information. It is also established that SAT Kolmogorov complexity is constant. It is argued that the amount of information in SAT grows at least exponentially with the size of the input instance. The amount of information in SAT is compared with the amount of information in the fixed code algorithms and generated over runtime.

Keywords: computational complexity, information theory.

# 1 Introduction

A number of observations regarding the performance of algorithms solving combinatorial problems and the amount of information they handle were made:

• In [4] a connection between entropy of the Markov chains representing behavior of simulated annealing algorithms and the convergence of the expected objective function value has been made for maximum 3-SAT problem.

• In [9] it is argued that there is a link between the fraction of problem instances achieving certain histogram of values and the entropy of the histogram.

• In evolutionary optimization it is widely accepted rule of thumb that with growing population diversity and size, the chances of producing high quality solutions improve. Intuitively, such populations have more information.

• Structural entropy of graphs representing linking between variables in SAT clauses correlates with practical solvability of SAT [10].

• There is a notion of a graph *hard-to-color* for a certain algorithm in graph node coloring [6, 7]. A graph that is hard-to-color is colored by the considered algorithm with more colors than the optimum. There are examples of graphs hard-to-color for many deterministic algorithms. Random sequential algorithm visits graph nodes in a random sequence and assigns to a node the lowest feasible color. For random sequential algorithm no hard-to-color graph exists, and hence, this algorithm cannot deterministically fail. Ominously, this algorithm is connected to a source of randomness, that is, a source of unlimited amount of information.

In this paper we attempt to analyze the connection between computational and information complexity of combinatorial problems. The main result of this study is Theorem 8 and the following Corollary 9 stating that the amount of information in SAT grows exponentially in the size of the input instance. In the next section notions and assumptions are introduced. Two reference points on the time-information space of SAT solvability are presented in sections 3 and 4. In Section 5 the main result on SAT information content is provided. Section 6 is dedicated to the potential consequences of the obtained SAT information amount estimate.

# 2 Notions and Postulates

The notations used in this paper are summarized in Tab.1. Search version of SAT problem is defined as follows:

#### SAT – SEARCH VERSION

INPUT: sums  $k_j$ , j = 1, ..., m, of binary variables, or their negations, chosen over a set of *n* binary variables  $x_1, ..., x_n$ . The input data is SAT instance *I*.

REQUEST: Find the assignment of values 0/1 to binary variables  $x_1, \ldots, x_n$ , i.e. vector  $\overline{\mathbf{x}}$  of n 0/1 values, such that the conjunction of the clauses  $F(I, \overline{\mathbf{x}}) = \prod_{i=1}^{m} k_i$  is 1. If such a vector does not exist then signal  $\emptyset$ .

If the binary vector  $\overline{\mathbf{x}}$  such that  $F(I, \overline{\mathbf{x}}) = 1$  exists then we will be saying that I is a "yes" instance. Otherwise I is a "no" instance. The input sums  $k_j$  will be alternatively referred to as clauses. If clauses  $k_j$  comprise exactly three variables we will say that it is a 3-SAT problem instance.

Let  $\Sigma^+$  be a set of strings comprising instance encodings as well as solution encodings for some search problem, such as SAT, using some reasonable

Table 1: Summary of notations.

Ø	symbol returned as a solution of a SAT "No"-instance
A	Size of algorithm $A$ in bits
$D_{\Pi}$	set of instances for problem $\Pi$
F	$F = \prod_{j=1}^{m} k_j$ conjunction of clauses $k_j$
$F(I, \overline{\mathbf{x}})$	value of F for instance I and bit assignment $\overline{\mathbf{x}}$
Ι	instance of a problem
I	instance size, i.e., length of the string encoding instance $I$
	according to some reasonable encoding rule (e.g. numbers
	encoded at base greater or equal 2)
$k_{j}$	<i>j</i> th clause of SAT instance, for $j = 1, \ldots, m$
n	number of variables in the SAT problem
m	number of clauses in the SAT problem
$\rho$	upper bound on the bitrate of external information source,
	e.g., random bits source
$S_{\Pi}(I)$	set of solutions for instance $I$ of search problem $\Pi$
$x_i$	<i>i</i> th variable in SAT problem, for $i = 1, \ldots, n$
$\widetilde{x_i}$	<i>i</i> th variable $x_i$ with or without negation
$\overline{\mathbf{x}}$	vector of $n$ binary values

encoding scheme e over alphabet  $\Sigma$ . Search problems are string relations [5]:

