(Dated: January 9, 2024)

Magnetic domain walls (DWs) are topological defects that exhibit robust low-energy modes that can be harnessed for classical and neuromorphic computing. However, the quantum nature of these modes has been elusive thus far. Using the language of cavity optomechanics, we show how to exploit a geometric Berry-phase interaction between the localized DWs and the extended magnons in short ferromagnetic insulating wires to efficiently cool the DW to its quantum ground state or to prepare nonclassical states exhibiting a negative Wigner function that can be extracted from the power spectrum of the emitted magnons. Moreover, we demonstrate that magnons can mediate long-range entangling interactions between qubits stored in distant DWs, which could facilitate the implementation of a universal set of quantum gates. Our proposal relies only on the intrinsic degrees of freedom of the ferromagnet, and can be naturally extended to explore the quantum dynamics of DWs in ferrimagnets and antiferromagnets, as well as quantum vortices or skyrmions confined in insulating magnetic nanodisks.

Introduction.—Magnetic domain walls (DWs) are stable topological magnetic configurations that are robust against local deformations [\[1\]](#page-4-0). Because of their topological stability, capacity for high-density packing, and flexible design, magnetic DWs in ferromagnetic nanowires have emerged as a promising avenue for data storage and information processing in spintronic devices [\[2–](#page-4-1)[6\]](#page-4-2). Understanding their dynamics and motion is crucial for achieving high-speed operation and efficient manipulation of spintronic devices.

Miniaturization naturally raises the question of the importance of quantum effects in future DW-based devices. Indeed, several works have proposed recently to harness their quantum properties in order to encode and process quantum information at the nanoscale [\[7–](#page-4-3)[12\]](#page-4-4). However, such endeavors require the DW to be in the ground state, or at least near its ground state. Until now, no such achievement has been demonstrated experimentally, largely because the required operation temperatures are too low (\sim mK). This raises the question of whether the quantum regime can be reached in practice and, if so, under what conditions? In this work, we answer these questions affirmatively by proposing a ground-state cooling method that exploits the intrinsic magnons (or spin waves) in insulating ferromagnetic devices hosting DWs.

We focus on a finite ferromagnetic insulating wire of length $2L$ and easy-axis anisotropy K_e that harbors one (or several) DW(s) of size $\lambda \ll L$ along its length, as depicted in Fig. [1.](#page-0-0) When the DW is pinned in the z direction, the low-energy spectrum is determined by the dynamics of the collective coordinate Φ , which parameterizes the angle of the spin texture of the DW [\[13\]](#page-4-5). The resulting (quantum) level structure can be manipulated by an external magnetic field B that modifies the confining potential $U(\Phi)$ (see Fig. [1\)](#page-0-0), rendering it highly anharmonic. Therefore, the two lowest energy levels localized at the DW, $\{|1\rangle, |2\rangle\}$, can be used to encode a qubit below the gapped magnonic levels [\[8,](#page-4-6) [12\]](#page-4-4). However, the external magnetic field, in-plane anisotropies, and – most importantly – the DW rotational motion induce interactions between the local-

FIG. 1. Magnonic cavity with a DW: a ferromagnetic insulator wire of length 2L and magnetization profile $n(z)$ harbors a DW of size $\lambda \ll L$ pinned at position Z_0 in the wire. An external magnetic field $\mathbf{B} \parallel y$ controls the collective angle Φ , allowing to encode a qubit with energy ϵ_q in the lowest two levels. The magnons gapped by the easy z-axis anisotropy K_e couple to the DW with a coupling strength g by altering its collective Berry phase. Coupling the cavity magnons to a magnonic waveguide facilitates the manipulation [by the input magnons $a_{\text{in}}(t)$ and the detection [from the power spectrum of the output magnons $a_{\text{out}}(t)$ of the DW levels.

ized DW states and the gapped, extended magnons, which in turn alter their collective dynamics. Instead of viewing this as a nuissance, here we harness such interactions to control the DW dynamics. Using the theoretical framework of cavity optomechanics [\[9,](#page-4-7) [14](#page-4-8)[–17\]](#page-4-9), we find that the large anharmonicity of the DW (supplemented by dissipation) in the presence of coherently driven magnons enables means of controlling the motion of DW at the quantum level. Specifically, we advance the conditions for efficient cooling to the ground state as well as preparing stationary DW states that exhibit a negative Wigner function – a hallmark of a pure quantum regime. Experimentally, such features can be extracted from the power spectrum of the emitted magnons.

Phenomenology of DW-magnon dynamics.—To grasp the essentials of our proposal, we start with a heuristic discussion of our main findings, relegating the technical details to later sections and the Supplementary Material (SM) [\[18\]](#page-4-10). A DW is described by the collective (and canonically conjugate) coordinates Z and Φ [\[13\]](#page-4-5), denoting its position (scaled by λ) and the rotation angle in the wire, respectively. In the presence of a strong pinning potential $V_{\text{pin}}(Z) = \delta K_e (Z - Z_0)^2 / 2$, with δK_e being its strength, the motion along z is quenched and the low-energy dynamics of a DW with spin S_{dw} (per length λ) is described by the following rotational Hamiltonian ($\hbar = 1$):

$$
H_{\Phi} = \frac{1}{2M_{\Phi}} P_{\Phi}^2 + U(\Phi). \tag{1}
$$

Here, $M_{\Phi} = (2S_{dw})^2/\delta K_e$ and P_{Φ} are the mass of the DW and the canonical momentum associated with rigid rotations of the DW, respectively, while $U(\Phi)$ describes the potential that depends on the magnetic anistrotropies and the external magnetic field. The latter can adjust $U(\Phi)$ from a doublewell potential to a single-well potential that is harmonic in nature [\[12\]](#page-4-4). Promoting the momentum to a quantum variable, i.e., $P_{\Phi} \rightarrow -i\partial_{\Phi}$, allows to solve the Schrodinger equation $H_{\Phi}\psi_i(\Phi) = \epsilon_i\psi_i(\Phi)$, with $\psi_i(\Phi)$ and ϵ_i being, respectively, the eigenstate and energy of mode $j = 1, 2, \ldots$ of the DW. Importantly, the anharmonicities facilitate the implementation of a qubit in the subspace spanned by the two lowest energy levels with splitting $\epsilon_q \equiv \epsilon_2 - \epsilon_1$ [\[8,](#page-4-6) [12\]](#page-4-4).

When the external magnetic field is adjusted to make the potential quartic, $U(\Phi) \approx \tilde{K}_h \Phi^4 / 4$, both the qubit splitting and the anharmonicity are large, K_h being an effective DW hard-axis anisotropy strength in the y direction [\[18\]](#page-4-10). The resultant spectrum and wave functions are shown in Fig. [2a](#page-1-0). We can gain further insight into the anharmonicity in this limit by using the quasiclassical Bohr-Sommerfeld quantization con-dition [\[18\]](#page-4-10), to find $\epsilon_j \approx \epsilon_1 (j - 1/2)^{4/3}$, with $j = 1, 2, \ldots$ and

$$
\epsilon_1 \approx \frac{0.86}{S_{dw}^{4/3}} \left(\widetilde{K}_h \delta K_e^2 \right)^{1/3} . \tag{2}
$$

To provide some estimates, for a DW with $S_{dw} \approx 50$, $K_h =$ $5\delta K_e$, and $\delta K_e \approx 10$ GHz, we find a qubit splitting $\epsilon_q \approx$ $\times 10^{-2} K_h \approx 100$ MHz. We stress that it is possible to achieve larger qubit splittings by selecting ferrimagnetic wires that are close to the compensation point, $S_{dw} \approx 0$ [\[12\]](#page-4-4).

The decoherence of the DW quantum levels can be accounted for by substituting $H_{\Phi} \to H_{\Phi} - \Phi \xi(t)$, where $\xi(t)$ is the Langevin force obeying the fluctuation-dissipation condition $\langle \xi(t)\xi(0)\rangle = \alpha S_{dw} \int (d\omega/2\pi) e^{-i\omega t} \omega \coth(\omega/2k_BT)$ at temperature T, with k_B being the Boltzmann constant and α the Gilbert damping [\[7\]](#page-4-3). In a quantum description, it corresponds to a bosonic bath that discriminates between the emission and absorption processes. The transition rate γ_{ik} from state j to state k can be evaluated using Fermi's golden rule [\[19\]](#page-4-11), giving $\gamma_{jk} = \alpha S_{dw} |\langle j|\Phi|k\rangle|^2 \epsilon_{jk} [1 + \coth(\epsilon_{jk}/2k_BT)],$

FIG. 2. (a) The DW energy levels ϵ_i and wave-functions $\psi_i(\Phi)$, with $j = 1, 2, \ldots$, for a reduced magnetic field $\tilde{b} = \pi b/2K_h = 1$ leading to a quartic effective potential $U(\Phi)$ (dashed line). (b) Occupation of DW levels for $T = 10\epsilon_q$, indicating a highly thermal (or classical) state. The other parameters are $\tilde{K}_h = 5\delta K_e$ and $S_{dw} = 50$, while all energies are expressed in terms of δK_e .

with $\epsilon_{jk} = \epsilon_j - \epsilon_k$, while $\gamma_{kj} = \gamma_{jk} \exp(-\epsilon_{jk}/k_BT)$, in thermal equilibrium. Using the same qubit parameters, we find $\gamma_{12} \sim \gamma_{21} \approx 10^{-3} \epsilon_q$ for $T = 0.05$ K $(\approx 10 \epsilon_q)$. Although the qubit exhibits low relaxation rates, the occupation of the DW levels at $T = 0.05$ K is highly thermal, as shown in Fig. [2b](#page-1-0), thus far from its ground state, as desired for qubit initialization.

ext, we qualitatively discuss the interaction with the magnons, fluctuations around the localized DW that extend throughout the wire $[20]$, which can be used to cool the DW towards its ground state. In a frame rotating with the DW, the magnons are subject to a fictitious magnetic field pointing along the wire axis $B_m(Z_0) \propto \dot{\Phi}_{mdw}$, with $m_{dw} = (N_{\leftarrow} (N_{\rightarrow})/N_{\text{tot}} \equiv Z_0/L$ being the spin up/down fraction of the magnon (which moves ballistically across the DW), $N_{\leftarrow (\rightarrow)}$ the number of spins pointing along the left (right) direction, while $N_{\text{tot}} = N_{\leftarrow} + N_{\rightarrow}$ [\[21\]](#page-4-13). Its physical manifestations are revealed when considering the proximity to a magnetic lead at the wire boundary (see Fig. [1\)](#page-0-0), with a coupling that picks a term $\exp(i\Phi)$ in a frame rotating with the DW. This latter contribution can be removed by a gauge transformation, resulting in a net magnetic field $B_{\text{m}} \to B'_{\text{m}} \propto \dot{\Phi}(1 - m_{dw})$ acting on the magnons. In a Hamiltonian description, the velocity coupling corresponds to a vector potential that acts on the magnons $[18]$, with a maximum (minimum) strength at $Z_0 = -L$ ($Z_0 = L$). If a specific magnonic mode of energy ω_n is triggered by an external driving of frequency Ω_n and strength h_n at the left end, only this mode effectively participates in the dynamics. Then, we arrive at the following DW-magnon coupling Hamiltonian:

$$
H_{\text{tot}} \approx \frac{(P_{\Phi} - P_n a_n^{\dagger} a_n)^2}{2M_{\Phi}} + \Delta_n a_n^{\dagger} a_n + h_n (a_n^{\dagger} + a_n), \quad (3)
$$

where a_n (a_n^{\dagger}) are the annihilation (creation) operator for the magnon mode with energy $\Delta_n \equiv \omega_n - \Omega_n$, while $P_n \equiv$ $P_n(Z_0) = 1 - m_{dw}$ quantifies the Berry-phase mediated DWmagnon coupling $[22]$. Eq. (3) is formally analogous to an optomechanical system, with the DW angle and the magnons replacing the mechanical position and the cavity photons, re-spectively [\[14\]](#page-4-8). Note that in the absence of the drive $(h_n = 0)$, the coupling is a pure gauge shift and therefore inconsequential. Eq. [\(3\)](#page-1-1) represents one of our main findings, and its heuristic derivation is complemented by a microscopic calculation in the next section, and further technical details are provided in the SM $[18]$. Importantly, Eq. (3) is general and universal (since it is rooted in Berry-phase effects), and it is the starting point for unraveling the quantum dynamics of the macroscopic DW states.

Microscopic model.—We assume that the ferromagnetic wire is well below the Curie temperature T_c , such that the long-wavelength dynamics can be described in terms of coarse-grained continuous fields $n(z)$ $\{\sin \theta \cos \phi, \sin \theta \sin \phi, \cos \theta\}$. The Lagrangian for the magnetic wire reads [\[13\]](#page-4-5):

$$
\mathcal{L}_w[\boldsymbol{n}, \dot{\boldsymbol{n}}] = -\int_{-L}^{L} dz \left(s \frac{\boldsymbol{d} \times \boldsymbol{n}}{1 + \boldsymbol{n} \cdot \boldsymbol{d}} \dot{\boldsymbol{n}} + \mathcal{H}_F[\boldsymbol{n}] \right),
$$

$$
\mathcal{H}_F[\boldsymbol{n}] = \frac{1}{2} [A(\partial_z \boldsymbol{n})^2 - K_e n_z^2 + K_h n_y^2 + b n_y], \quad (4)
$$

where d is the (arbitrary) direction of the Dirac string, while s, A, K_e , K_h , and b are the spin density, exchange (stiffness), the easy-axis anisotropy, the hard-axis anisotropy, and the magnetic field, respectively. To account for dissipation consistent with the Landau-Lifhitz-Gilbert (LLG) equation obeyed by the magnetization dynamics, the above Lagrangian can be supplemented with the Rayleigh function $\mathcal{R}[\dot{n}]$ = $\alpha s \int dz \dot{\mathbf{n}}^2(z)/2$. Finally, the coupling between the wire and the magnetic lead reads $H_c = \mathcal{T} \mathbf{n}_l(-L) \cdot \mathbf{n}(-L)$, where $\mathcal T$ is the coupling strength, while $n_l(z)$ describes the magnetization of the lead whose dynamics is dictated by a similar Lagrangian as in Eq. [\(4\)](#page-2-0) for $z \in (-\infty, -L)$.