**Definition 1** A search problem  $\Pi$  is a string relation

$$R[\Pi, e] = \left\{ \begin{aligned} a \in \Sigma^+ \text{ is the encoding of an instance } I \in D_{\Pi} \text{ and} \\ (a, b) : b \in \Sigma^+ \text{ is the encoding of a solution } s \in S_{\Pi}(I) \\ under \text{ coding scheme } e \end{aligned} \right\},$$

where  $D_{\Pi}$  is a set of instances for problem  $\Pi$  and  $S_{\Pi}(I)$  is a set of solutions for instance I of  $\Pi$ .

Let |I| denote instance I size, i.e., length of the string encoding I according to some reasonable rule. For simplicity of the exposition we assume that I is binary-encoded. We will conventionally refer to bits as information amount units although other units are also possible.

**Definition 2** Fixed code algorithm is an algorithm which is encoded in limited number of bits.

It is necessary to explain how size of an algorithm can be practically measured in bits. Let us consider two models of algorithms: a Turing machine and a Random Access Machine (RAM). Turing machine [5] is defined by set  $\Gamma$  of tape symbols, set Q of states with distinguished halt states  $Q_H$  and a transit function  $\delta: (Q - Q_H) \times \Gamma \to Q \times \Gamma \times \{-1, +1\}$  determining for each pair of the current state in  $Q - Q_H$  and read tape symbol from  $\Gamma$ , the next state in Q, the symbol to be written on the tape and the direction of tape read-write head move. The information content of all these objects is limited and an algorithm can be stored (e.g. in an array data structure, or a table of numbers) in limited number of at most  $(\lceil \log |\Gamma| \rceil + \lceil \log |Q| \rceil + 1) \times |\Gamma| \times |Q|$ bits. Random Access Machine [1] has input and output tapes and a program embodying the algorithm. The program is a finite sequence of instructions from a limited instruction set and possibly some initial data (e.g. preset variables and constants defined by the programmer or the compiler). Let PIdenote the number of program instructions from an instruction set of size IS. The size of RAM program embodying some algorithm is upper-bounded by  $\log(IS) \ge PI$  bits. All data that a RAM program comprises at the outset of the computation are also of limited size and can be counted in into the RAM code size. RAM can be considered a simplified version of programs executed by the contemporary computers. Hence, the programs executable on the contemporary CPUs that encode some abstract algorithms have limited information size. The CPUs themselves comprise some algorithms which can be executed. But likewise, CPUs need only a limited amount of information to be represented because the CPUs can be perceived as logical gates, connections between the gates and the microcode. The number of program code bits and CPU representation bits is upper-bounding the information content of an algorithm. Overall, the above objects representing algorithms can be described in fixed number of bits. Let |A| denote the size of algorithm A in bits.

Let us consider the relationship between fixed code algorithm, its data structures, deterministic and randomized algorithms. An essential requirement for the further discussion is that algorithm information contents size is upper-bounded by a constant. A fixed code algorithm does not change its code size during the runtime. The data-structures that the algorithm comprises at the outset of the computation may change its content during the runtime, but their sizes must remain fixed. A fixed code algorithm can generate information as well as acquire information from external sources. The data obtained and created during runtime is not counted into the size of the fixed code algorithm size. A fixed code algorithm can operate deterministically, but also can use external source of information as, for example, a stream of random bits used in randomized algorithms. Thus, there can be fixed code deterministic and fixed code randomized algorithms. These cases will be tackled in Section 6. Overall, the fixed code, deterministic and randomized algorithms are different but non-disjoint types of objects.

**Postulate 3 (Information conservation postulate)** In order to solve a problem, an algorithm, an instance, algorithm states and other sources of information must be capable of representing at least the same amount of information as the amount of the information in the problem.

**Definition 4** Truly random bit sequence (TRBS) is a sequence of bits, that has no shorter representation.

In effect, a TRBS cannot be compressed, and the way to represent a TRBS of length N bits, is to store it in its whole entirety on N bits.

Postulate 5 Truly random bit sequences exist.