In the absence of an external magnetic field, the ferromagnet has two classical ground states, $n(z) = \pm e_z$, which are uniformly polarized along the easy axis. Additionally, in the limit $L \to \infty$ the model above admits a DW solution n_0 that minimizes the Hamiltonian part [second term in Eq. [\(4\)](#page-2-0)] for boundary conditions $n_0(z = \pm \infty) = \pm e_z$:

$$
\cos \theta_0(z) = \tanh [Q(z - Z)]; \phi(z) \equiv \Phi, \quad (5)
$$

where $Q = \int_{-\infty}^{\infty} dz \partial_z \theta / \pi = \pm 1$ is the topological charge determined by the boundary conditions (at the edges of a long wire), while Z and Φ are the unconstrained position and angle of the domain wall, with all lengths expressed in terms of $\lambda \equiv$ $\sqrt{A/K_e}$. The low-energy dynamics of the DW for $b, K_h \neq 0$ is described by the Lagrangian [\[13\]](#page-4-5)

$$
\mathcal{L}_{dw} = -2S_{dw}Z\dot{\Phi} + U(\Phi) - V_{\text{pin}}(Z),
$$

$$
U(\Phi) = \widetilde{K}_h(\sin^2\Phi + \widetilde{b}\sin\Phi),
$$
 (6)

where $S_{dw} = s\lambda$, $\widetilde{K}_h = K_h\lambda$, $\widetilde{b} = \pi b/2K_h$, and we introduced also a pinning potential $V_{\text{pin}}(Z)$ = $-(\delta K_e/2) \cosh^{-2}(Z - Z_0)$, stemming from a point-like defect at position Z_0 that causes a local reduction of the easyaxis anisotropy by $\delta K_e (> 0)$ [\[13\]](#page-4-5). Using $P_{\Phi} = \partial_{\dot{\Phi}} \mathcal{L}_{dw}$ = $-2S_{dw}Z$ and $P_Z = \partial_{\dot{Z}}\mathcal{L}_{dw} = 0$, we can identify that $\{Z, \Phi\}$

are canonically conjugate variables. In the limit of strong pinning $\delta K_e \gg \widetilde{K}_h$ max $(1,\tilde{b})/S_{dw}^2$ (but $\delta K_e \ll K_e/s$), Z becomes a purely harmonic variable defining inertia of a generally nonlinear dynamics of Φ that is governed by Eq. [\(1\)](#page-1-2).

In the presence of high-frequency fluctuations, the magnetization profile becomes $n(z, t) = n_0(z - Z) + \delta n(z, t)$, where $\delta n(z, t) \perp n_0(z - Z)$ describes the magnons. We can further write $\delta n(z, t) = e_1 \delta n_1(z, t) + e_2 \delta n_2(z, t)$ with $e_1 = \partial_{\theta_0} n_0$ and $e_2 = \sin^{-1} \theta_0 \partial_{\Phi} n_0$, with $\delta n_{1,2} \ll 1$ being the corresponding magnonic amplitudes. Let us assume that $K_h = b = 0$, as well as Z and Φ are fixed. Then, the resultant Lagrangian describing the fluctuations is

$$
\mathcal{L}_{\rm m} = -\frac{1}{2} \int_{-L}^{L} dz \left[2s \delta n_1 \partial_t \delta n_2 + \delta n_1 \mathcal{H}_0 \delta n_1 + \delta n_2 \mathcal{H}_0 \delta n_2 \right],
$$

$$
\mathcal{H}_0 = \widetilde{K}_e \left(-\frac{\partial^2}{\partial z^2} + 1 - 2 \text{sech}^2(z - Z) \right), \tag{7}
$$

with $K_e = K_e \lambda$, and which describes magnons moving in a potential well $U(z) = 2\text{sech}^2(z - Z)$. We can parameter- $\sum_{n} \Psi_n(z, Z) a_n(t)$, where $\Psi_n(z, Z)$ with $n = 0, 1, \dots$ are ize the magnonic field as $\delta n(z, t) \equiv \delta n_1(z, t) + i \delta n_2(z, t) =$ the standing wave solutions pertaining to a magnetic wire of length 2L described by the Hamiltonian H , while $a_n(t)$ are the complex-valued amplitudes of the magnon in the state with energy ω_n . In a quantum description, $a_n(t)$ [$a_n^*(t)$] becomes the magnon annihilation (creation) operator that satisfies $[a_n, a_m^{\dagger}] = \delta_{nm}$ [\[18\]](#page-4-10). For a finite wire of length 2L, standing waves of energy ω_k can be written as $\Psi_k(z, Z) =$ $\alpha_k \psi_k(z, Z) + \beta_k \psi_{-k}(z, Z)$, subject to the vanishing spin current at the boundaries $J_s^z \equiv \partial_z \Psi_k(\pm L, Z) = 0$, while $\psi_k(z, Z)$ are normalized magnon solutions in an infinite system that can be found explicitly by exploiting the property that they scatter over the potential $U(z)$ without any reflection [\[18,](#page-4-10) [20\]](#page-4-12), resulting in

$$
\psi_k(z, Z) = \frac{\tanh(z - Z) - ik}{\sqrt{s(1 + k^2)}} e^{ikz}.
$$
 (8)

Above, k is the magnon momentum along the wire, while the corresponding spectrum is $\omega_k = \omega_0(1 + k^2)$, with $\omega_0 = K_e/s$ being the magnonic gap. When $L \gg 1$ and the DW location is far from the edges, that is, $L - |Z| \gg 1$, the boundary conditions result in the transcendental equation $tan(2k_nL)$ = $2k_n/(1 - k_n^2)$ for the set of allowed magnonic momenta k_n , with $n = 0, 1, \ldots$, while normalization of the wave function gives $\beta_n = \pm \alpha_n = 1/\sqrt{2L}$ [\[18\]](#page-4-10). Here, the sign + (-) corresponds to the set of solutions that satisfy $tan(k_nL) = k_n$ [tan(k_nL) = $-1/k_n$]. The energy separation between neighboring levels is $\Delta \omega_n \equiv \omega_{n+1} - \omega_n \approx \omega_0 \pi^2 (2n+1)/L^2$. Promoting Φ to a dynamical variable results in the following magnon-DW interaction in a frame rotating with the DW:

$$
\mathcal{L}_{int}(Z) = \frac{s\dot{\Phi}}{2} \int_{-L}^{L} dz (\delta n_1^2 + \delta n_2^2) \cos \theta_0 ,\qquad (9)
$$

which, as anticipated, pertains to a fictitious magnetic field that alters the DW Berry phase by the excited magnons [\[23\]](#page-5-1).

DW manipulation and detection.—The dynamics of the wire induced by the Hamiltonian in Eq. [\(3\)](#page-1-1) is captured by a Lindblad evolution of the density matrix ρ_S [\[24\]](#page-5-2):

$$
\dot{\rho}_{\rm S} = i[\rho_{\rm S}, H_{\rm tot}] + \kappa_n \mathcal{D}(a_n)\rho_{\rm S} + \sum_{j,k} \gamma_{jk} \mathcal{D}(A_{jk})\rho_{\rm S}, \tag{10}
$$

where $\mathcal{D}(\mathcal{O})\rho_{\rm S} = \mathcal{O}\rho_{\rm S}\mathcal{O}^{\dagger} - {\mathcal{O}^{\dagger}\mathcal{O}, \rho_{\rm S}}/2$ represents the dissipator, κ_n is the total decay rate of the magnonic mode n (including the intrinsic Gilbert damping), and A_{ik} = $|j\rangle\langle k|$. Above, we retained only the emission processes in the magnonic dissipator, which is justified in the limit $\omega_0 \gg k_B T$ considered here. We can further expand the magnonic operators around their steady-state values, $a_n \rightarrow \alpha_n + a_n$, with $\alpha_n \approx -h_n/(\Delta_n - i\kappa_n/2)$, so that the resulting master equation is the same as above, but with the Hamiltonian:

$$
H'_{\text{tot}} \approx H_{\Phi} + g_n P_{\Phi}(a_n^{\dagger} + a_n) + \Delta_n a_n^{\dagger} a_n , \qquad (11)
$$

where $g_n = P_n(Z_0)|\alpha_n|/M_{\Phi}$, and the detunings Δ_n are slightly shifted by the DW-induced Lamb shifts of the magnons [\[24\]](#page-5-2). This Hamiltonian is identical to that describing (nonlinear) optomechanical setups [\[14\]](#page-4-8) and can therefore be used to manipulate the DW states.