# 3 SAT Polynomial-time Solvability

**Observation 6** SAT can be solved in  $O(|I|^2)$  time, at least in principle, by referring to precomputed solutions.

**Proof.** Given instance I of SAT, the statement of the above observation can be expressed by the following pseudocode:

```
solution \leftarrow SolutionsTable[I];
```

In the above peseudocode, SAT solution is retrieved from a table of precomputed solutions SolutionsTable and the input instance I is used as a position-index in SolutionsTable. Let us observe, that a simplifying assumption is often made that a table (an array) item can be referenced in constant time. This simplification is not justified in the current case because SolutionsTable may be very large. Therefore, and index data structure, in the sense of a database index, is needed to prove that given I, its corresponding solution can be retrieved in  $O(|I|^2)$  time. To this end, the search for a precomputed solution of I can be conducted in a binary tree with  $2^{|I|}$  leaves and  $2^{|I|} - 1$  internal nodes using pointers (addresses) of length |I| + 1 to arrive at the leaves. An internal node holds two pointers to its successors. A leaf holds an answer to a SAT instance (that is  $\overline{\mathbf{x}}$  or  $\emptyset$ ). The data-structure has size  $O(2^{|I|}|I|)$  because it has  $2^{|I|+1} - 1$  nodes each holding at most 2(|I| + 1)bits (which applies also to the leaves holding solutions). The tree can be traversed top-down in O(|I|) steps while reading instance I bits. Each read bit of I determines whether the left, or the right, successor of the current node is followed. Retrieving the left or the right successor requires operation on a |I| + 1-bit-long addresses. The total solution retrieval time is  $O(|I|^2)$ .

Thus, SAT can be solved in polynomial time, at least in principle, provided that an algorithm for SAT has unlimited (precisely, exponential in |I|) amount of information about SAT.

# 4 Kolmogorov Complexity of SAT

**Observation 7** SAT has constant Kolmogorov complexity.

**Proof.** The minimum amount of information required to represent SAT as a string relation is at most |E|+|V|, where E is an algorithm that enumerates all SAT instances I and solutions according to some encoding scheme, while V is an algorithm verifying if a given solution for I is correct. The proof that fixed code E and V exist is very technical because it refers to serialized representation of numbers for which addition can be executed by fixed size code without a need for a circuitry which complexity grows with the values of the numbers. In the following we outline key elements of E and V operation.

For simplicity of the exposition algorithms E (enumerator) and V (verifier) will be represented as two Turing machines, while V has read access to the tapes of E. Let us consider certain number  $n = 1, \ldots$  of binary variables. Given n, a SAT instance may be encoded as a sequence of values:  $(n, m, k_1, \ldots, k_m)$ . Since each variable can be present or missing in a clause, and if present in a clause, the variable can be used with or without negation, the number of possible clauses is at most  $2^{2n}$  and m can be encoded in at most 2n bits. Each clause can be encoded as a sequence of n bit pairs representing at position  $i = 1, \ldots, n$ :  $00_i$  or  $01_i$  – variable  $x_i$  is absent in the current clause,  $10_i$  – variable  $x_i$  is present in the current clause as  $x_i$  (with out negation),  $11_i$  – variable  $x_i$  is present in the current clause as  $\overline{x_i}$  (with negation). Thus, each clause can be encoded in 2n bits. The clauses of the instance can be encoded in  $2nm \leq 2n \times 2^{2n}$  bits. The whole SAT instance can be encoded as a binary number of length  $\lfloor \log n \rfloor + 1 + 2n + 2nm$  bits. Similarly, it is possible to enumerate all  $2^n$  potential solutions  $\overline{\mathbf{x}}$  of a SAT instance with *n* variables on an *n*-bit-long binary string.

All possible pairs  $(I, \overline{\mathbf{x}})$  can be enumerated by a constant information size Turing machine (i.e. a fixed code algorithm) E with four tapes: tape 1 holding value n (this corresponds to the outermost enumeration loop), tape 2 holding m (2nd outermost loop), tape 3 holding  $(k_1, \ldots, k_m)$  (3rd outermost loop), and tape 4 holding  $\overline{\mathbf{x}}$  (the innermost loop). The tapes extend to infinity in both directions. Ends of the information on the tapes in E and V can be sensed by reading a special blank symbol "b". The found pairs  $(I, \overline{x_i})$  or  $(I, \emptyset)$  of SAT as a string relation, are stored on the 5th tape as quadruplets:  $n, m, (k_1, \ldots, k_m), \overline{\mathbf{x}}$ , i.e. contents of tapes 1, 2, 3, 4, is copied, separated by and ending with symbol b. At the outset of the computation tapes 1, 2, 3, 4 comprise only blank symbols b, tape 5 comprises symbols  $\ldots, b, s, b, \ldots$ to mark that no pair from the string relation has been found. The Turing machine E is working on the following principles:

(1) It is adding 1 to a binary-encoded  $\overline{\mathbf{x}}$  on tape 4. Such addition can be implemented with a 3-state, 9-arc transit function. If the end of tape 4 is reached, that is 1 is successfully added, the second Turing machine V is called (it is presented in the following) with the tapes 3 and 4 of E as an input. If V returns that  $\overline{\mathbf{x}}$  on tape 4 satisfies the formula encoded on tape 3 then the content of tapes 1,2,3,4 is copied to tape 5 as described above. E proceeds to the beginning of (1).

(2) If the 4th tape overflows, that is all  $2^n$  possible values of  $\overline{\mathbf{x}}$  are enumerated, then machine E reads the symbol on tape 5. If it is b then this symbol is replaced with s to mark the end of the block of solutions for the instance currently encoded on tapes 1, 2, 3. If symbol s is read from tape 5, then no solution has been found for the current instance, and contents of tapes 1,2,3 is copied to tape 5, after which symbols  $\emptyset$ , s are appended. Next, E adds 1 to number  $(k_1, \ldots, k_m)$  on tape 3 and returns to the enumeration of  $\overline{\mathbf{x}}$  on tape 4 (step 1).

(3) If tape 3 overflows (i.e. exceeds 2nm), then 2n zeros are appended on tape 3 to the string encoding  $(k_1, \ldots, k_m)$ , this operation can be facilitated by referring to the length of the string encoding m on tape 2, as it also has length of 2n bits. Furthermore, m is increased by one. If m on tape 2 does not overflow, E returns to (1).

(4) If m overflows (i.e. exceeds  $2^{2n}$ ), then bits 10 are appended to the binary

encoding of m and n is increased on tape 1.

Thus, a fixed code algorithm E enumerating all input instances and all solutions for arbitrary n exists.

It remains to show that algorithm V checking if the binary-encoded  $\overline{\mathbf{x}}$  on tape 4 satisfies formula  $(k_1, \ldots, k_m)$  on tape 3 can be implemented in a in transit function with limited number of states and arcs. V has two read heads for tapes 4 and 3 of E, the tapes are read from left to right, and while reading literals in clauses  $(k_1, \ldots, k_m)$  on tape 3 it moves the read head on tape 4 accordingly. In detail, V operates on the following principles:

state 0: start with the read heads at the beginnings of tapes 3 and 4 (the leftmost positions).

state 1:

If head 4 reads b (end of tape 4, values of all binary variables were verified, but none satisfied the current clause k<sub>j</sub> on tape 3), move both heads to the beginnings o the tapes, return to E to the state accepting an answer that x on tape 4 does not satisfy formula (k<sub>1</sub>,..., k<sub>m</sub>) on tape 3 (i.e. return to the beginning of E point (1)). Otherwise head 4 reads 0/1, then do the following:
If head 3 reads 0 (the current variable x<sub>i</sub> is not present in the current clause k<sub>j</sub>), then tape 3 is moved by two and tape 4 by one position to the right, next jump to state 1.

• If head 3 reads 1 ( $x_i$  is present in  $k_j$ ), then move tape 3 one position to the right, and proceed to state 2.

• If head 3 reads b (b-blank, end of the tape 3 is reached, all clauses satisfied) move heads 3 and 4 to the beginning of the tapes and return to E to the state accepting "yes" answers.

state 2:

• If head 3 reads 0 and head 4 reads 1, or head 3 reads 1 and head 4 reads 0  $(k_j \text{ is satisfied by } x_i)$ , then iteratively move head 4 by one position to the right and head 3 two positions to the right at an iteration, until reaching end of tape 4 (head 3 is at the start of clause k + 1 or moved beyond the end of tape 3). Move head 4 to the beginning of the tape. Proceed to state 1.

• Otherwise,  $(k_j \text{ is not satisfied by } x_i)$  move both heads one position to the right and proceed to state 1.

Hence, SAT as a string relation can be reconstructed by enumerating all input instances of increasing sizes n using algorithm E and choosing the correct answer by the use of algorithm V.