A first application concerns the sideband cooling of the DW levels via frequency-up conversion of the magnons, which could facilitate the initialization of the DW qubit. For efficient cooling, the following conditions must be met [\[14\]](#page-4-8)

$$
(i) \ g_n \vert \langle 1 \vert P_{\Phi} \vert 2 \rangle \vert \ll \kappa_n \ll \epsilon_q \, ; \ \ (ii) \ \gamma_{21} \ll \frac{g_n^2 \vert \langle 1 \vert P_{\Phi} \vert 2 \rangle \vert^2}{\kappa_n} \, ,
$$

allowing to eliminate adiabatically the magnons and ensuring that the cooling overcomes the environmental heating of the DW via the Gilbert damping, respectively. The reduced density matrix that describes the dynamics of the DW, $\rho_{\Phi} = \text{Tr}_{\text{m}}[\rho_{\text{S}}]$, obeys the Lindblad equation as in Eq. (10), but with bare Hamiltonian H_{Φ} and the total transition rate from state j to state k given by $\Gamma_{jk}^{\text{tot}} = \gamma_{jk} + \Gamma_{jk}^n$, where

$$
\Gamma_{jk}^{n} = \frac{1}{2} \frac{g_n^2 |\langle j| P_{\Phi} |k\rangle|^2 \kappa_n}{(\Delta_n + \epsilon_{jk})^2 + (\kappa_n/2)^2}.
$$
 (12)

 $\sum_j p_j |j\rangle\langle j|$, where p_j is the occupation of the level $j =$ In the stationary limit, the DW density matrix becomes $\rho_{\Phi} =$ $1, \dot{2}, \ldots$ When $\Delta_n = -\epsilon_q$, the driven magnons can extract energy from the DW, cooling it towards the ground state, as depicted in Fig. [3\(](#page-3-0)a). On the other hand, when $\Delta_n = \epsilon_q$ the interplay of the driven magnons and the anharmonicity of the DW spectrum results in an enhancement of p_2 with respect to the other DW levels, as shown in Fig. [3\(](#page-3-0)b) for $n = 1$ (uniform magnonic mode). Importantly, such a state can exhibit a negative Wigner function at the origin $W(\Phi = 0, P_{\Phi} = 0) =$ $\sum_j (-1)^{j+1} p_j$ [\[25,](#page-5-3) [26\]](#page-5-4) that characterizes a nonclassical DW state (see also [\[18\]](#page-4-10)).

The steady state of a DW can be probed with an additional microwave field, weakly driving one magnonic mode ω_p on

FIG. 3. (a) Occupation of the first ten DW levels when the uniform magnon (n = 1) is driven such that $\Delta_1 = -\epsilon_q$, and $Z_0 = -L$. (b) Same, for $\Delta_1 = \epsilon_q$ and $Z_0 = 0$, resulting in a nonclassical state with negative Wigner function, $W(0, 0) = -0.02$. (c) The ground state population p_1 as a function of the position of the DW, Z_0/L , for $\Delta_1 = -\epsilon_q$ (cooling). The black, dashed-red and dotted-blue curves correspond to $T = 5\epsilon_q$, $T = 10\epsilon_q$, and $T = 20\epsilon_q$, respectively. (d) The Wigner function $W(0, 0)$ as a function of Z_0/L for $\Delta_1 = \epsilon_q$ (heating), with the same parameters as in (c); $W(0,0) < 0$ (shaded area) describes nonclassical states. Note that $Z_0 = 1$ refers to a thermal distribution because the DW-magnon interaction vanishes. Also, $|\alpha_1| = 0.1$, while all other parameters are the same as in Fig. [2.](#page-1-0)

resonance, i.e. with $\Omega_p = \omega_p$ (e.g. the $p = 2$ magnonic mode). The power spectrum of the emitted magnons reads

$$
\mathcal{S}_p(\omega) = \frac{1}{2\pi} \int_{-\infty}^{\infty} d\tau e^{-i(\omega - \Omega_p)\tau} \langle a_{p,\mathrm{out}}^\dagger(t+\tau) a_{p,\mathrm{out}}(t) \rangle \, ,
$$

where the output field $a_{p,\text{out}}(t)$ is related to the magnonic mode a_p via the standard input-output relation $a_{p,\text{out}}(t)$ = $\sqrt{2\kappa_{p,ex}}a_p(t) + a_{p,\text{in}}(t)$, and $\langle \dots \rangle$ means average over the stationary state of the DW. The dynamics of the intra-cavity field can be described by a quantum Langevin equation [\[27\]](#page-5-5):

$$
\dot{a}_p(t) = -\frac{\kappa_p}{2} a_p(t) + i \frac{P_p(Z_0) P_{\Phi}}{M_{\Phi}} a_p(t) + \sqrt{\kappa_{p,ex}} a_{p,\text{in}}(t) ,
$$

where $a_{p,in}(t)$ represents the input field in the probe mode, $\kappa_{p,ex}$ the decay rate of mode p into the leads, and all operators are in the Heisenberg picture. Eq. [\(13\)](#page-3-1) can be formally integrated, and then subjected to a Dyson series-type expansion to the first order in g_p . Assuming $\Gamma_{jk}^p \ll \Gamma_{jk}^{\text{tot}}$, such that the measurement does not affect the DW level occupations induced by the other drivings, we find for the side-band transitions (i.e. $\omega \neq \omega_p$) [\[18\]](#page-4-10):

$$
S_p(\omega) \approx \frac{\kappa_{p,ex}}{\pi \kappa_p} \sum_{j,k} \frac{\Gamma_{jk}^p \Gamma_{jk}^{\text{eff}}}{(\omega - \Omega_p - \epsilon_{jk})^2 + (\Gamma_{jk}^{\text{eff}})^2} p_j , \quad (13)
$$

where $\Gamma_{jk}^p = \Gamma_{kj}^p$ at $\Delta_p = 0$, while $\Gamma_{jk}^{\text{eff}} = \sum_s (\Gamma_{sk}^{\text{tot}} +$ Γ_{sj}^{tot}) = Γ_{kj}^{eff} represents the peak's linewidth. Consequently, the power spectrum of the emitted magnons exhibits a sideband structure because of the DW-assisted frequency up- or down-conversion processes. For example, when $\Delta_n = -\epsilon_q$ (ground-state cooling), $S_p(\Omega_p - \epsilon_q)/S_p(\Omega_p + \epsilon_q) \approx p_1/p_2$, which allows us to infer the ground-state population from the power spectrum of the emitted magnons (together with $\sum_j p_j = 1$).

Magnons can mediate interactions between two such DWs, facilitating the implementation of two-qubit gates. Indeed, assuming that both DWs are cooled down to their respective ground states, and sufficient nonlinearity in the spectrum, their dynamics are restricted to the subspace spanned by the lowest two states, $\{|1_a\rangle, |2_a\rangle\}$, with $a = 1, 2$ labeling the DW. In the limit $g_{n,a} \ll ||\Delta_n| - \epsilon_{q,a}|| \ll ||\Delta_n| + \epsilon_{q,a}||$ (dispersive regime), we can eliminate perturbatively the magnons (here neglecting their decay κ_n) to obtain $H_{1-2} = J_{1-2}(\sigma_1^+\sigma_2^- + \text{h.c.})$ with the exchange coupling

$$
J_{1-2} = \sum_{a=1,2} \frac{g_{n,1}g_{n,2}|\langle 1_1|P_{1,\Phi}|2_1\rangle||\langle 1_2|P_{2,\Phi}|2_2\rangle|}{\Delta_n - \epsilon_{q,a}}, \quad (14)
$$

where we assumed identical DWs, and $\sigma_a^+ = |2_a\rangle\langle 1_a| \left(\sigma_a^- - \sigma_a^-\right)$ $|1_{a}\rangle\langle2_{a}|$) are the raising (lowering) Pauli operators associated with qubit $a = 1, 2$. Above, we also performed the rotating wave approximation (therefore neglecting terms \propto $\sigma_1^+ \sigma_2^+, \sigma_1^- \sigma_2^-$ and disregarded small corrections to each individual qubit Hamiltonian [\[28\]](#page-5-6). The evolution of the combined system with H_{1-2} for $t_g = \pi/4J_{1-2}$, implements a \sqrt{i} SWAP operation which, up to single-qubit rotations, is equivalent to a controlled-NOT gate [\[29\]](#page-5-7). Together with single-qubit gates, which can be implemented by locally pulsing ac magnetic fields, the interaction H_{1-2} is therefore sufficient for universal quantum computation.

Conclusions.—In summary, we have shown that magnons in short insulating ferromagnetic wires can be leveraged to initialize, entangle and detect quantum states encoded in macroscopic DWs. These features are enabled by universal (and intrinsic) Berry-phase mediated interactions between the magnons and the DW, rendering our approach promising in terms of scalability, since it does not require extrinsic degrees of freedom (e.g. photons) to be integrated with the ferromagnetic wire. By the same token, it could be naturally extended to 2D topological objects, such as skyrmions, or even to other magnetic materials, such as ferrimagnets or antiferromagnets, which can exhibit faster time scales for manipulations.

I. ISOLATED DW DYNAMICS

As described in the main text, the isolated dynamics of a DW positioned far from the boundaries, i.e. $L \gg Z$, is governed by the Lagrangian [\[13\]](#page-4-5):

$$
\mathcal{L}_{dw} \approx -2S_{dw}Z\dot{\Phi} - \widetilde{K}_h(\sin^2\Phi + \tilde{b}\sin\Phi) - V_{\text{pin}}(Z)\,,\tag{S1}
$$

where $S_{dw} = s\lambda$, $\widetilde{K}_h = K_h\lambda$, and $\widetilde{b} = \pi b/2K_h$. Furthermore, the pinning potential $V_{\text{pin}}(Z)$ (around $Z = Z_0$) may be due to inhomogeneous magnetic anisotropies in the sample (e.g., reduced local K_e that can be controlled electrically). The dissipation function, on the other hand, becomes

$$
\mathcal{R}_{dw} = \frac{S_{dw}\alpha}{2} \left(\dot{Z}^2 + \dot{\Phi}^2\right). \tag{S2}
$$

The equations of motion engendered by the Lagrangian stated in Eq. $(S1)$ are

$$
P_{\Phi} = \frac{\partial \mathcal{L}_{dw}}{\partial \dot{\Phi}} = -2S_{dw}Z, \quad P_Z = \frac{\partial \mathcal{L}_{dw}}{\partial \dot{Z}} = 0,
$$
\n^(S3)

which indicates that $\{Z, \Phi\}$ are Hamiltonian canonically conjugate variables. With dissipation, the generalized Euler-Lagrange equations of motion read:

$$
\widetilde{K}_h[\sin(2\Phi) + \widetilde{b}\cos\Phi] - 2S_{dw}\dot{Z} = -\alpha S_{dw}\dot{\Phi},
$$

$$
2S_{dw}\dot{\Phi} + \frac{\partial V_{\text{pin}}(Z)}{\partial Z} = -\alpha S_{dw}\dot{Z}.
$$
 (S4)

By replacing \dot{Z} in the second line and taking the time-derivative of the equation that follows, we can obtain (while only considering the Rayleigh dissipation of Φ in the case of strong pinning):

$$
2S_{dw}\ddot{\Phi} + \frac{\partial^2 V_{\text{pin}}(Z)}{\partial Z^2} \left(\widetilde{K}_h(\sin(2\Phi) + \widetilde{b}\cos\Phi) + \alpha S_{dw}\dot{\Phi} \right) / 2S_{dw} = 0,
$$

$$
M_{\Phi}\ddot{\Phi} + \widetilde{K}_h \left(\sin(2\Phi) + \widetilde{b}\cos\Phi \right) + \alpha S_{dw}\dot{\Phi} = 0,
$$
 (S5)

where

$$
M_{\Phi} = (2S_{dw})^2 \left(\frac{\partial^2 V_{\text{pin}}(Z)}{\partial Z^2}\right)^{-1}
$$
 (S6)

is the inertia of the DW associated with rigid rotations. Assuming

$$
V_{\rm pin}(Z) \approx \frac{\delta K_e (Z - Z_0)^2}{2} \,,\tag{S7}
$$

results in the mass $M_{\Phi} = (2S_{dw})^2/\delta K_e$. The effective Lagrangian describing the dynamics of the angle Φ only (in the absence of dissipation) becomes

$$
\mathcal{L}_{\Phi} = \frac{1}{2} M_{\Phi} \dot{\Phi}^2 - \underbrace{\tilde{K}_h (\sin^2 \Phi + \tilde{b} \sin \Phi)}_{U(\Phi)},
$$
\n(S8)

which in turn pertains to the following effective Hamiltonian

$$
H_{\Phi} = \frac{1}{2M_{\Phi}} P_{\Phi}^2 + U(\Phi) \,, \tag{S9}
$$

which is depicted in Eq. (1) in the main text.

We can now promote the momentum P_{Φ} to its operator version, $P_{\Phi} \to -i\partial_{\Phi}$, which eventually allows determining the Hamiltonian that describes the quantum dynamics of the isolated DW.

To make progress on that end, it is beneficial to identify the classical potential minima of $U(\Phi)$, which implicate solving

$$
\cos \Phi_{eq} \left(\sin \Phi_{eq} - \tilde{b} \right) = 0, \tag{S10}
$$

along with the local maximum condition

$$
2\cos 2\Phi_{eq} + \tilde{b}\sin \Phi_{eq} \ge 0. \tag{S11}
$$

We see that $\Phi_{eq} = \pi/2$ becomes an inflection point at $\tilde{b}_c = 1$ (rendering the effective potential quartic in Φ), while the two minima before reaching this point are located at $\{\Phi_{eq}^1, \Phi_{eq}^2\} = \{-\pi + \arcsin \tilde{b}, -\arcsin \tilde{b}\}.$

There are three regimes for the operation of the DW: (i) $0 < \tilde{b} < 1$, (ii) $\tilde{b} = 1$ (the case studied in detail in this work), and $(iii) \tilde{b} > 1.$