It is an interesting coincidence that SAT is polynomial-time solvable if

exponential amount of information is held by an algorithm (Observation 6) and a fixed-size information object is sufficient to recreate SAT in exponential time (Observation 7). Note that information in one form of SAT representation, that is concise E and V, is transformed to different information in alternative SAT representation (string relation).

# 5 Amount of Information in SAT

In this section we introduce the idea of quantifying information content of search problems as string relations. A string relation  $R[\Pi, e]$  is a mapping from strings *a* representing instances to strings *b* representing solutions. The information content of problem  $\Pi$  can be measured in the terms of the amount of information carried by this mapping.

SAT-search is also an example of a search problem. Thus, also SAT can be thought of as a mapping from strings a representing instances to strings brepresenting solutions and this mapping can be measured in the terms of the amount of carried information. Each string a is either a "yes" instance, or a "no" instance. In the former case an *n*-bit solution  $\overline{\mathbf{x}}$  must be provided by the mapping. In the latter case symbol  $\emptyset$  must be provided. We will assume conventionally that if the a string, according to encoding scheme e, is not encoding any SAT instance, then such a case can be represented in the same way as a "no" instance with answer  $\emptyset$ . In order to encode each pair (a, b) of the relation representing SAT it is necessary to have an equivalent of a graph arc from string a to its solution b. Such an arc requires |I| + n bits of information which is at least  $\Omega(|I|)$  bits. There are  $2^{|I|}$  strings of some size |I|. Since it is necessary to at least distinguish whether b strings represent  $\emptyset$  or  $\overline{\mathbf{x}}$ , at least  $\Omega(2^{|I|})$  bits of information seem necessary to encode SAT as string relation R[SAT, e]. However, it is still possible that SAT can be encoded in fewer than  $\Omega(2^{|I|})$  bits. Thus, some more compact, or compressed, representation of SAT may exist.

# **Theorem 8** The amount of information in SAT grows at least exponentially with instance size.

**Proof.** Assume there are *n* variables and 4*n* clauses in 3-SAT. Let there be 4 clauses  $k_{i1} = x_a + x_b + \widetilde{x_i}, k_{i2} = \overline{x_a} + x_b + \widetilde{x_i}, k_{i3} = x_a + \overline{x_b} + \widetilde{x_i}, k_{i4} = \overline{x_a} + \overline{x_b} + \widetilde{x_i}$  for each  $i = 1, \ldots, n$ .  $\widetilde{x_i}$  denotes that variable  $x_i$  will be set with or without negation. No valuing of  $x_a, x_b$  makes the four clauses simultaneously

equal 1. The four clauses may simultaneously become equal 1 only if  $\widetilde{x_i} = 1$ . Satisfying formula  $F = k_{11}k_{12}k_{13}k_{14} \dots k_{n4}$  depends on valuing of variables  $\widetilde{x_i}$  for  $i = 1, \dots, n$ . Depending on whether binary variable *i* is negated or not (i.e. written either  $x_i$  or  $\overline{x_i}$  consistently in  $k_{i1}, k_{i2}, k_{i3}, k_{i4}$ ) there can be  $2^n$  different ways of constructing formula *F*, thus leading to  $2^n$  different "yes" instances with  $2^n$  different solutions. Variables  $x_a, x_b$  are chosen such that  $a \neq b$  and  $a, b \neq i$ . Since there are (n-1)(n-2)/2 possible pairs a, b for each *i*, it is possible to generate pairs a, b satisfying the above conditions for  $n \geq 3$ .

We are now going to calculate the number of different "yes" instances as a function of instance size |I| because instance size |I|, not n, is used in the complexity assessment. Suppose the uniform cost criterion [1] is assumed, then each number has value limited from above by constant K. The length of the encoding of the instance data is  $|I| = 4n \times 3 \log K + \log K = 12n \log K + \log K$  because it is necessary to record the indexes of variables in  $\log K$  bits, each binary variable induces 4 clauses of length  $3 \log K$ . Negation of a variable, or lack thereof, is encoded on one bit within  $\log K$ . Consequently, the number of possible unique solutions is  $2^n = 2^{(|I| - \log K)/(12 \log K)} = 2^{|I|/(12 \log K)}2^{-1/12}$ , which is  $\Omega(2^{d_1|I|})$ , where  $d_1 = 1/(12 \log K) > 0$ .