1. Double-well potential limit: $0 \leq \tilde{b} < 1$

The first case corresponds to a double-well potential and has been discussed in many previous works (see, for example, [\[12\]](#page-4-4)). To determine the spitting of the lowest levels, we calculate the amplitude of the transition between the two minima, $G(\Phi_{eq}^1, \Phi_{eq}^2)$, using the Euclidian path integral approach by switching to the imaginary time representation $t \to i\tau$. Thus, we write:

$$
G(\Phi_{eq}^1, \Phi_{eq}^2, \tau) \equiv \langle \Phi_{eq}^1 | e^{-\tau H_{\Phi}} | \Phi_{eq}^2 \rangle = \int_{\Phi(0) = \Phi_{eq}^1, \Phi(\tau) = \Phi_{eq}^2} \mathcal{D}\Phi \, e^{-\int_0^{\tau} d\tau' \mathcal{L}_{\Phi}(\Phi, \partial_{\tau'} \Phi)}, \tag{S12}
$$

where

$$
\mathcal{L}_{\Phi}(\Phi, \partial_{\tau'} \Phi) = \frac{1}{2} M_{\Phi} \dot{\Phi}^2 + U(\Phi)
$$
 (S13)

represent the Lagrangian for the DW particle moving in the inverted potential $-U(\Phi)$. The corresponding classical equations of motions hence read as follows

$$
M_{\Phi}\ddot{\Phi}_{cl} - \frac{\partial U(\Phi_{cl})}{\partial \Phi_{cl}} = 0, \qquad (S14)
$$

so that the classical trajectories Φ_{cl} will satisfy:

$$
\frac{1}{2}M_{\Phi}\dot{\Phi}_{cl}^{2} - U(\Phi_{cl}) = \text{const.}
$$
\n(S15)

We are looking for solutions that do not allow the particle to "escape" the maxima of the inverted potential, that is, $\dot{\Phi}|_{\Phi_{eq}^{1,2}} = 0$, so we get const= $U(\Phi_{eq}^{1,2}) \equiv U_c$. We can define a new (shifted) potential $U'(\Phi_{cl}) = U(\Phi_{cl}) - U_c$ such that $U'(\Phi_{eq}^{1,2}) = 0$ (note that adding a constant term does not influence the dynamics). Thus, the classical trajectory Lagrangian is given by $\mathcal{L}_{\Phi}(\Phi_{cl}, \partial_{\tau} \Phi_{cl}) = M_{\Phi} \dot{\Phi}_{cl}^2 \equiv \sqrt{2M_{\Phi}U'(\Phi_{cl})} \dot{\Phi}_{cl}$. Since the lowest barrier between the two minima is $\Phi = -\pi/2$, we can retain in the action only the trajectories that involve this barrier. The classical action is then obtained:

$$
\mathcal{S}_{cl} = \int_0^\tau d\tau' \mathcal{L}_{\Phi}(\Phi_{cl}, \partial_\tau \Phi_{cl}) = \int_{\Phi_{eq}^1}^{\Phi_{eq}^2} d\Phi_{cl} \sqrt{2M_{\Phi} U'(\Phi_{cl})} = 2\sqrt{2M_{\Phi}} \left[\sqrt{1 - \tilde{b}^2} - \tilde{b} \arccos \tilde{b} \right]. \tag{S16}
$$

Following the discussion in [\[30\]](#page-5-8), we find the following.

$$
G(\Phi_{eq}^1, \Phi_{eq}^2, \tau) \approx C e^{-\omega \tau} \sum_{n \in \text{odd}} \frac{(\tau K)^n}{n!} e^{-n\mathcal{S}_{cl}} = C e^{-\omega \tau} \sinh\left[\tau K e^{-\mathcal{S}_{cl}}\right],\tag{S17}
$$

where ω is the oscillation frequency associated with one of the wells only

$$
\omega = \sqrt{\frac{2\widetilde{K}_h(1-\tilde{b}^2)}{M_{\Phi}}} = \frac{1}{S_{dw}}\sqrt{\frac{\delta K_e \widetilde{K}_h(1-\tilde{b}^2)}{2}},\tag{S18}
$$

while C is a constant that can be extracted from treating an isolated well analytically [\[30\]](#page-5-8). Moreover,

$$
K = \gamma \omega \sqrt{\frac{\mathcal{S}_{cl}}{2\pi}},\tag{S19}
$$

where $\gamma \approx 1$. Physically, the two initially degenerate minima at $\Phi_{eq}^{1,2}$ become mixed due to macroscopic quantum tunneling, and the states split into symmetric $|S\rangle$ and antisymmetric $|A\rangle$ configurations of the wave functions. Projecting the transition probability onto this subspace, we can write:

$$
G(\Phi_{eq}^{1}, \Phi_{eq}^{2}, \tau) \approx \langle \Phi_{eq}^{1} | (|S\rangle e^{-\epsilon_{S}\tau} \langle S| + |A\rangle e^{-\epsilon_{A}\tau} \langle A|) |\Phi_{eq}^{2}\rangle
$$

=
$$
\frac{C}{2} e^{-\bar{\epsilon}\tau} / (e^{-\Delta\epsilon\tau/2} - e^{\Delta\epsilon\tau/2}) = C e^{-\bar{\epsilon}\tau} \sinh(\tau \Delta\epsilon),
$$
 (S20)

with $\bar{\epsilon} = (\epsilon_A + \epsilon_S)/2$, $\Delta \epsilon = \epsilon_A - \epsilon_S$, and $C = 2|\langle \Phi_{eq}^{1,2} | S \rangle|^2$. Comparing the above expression with the quasi-classical calculation, we obtain the following.

$$
\epsilon_{S,A} = \frac{\omega}{2} \pm Ke^{-\mathcal{S}_{cl}} = \frac{\omega}{2} \pm \gamma \omega \sqrt{\frac{\mathcal{S}_{cl}}{2\pi}} e^{-\mathcal{S}_{cl}},
$$
\n(S21)

and thus the splitting between the two states (qubit splitting) is:

$$
\Delta \epsilon = 2\gamma \omega \sqrt{\frac{\mathcal{S}_{cl}}{2\pi}} e^{-\mathcal{S}_{cl}}.
$$
\n(S22)

Above, we assumed $\langle\Phi_{eq}^1|\Phi_{eq}^2\rangle\approx 0$, i.e. the two states localized at the potential minima have negligible overlap (such a condition only applies for large barriers).

2. Single-well potential limit: $\tilde{b} \ge 1$

In this case, $U(\Phi)$ can be expanded around the minimum located at $\Phi_0 = 3\pi/2$, which will be set to zero from now on. Hence, writing $\Phi \to \Phi_0 - \Phi$, we obtain:

$$
U(\Phi) \approx \underbrace{\tilde{K}_h(\tilde{b}-1)}_A \Phi^2 + \underbrace{\frac{\tilde{K}_h(4-\tilde{b})}{12}}_B \Phi^4,
$$
\n(S23)

near the critical point $\tilde{b} > 1$.

First, we establish the spectrum at the transition point $\tilde{b} = 1$. In that case, $A = 0$, and $B = \tilde{K}_h/4$. Although this can be solved exactly only numerically, we can employ the quasi-classical (Bohr-Sommerfeld quantization) approach to estimate the eigenenergies and the corresponding level spacing. That is:

$$
\int_{-\Phi_j}^{\Phi_j} d\Phi \sqrt{2M_{\Phi}[\epsilon_j - U(\Phi)]} = \left(j - \frac{1}{2}\right)\pi,
$$
\n(S24)

where $j = 1, 2, 3, \dots$, and $\pm \Phi_j = \pm (\epsilon_j/B)^{1/4}$ represent the classical turning points. We find:

$$
\epsilon_j = \left[\frac{\pi}{C} \frac{B^{1/4}}{\sqrt{2M_{\Phi}}} \right]^{4/3} \left(j - \frac{1}{2} \right)^{4/3},
$$

$$
\mathcal{C} = \int_{-1}^{1} dx \sqrt{1 - x^4} \approx 1.75.
$$
 (S25)

FIG. S1. The DW energy levels ϵ_j (scaled with δK_e), and the wave-functions $\psi_j(\Phi)$, with $j = 1, 2, 3, \ldots$ for several reduced magnetic fields around $\tilde{b} = \pi b/2K_h = 1$ that control the effective potential $U(\Phi)$ (dashed line). (a)–(c) correspond to $\tilde{K}_h = 5\delta K_e$, $S_{dw} = 50$, and $N_l \equiv \lambda/a = 50$ unit cells along the wire, while (d)–(f) $\widetilde{K}_h = 10\delta K_e$ and $S_{dw} = 100$, and $N_l = 100$ unit cells along the wire.