Assume logarithmic cost criterion [1], then the number of bits necessary to record n is  $\lfloor \log n \rfloor + 1$ , and  $\lfloor \log n \rfloor + 2$  bits are needed to encode the index of a variable and its negation, or lack thereof. Length of the encoding string is  $|I| = 12n(\lfloor \log n \rfloor + 2) + \lfloor \log n \rfloor + 1 \leq 15n \log n = dn \ln n$ , for  $n > 2^{24}$  and  $d = 15/\ln 2 \approx 21.6404$ . An inverse function of  $(cx \ln x)$ , for some constant c > 0, is  $\frac{x}{c}/W(\frac{x}{c})$ , where W is Lambert W-function [8]. Lambert W function for big x can be approximated by  $W(x) = \ln x - \ln \ln x + O(1)$ . Given instance size |I|, we have  $n \geq \frac{|I|}{d}/W(\frac{|I|}{d}) \approx \frac{|I|}{d}/(\ln \frac{|I|}{d} - \ln \ln \frac{|I|}{d} + O(1)) \geq \frac{|I|}{d}/(2\ln \frac{|I|}{d}) \geq \frac{|I|}{d}/(2\ln |I| - 2\ln d) \geq |I|/(2d\ln |I|)$ , for sufficiently large |I|. Note that |I|,  $dn \ln n$ ,  $\frac{x}{c}/W(\frac{x}{c})$  are increasing in n, x. Thus, by approximating |I| from above we get a lower bound of n after calculating an inverse of the upper bound of |I|. The number of possible unique solutions is  $2^n \geq 2^{|I|/(d_2\ln |I|)}$  where  $d_2 = 2d$ . Observe that  $2^{|I|/(d_2\ln |I|)}$  exceeds any polynomial function of |I| for sufficiently large |I|, because for any polynomial function  $O(|I|^k)$ ,  $\ln(|I|^k) < |I|/(d_2\ln |I|)$  with |I| tending to infinity.

Consider a truly random bit sequence (TRBS) of length  $2^n$ . Assume that  $j \in \{1, \ldots, 2^n\}$  is one of the instances of 3-SAT constructed in the above way. Let j[i] for  $i = 1, \ldots, n$  be the *i*-th bit of *j* binary encoding. If bit *j* 

of the TRBS is equal to 1, we set variables  $\widetilde{x_i}$ , for  $i = 1, \ldots, n$ , such that  $\widetilde{x_i} = j[i]$  satisfy clauses  $k_{1i}, \ldots, k_{4i}$ . For example, if j[i] = 1 and the *j*-th bit of the TRBS is 1, then  $\widetilde{x_i}$  is written as  $x_i$ . If j[i] = 0 and the *j*-th bit of the TRBS is 1, then  $\widetilde{x_i}$  is written as  $\overline{x_i}$ . Thus, if bit *j* of the TRBS is equal to 1 then a "yes" instance is constructed. Conversely, if the TRBS bit j = 0 then at least one variable  $x_i$  in the corresponding clauses  $k_{1i}, \ldots, k_{4i}$  is set inconsistently, i.e., some  $\widetilde{x_i}$  appears in  $k_{1i}, \ldots, k_{4i}$  both with negation and without. Hence, if bit *j* of the TRBS is equal to 0, the *j*-th instance constructed in the above way becomes a "no" instance. Note that in this way the TRBS of length  $2^n$  was encoded in 3-SAT search problem. The amount of information in 3-SAT grows at least in the order of  $\Omega(2^{d_1|I|})$  for uniform (or  $\Omega(2^{|I|/(d_2 \ln |I|)})$  for logarithmic) cost criterion.

Let us observe that there can be  $2^{2^n}$  different TRBSes of length  $2^n$  used in the proof of Theorem 8. However, it does not mean that  $2^{2^n}$  SAT examples (i.e. batches of  $2^n$  SAT instances constructed as described in Theorem 8) can be delivered. Note that in the construction of Theorem 8 it is important whether instance  $j \in \{1, \ldots, 2^n\}$  is a "yes", or a "no" instance. After presenting the 2<sup>n</sup>-bit-long TRBS, only when instance  $j \in \{1, \ldots, 2^n\}$ is presented in the alternative form to the TRBS a new piece of information emerges. That is, if instance j was a "yes" instance in the construction of Theorem 8, then a new information on j is that it can be also made a "no" instance. And vice versa, new information emerges when some "no" instance i in the TRBS of Theorem 8 is later presented as a "yes" instance. Thus, information on the permutation in which alternative versions of instances  $j \in \{1, \ldots, 2^n\}$  are revealed can be added to the  $2^n$  bits of the Theorem 8 TRBS. Since there are  $2^{n!}$  permutations of instances j alternative forms, the additional amount of information in their permutation is  $|\log 2^n!| + 1$ . This results in SAT information estimation  $\Omega(n2^n)$  which is  $\Omega(|I|2^{d_1|I|})$  for uniform (or  $\Omega(|I|/(d_2 \ln |I|)2^{|I|/(d_2 \ln |I|)})$  for logarithmic) cost criterion and the construction used in Theorem 8. Conversely, the amount of information necessary to record directly all  $2^n$  solutions to the instances of length |I| with n binary variables is  $O(|I|2^n)$ . Since  $n \leq |I|$  (for both types of cost criteria) we have a corollary:

**Corollary 9** Information content of SAT is  $\Theta(|I|2^{|I|})$ .

## 6 On the Consequences

### 6.1 Polynomial-time Solvability and Information Size

Let us estimate the amount of information that can be created by a fixed code algorithm running in time T.

**Proposition 10** A fixed code deterministic algorithm can produce  $\Omega(T \log T)$  bits of information in T units of time.

**Proof.** The information represented in the evolution of the algorithm state can be estimated in at least three ways, all leading to the same lower bound. The number of algorithm different states is T because the algorithm stops and hence it does not loop. The number of different sequences in which the states of the algorithm can be visited can be bounded from above by T!. The number of bits necessary to distinguish the sequences is  $\log(T!) + 1$ which is  $\Theta(T \log T)$ . An attempt of distinguishing the states of the algorithm by counting them, or assigning time stamps, gives only  $T \log T$  bits of information. It is also possible to assess the amount of information in the evolution of the algorithm state by use of mutual information between the progressing time and algorithm state. Assume that time variable  $\mathcal{T}$  progresses deterministically in steps  $1, \ldots, T$ , then the probability that step t is achieved by time t is p(t) = 1. The algorithm state variable S progress through states  $s_1, \ldots, s_T$ . The deterministic algorithm is in certain state  $s_t$  at time t with probability  $p(s_t, t) = 1$  and  $\forall s_i \neq s_t, p(s_i, t) = 0$ . The probability that algorithm is in state  $s_t$  disregarding time is 1/T. Mutual information from time variable  $\mathcal{T}$  to algorithm state  $\mathcal{S}$  is  $I(\mathcal{S}, \mathcal{T}) = \sum_{i=1}^{T} \sum_{s_i \in \mathcal{S}} p(s_i, i) \log \frac{p(s_i, i)}{p(s_i)p(i)} = \sum_{i=1}^{T} p(s_t, t) \log \frac{p(s_t, t)}{p(s_t)p(t)} = \sum_{i=1}^{T} 1 \times \log \frac{1}{1/T \times 1} = T \log T.$ 

According to the information conservation postulate 3, the input instance, the algorithm, the information derived from changing algorithm states and obtained from external sources over the runtime must represent equivalent amount of information as the mapping from the instances to the solutions in the considered problem. An algorithm solves a problem if it provides an answer *for each* input instance [5]. However, at the outset of computation only one instance is given, and the amount of information in a fixed code algorithm and in the input instance is |I| + |A| bits. We argue that the amount of information derived from changing algorithm states or from external sources can be insufficient for some algorithm classes. Let  $\rho$  denote an upper limit on the amount of information that can be transferred in a unit of time ( $\rho$  is a bitrate limit). The assumption on upper-bounding of  $\rho$  is practical because it is not possible to transfer arbitrary amounts of information in limited time. The bitrate limit applies both to the transfers of the algorithm internally created information and to the transfers of external information, e.g. a stream of random bits, which can be acquired by an algorithm.

# **Proposition 11** Fixed code algorithm is not capable of representing SAT in polynomial time even with external source of information of constant bitrate.