Therefore, we can write $\epsilon_j = \epsilon_1(j-1/2)^{4/3}$, with

$$
\epsilon_1 \approx \frac{0.86}{S_{dw}^{4/3}} \left(\widetilde{K}_h \delta K_e^2\right)^{1/3} . \tag{S26}
$$

We see that the spectrum is highly anharmonic $\epsilon_2 - \epsilon_1 \approx 1.32\epsilon_1$, $\epsilon_3 - \epsilon_2 \approx 1.67\epsilon_1$, which is beneficial for any quantum information processing with these states.

Next, let us focus on the $\ddot{b} > 1$ regime. In this case, the quadratic term is non-zero, and we can define the (harmonic) frequency associated with it as:

$$
\Omega = \sqrt{\frac{2A}{M_{\Phi}}} = \frac{1}{S_{dw}} \sqrt{\frac{(\tilde{b} - 1)\tilde{K}_h \delta K_e}{2}},
$$
\n(S27)

as well as introducing:

$$
\Phi = \sqrt{\frac{1}{2M_{\Phi}\Omega}} (a^{\dagger} + a), P_{\Phi} = i\sqrt{\frac{M_{\Phi}\Omega}{2}} (a^{\dagger} - a), \qquad (S28)
$$

where $a(a^{\dagger})$ is the annihilation (creation) operator associated with the harmonic motion. That in turn gives:

$$
H_{\Phi} = \hbar \Omega a^{\dagger} a + \frac{\Lambda}{2} (a^{\dagger} + a)^4 ,
$$

$$
\frac{\Lambda}{2} = \frac{B}{(2M_{\Phi}\Omega)^2} = \frac{(4 - \tilde{b})\delta K_e}{96S_{dw}^2(\tilde{b} - 1)} .
$$
 (S29)

This can be further simplified by performing the rotating wave approximation (RWA), leading to

$$
H_{\Phi} = \Omega a^{\dagger} a + \frac{\Lambda}{2} \left[(a^{\dagger})^2 a^2 + a^2 (a^{\dagger})^2 + a^{\dagger} a a^{\dagger} a + a a^{\dagger} a a^{\dagger} + a^{\dagger} a a a^{\dagger} + a a^{\dagger} a^{\dagger} a \right] = \Omega' a^{\dagger} a + \frac{\Lambda'}{2} a^{\dagger} a^{\dagger} a a,
$$

where $\Omega' = \Omega + \Lambda'$ and $\Lambda' = 6\Lambda$. Here, the RWA is warranted, provided that the relevant DW localized magnon numbers $n = 0, 1, 2, \ldots$, satisfy $n^2 \Lambda \ll \Omega$. Finally, let us estimate the maximal number of photons under which the above assumption works:

$$
n^2 < n_{max}^2 = \frac{\Omega}{\Lambda} = 24 S_{dw} \frac{(\tilde{b} - 1)^{3/2}}{4 - \tilde{b}} \sqrt{\frac{\tilde{K}_h}{\delta K_e}} \,. \tag{S30}
$$

Assuming $S_{dw} = 50$, $\tilde{b} = 1.5$, and $\tilde{K}_h = 5\delta K_e$, we find $n_{max} \approx 20$.

A comparison between all regimes is shown in Fig. [S1,](#page-9-0) where the spectrum and wave functions have been found using full diagonalization.

A. Dissipation via Gilbert damping

Here, we discuss briefly how to account for the dissipation introduced by the Gilbert damping in the quantized Hamiltonian. We start by writing the classical equation of motion pertaining to the DW Lagrangian in the presence of the damping (\mathcal{R}_{Φ} = $\alpha S_{dw}\dot{\Phi}^2/2$:

$$
M_{\Phi}\ddot{\Phi} + \widetilde{K}_h[\sin(2\Phi) + \widetilde{b}\cos\Phi] + \alpha S_{dw}\dot{\Phi} = \xi(t),
$$
\n(S31)

where $\xi(t)$ is the Langevin noise that is subject to the fluctuation-dissipation condition [\[7\]](#page-4-3)

$$
\int_{-\infty}^{\infty} dt e^{-i\omega t} \langle \xi(t)\xi(0) \rangle = \alpha \omega S_{dw} \coth(\omega/2k_B T). \tag{S32}
$$

In the quantum Hamiltonian description, this in turn can be included as:

$$
H_{\Phi} \to H_{\Phi} - \Phi \hat{\xi} + H_{\xi} , \qquad (S33)
$$

where $\hat{\xi} = \sum_p g_p(\xi_p + \xi_p^{\dagger})$ describe the bosonic environment with ξ_p (ξ_p^{\dagger}) being the annihilation (creation) operators satisfying $[\xi_p, \xi_{p'}^{\dagger}] = \delta_{pp'}$, while H_{ξ} dictates the environment dynamics. Following the approach described in one of the following sections, we can write the evolution of the DW density matrix as follows:

$$
\dot{\rho}_{\Phi} = -i[H_{\Phi}, \rho_{\Phi}] + \sum_{j,k} \gamma_{jk} \mathcal{D}(A_{jk}) \rho_{\Phi}, \qquad (S34)
$$

where $A_{ik} = |k\rangle\langle j|$, $\mathcal{D}(\mathcal{O})\rho_{\Phi} = \mathcal{O}^{\dagger}\rho_{\Phi}\mathcal{O} - {\mathcal{O}^{\dagger}\mathcal{O}, \rho_{\Phi}}/2$ is the dissipator, while

$$
\gamma_{jk} = 2\alpha S_{dw} |\langle j|\Phi|k\rangle|^2 (\epsilon_j - \epsilon_k)[1 + n_B(\epsilon_j - \epsilon_k)] = \gamma_{kj} e^{(\epsilon_j - \epsilon_k)/k_B T}, \qquad (S35)
$$

are the resulting rates that satisfy the detailed balance condition in thermal equilibrium. Above,

$$
n_B(\omega) = \frac{1}{e^{\omega/k_B T} - 1},\tag{S36}
$$

is the Bose-Einstein distribution.

II. DESCRIPTION OF THE MAGNONS

To address the magnons' dynamics and their coupling to the DW, we first analyze the case when the latter is static. This will allow us to express the dynamical solutions in terms of the instantaneous basis for a given position Z and orientation Φ of the DW.