**Proof.** |I| + |A| is the instance and the algorithm information size. By proposition 10 the amount of information created by a fixed code algorithm run in time T = q(|I|), where q is a polynomial, is  $\Omega(q(|I|) \log(q(|I|)))$ . The amount of acquired external information is  $O(\rho q(|I|))$ . Also no more than  $O(\rho q(|I|))$  information can be transferred by the algorithm internally, which applies also to the information created by the algorithm itself. Thus, for sufficiently large |I| the amount of available information an algorithm is able to use is limited by  $O(\rho q(|I|))$  rather than by the size  $\Omega(q(|I|) \log(q(|I|)))$ which could potentially be created. The information amount accessible for a fixed code algorithm for sufficiently large |I| is  $|I| + |A| + O(\rho q(|I|))$ . Overall, for sufficiently large |I| it is less information than  $\Omega(2^{|I|})$  bits comprised in SAT by Theorem 8.

Let us return to Kolmogorov complexity of SAT and SAT size as a string relation. On the one hand, Kolmogorov complexity of SAT is |E| + |V|, by Observation 7. On the other hand, by Theorem 8 SAT has  $\Omega(2^{|I|})$  (uniform criterion) or  $\Omega(2^{|I|/(\ln |I|)})$  (logarithmic criterion) incompressible bits. It can be speculated that the discrepancy between these two numbers can be attributed to qualitative difference of the two forms of SAT representation (two types of information). Transforming from the first form to the second requires  $\Omega(2^{|I|})$  information derived over runtime. Informally, SAT has exponential compression efficiency with respect to |I|. Since by Cook's theorem SAT is a foundation of all **NP**-complete problems, the above observations can be extended to all **NP**-complete problems.

### 6.2 On Polynomial Problems Information Content

A complement to the considerations in Section 6.1 is to show that polynomial-time-solvable problems have polynomial amount of information when represented as string relations. Unfortunately, a uniform and universal approach to achieve this is unknown.

As an attempt to study a string relation representing a polynomial problem and its information content, consider sorting n integers  $l_i$ . Input instances a can be any of the n! permutations of the numbers. The output string b is the sequence satisfying  $l_1 \leq l_2, \ldots \leq l_n$ . Note that the actual values of  $l_i$ s are immaterial. The actual input permutation of the numbers is also meaningless. Important is the fact that relations  $l_i \leq l_i$  can be established. The amount of information required to establish this fact is  $|l_i| + |l_j| + |cmp|$ , where  $|l_i|$  is binary-encoded string length of  $l_i$ , |cmp| is the size of a fixed code comparator algorithm. Such a comparator can be implemented as a 2-tape Turing machine with 3 states (including two finals states:  $l_i \leq l_j$ ,  $l_i > l_j$ ), or with 5 states if replacing positions of the numbers on the tapes is needed. Hence, the input information size is |I| on the side of input strings a of the string relation, independently of the numbers permutation. The amount of information on the side of the output strings b satisfying  $l_1 \leq l_2, \ldots \leq l_n$  is  $O(n \log n)$  which can be upper-bounded by O(|I|). In order to confirm that sorting numbers, transforming any input permutation a to the required sequence of numbers b, carries polynomial amount of information, consider, e.g., bubble-sorting network which has  $O(n^2)$  comparators and  $O(\log n)$  bits of information are needed to connect inputs of each comparator to the outputs of its predecessor in the sorting network. The sorting network has  $O(n^2 \log n)$  information which can be upper-bounded by  $O(|I|^2)$ . The overall information in sorting grows in  $O(|I|^2)$  with the instance size.

The above reasoning can be extended to all combinatorial problems which solutions are obtained by sorting input elements according to some rule, that is, to the problems solvable by greedy algorithms.

### 6.3 On Non-fixed Code Algorithms

In this study a concept of fixed code algorithms was used. A question naturally emerges, what the non-fixed code algorithms can be. Classic randomized metaheuristics, although they use external sources of randomness, remain within the realm of fixed code algorithms. Machine learning methods seem obvious candidates for the non-fixed code algorithms if the training and the inference stages together are considered one algorithm. The inference stage, when used stand-alone, also remains in the realm of fixed code algorithms. Let us note that by Theorem 8, combinatorial problems like SAT, are ultimately not learnable. This poses a question of the scalability of machine learning methods in solving hard combinatorial problems, possibility of machine learning auto-tuning and taking humans out of the training-inference loop.

# Acknowledgments

I thank Joanna Berlińska, Iwo Błądek, Piotr Formanowicz, Małgorzta Sterna, Tomasz Żok, Krzysztof Zwierzyński for discussing with me in the earlier stages of this consideration [2, 3]. To Patrick de Causmacker, Seffi Naor, Natasha Shakhlevich, Stanisław Gawiejnowicz for inspiring questions.