A. Magnons around a static DW at $K_h = b = 0$

The fluctuations around the DW magnetization texture $n_0(z) = (\sin \theta_0 \cos \Phi, \sin \theta_0 \sin \Phi, \cos \theta_0) \equiv n_0(z - Z)$ can be described as follows:

$$
\mathbf{n}(z,t) = \frac{1}{\sqrt{1 + \delta n_1^2 + \delta n_2^2}} (\mathbf{n}_0 + \mathbf{e}_1 \delta n_1 + \mathbf{e}_2 \delta n_2) \approx \left(1 - \frac{\delta n_1^2 + \delta n_2^2}{2}\right) \mathbf{n}_0(z) + \mathbf{e}_1 \delta n_1 + \mathbf{e}_2 \delta n_2, \tag{S37}
$$

where

$$
\boldsymbol{e}_1 = \frac{\partial \boldsymbol{n}_0}{\partial \theta_0} = (\cos \theta_0 \cos \Phi, \cos \theta_0 \sin \Phi, -\sin \theta_0); \ \boldsymbol{e}_2 = \frac{\partial \boldsymbol{n}_0}{\sin \theta_0 \partial \Phi} = (-\sin \Phi, \cos \Phi, 0)
$$
(S38)

are the unit vectors that are perpendicular to the DW magnetization at position z (and mutually perpendicular), while $\delta n_{1,2} \equiv$ $\delta n_{1,2}(z,t)$ are their amplitudes with respect to the DW position Z. Note that in the regime $\delta n_{1,2}(z,t) \ll 1$, we have retained only terms up to the second order in the fluctuations.

The resulting instantaneous magnon Lagrangian becomes:

$$
\mathcal{L}_{sw} = -\frac{1}{2} \int dz \left[2S_{dw} \delta n_1 \partial_t \delta n_2 + \delta n_1 \mathcal{H}_0 \delta n_1 + \delta n_2 \mathcal{H}_0 \delta n_2 \right],
$$

\n
$$
\mathcal{H}_0 = \widetilde{K}_e \left(-\frac{\partial^2}{\partial z^2} + 1 - 2 \text{sech}^2(z - Z) \right),
$$
\n(S39)

which means magnons moving in a Pösch and Teller potential well $U(z) = -2\text{sech}^2(z - Z)$, having the property that in an infinite system, the magnons pass through it without any reflection. In the following, we first determine the magnon solutions and spectrum for an infinite wire and then utilize these solutions to find the eigenmodes in the finite wire. We can formally write:

$$
\mathcal{H}_0 = \widetilde{K}_e \left(-\frac{\partial^2}{\partial z^2} + 1 - 2\mathrm{sech}^2(z - Z) \right) = \widetilde{K}_e a^\dagger a \,,\tag{S40}
$$

with

$$
a \equiv \frac{\partial}{\partial z} + \tanh(z - Z), \quad a^{\dagger} \equiv -\frac{\partial}{\partial z} + \tanh(z - Z). \tag{S41}
$$

The Euler-Lagrange equations in the absence of damping lead to the following equations of motion for the fields $\delta n_{1,2}$:

$$
is\left(\begin{array}{c}\n\delta\dot{n}_1 \\
\delta\dot{n}_2\n\end{array}\right) = \left(\begin{array}{cc} 0 & i\mathcal{H}_0 \\
-i\mathcal{H}_0 & 0\n\end{array}\right) \left(\begin{array}{c}\n\delta n_1 \\
\delta n_2\n\end{array}\right),
$$
\n(S42)

which can be solved efficiently by using the techniques of super-symmetric quantum mechanics [\[20\]](#page-4-12). We briefly present the rationale behind this approach. Let us first define another Hamiltonian density:

$$
\mathcal{H}'_0 = \widetilde{K}_e \left(-\frac{\partial^2}{\partial z^2} + 1 \right) = \widetilde{K}_e a a^\dagger \,, \tag{S43}
$$

which is translation invariant and allow for plane wave solutions $\delta n_0(z,t) \propto e^{i(kz-i\omega t)}$. The solutions to the initial problem are then simply found from $\psi(z) = a^{\dagger} \psi_0(z)$, while the two Hamiltonians share the same spectrum ω_k . Let us thus solve the simpler problem:

$$
\omega \left(\begin{array}{c} \delta n_1^0(\omega, k) \\ \delta n_2^0(\omega, k) \end{array} \right) = \frac{K_e(k^2 + 1)}{s} \sigma_y \left(\begin{array}{c} \delta n_1^0(\omega, k) \\ \delta n_2^0(\omega, k) \end{array} \right) , \tag{S44}
$$

where σ_y is a Pauli matrix acting in the space of the two orthogonal fluctuations. By applying the operator σ_y again on the right, we obtain the magnons' spectrum and the two types of eigenvectors:

$$
\omega_k = \pm \frac{K_e}{s} (k^2 + 1),
$$

$$
\Psi_{\pm}(k) = \frac{1}{\sqrt{2}} \begin{pmatrix} 1 \\ \pm i \end{pmatrix},
$$
 (S45)

S7

with \pm corresponding to $\pm\omega_k$. While in a classical theory we can choose either sign of the frequency, the quantum description requires more caution. Let us calculate the energy of the mode:

$$
\frac{1}{2}(\delta n_{1,s}^0 H_0 \delta n_{1,s}^0 + \delta n_{2,s}^0 H_0 \delta n_{2,s}^0) \propto \frac{1}{2} \Psi_s^{\dagger} H_0 \Psi_s = \omega_k , \qquad (S46)
$$

and therefore each of the negative and positive eigenvalue solution correspond to an energy $|\omega_k|$. Therefore, the fields $\delta n_{1,2}^0(z,t)$ can be presented in a compact way as:

$$
\delta \mathbf{n}^{0}(z,t) = [\delta n_{1}^{0}(z,t), \delta n_{2}^{0}(z,t)]^{T} = \frac{1}{\sqrt{2}} \sum_{k,s=\pm} a_{k,\pm}(t) \Psi_{\pm} \psi_{k}^{0}(z) e^{\pm i\omega_{k}t}, \qquad (S47)
$$

and, imposing the condition that the fields are real, we find:

$$
a_{k,\pm} = (a_{-k,\mp})^* \equiv a_k. \tag{S48}
$$

We can conclude that $\delta n_1^0(z,t)$ and $\delta n_2^0(z,t)$ are related to the Re and Im parts of the same function $\delta n^0(z,t) = \delta n_1^0(z,t) +$ $i\delta n_2^0(z,t)$. Therefore, we can write

$$
\delta n^{0}(z,t) \equiv \sum_{k} a_{k}(t) \psi_{k}^{0}(z) e^{i\omega_{k}t}, \qquad (S49)
$$

where

$$
a_k(t) = \int dz \delta n^0(z, t) (\psi_k^0)^*(z) , \qquad (S50)
$$

is the amplitude of the spin wave with momentum k that oscillates with frequency $\sim \omega_k$, and $\psi_k^0(z) = e^{ikz}$ is the associated wave-function. This in turn allows us to find the actual fields $\psi_k(z) = a^{\dagger} \psi_k^0(z)$, that is,

$$
\psi_k(z, Z) = \frac{\tanh(z - Z) - ik}{\sqrt{s(1 + k^2)}} e^{ikz} \equiv \psi_{-k}^*(z).
$$
\n(S51)

The factor $1/\sqrt{s(1+k^2)}$ was chosen to ensure that the following normalization condition is maintained:

$$
s\int_{-L}^{L} dz \psi_k^*(z)\psi_{k'}(z) = \frac{1}{\sqrt{(1+k^2)(1+k'^2)}} \int_{-L}^{L} dz \left[e^{i(k-k')z} (1+kk') - \frac{d}{dz} \left(e^{i(k-k')z} \tan(z-Z) \right) \right] = 2\pi \delta(k-k'),
$$
\n(S52)

where we neglected the last term that gives a highly oscillatory contribution when $L \to \infty$. Finally, a general solution can be written as follows

$$
\delta n(z,t) = \sum_{k} a_k(t) \psi_k(z,Z), \qquad (S53)
$$

leading to the Lagrangian describing an infinite system:

$$
\mathcal{L}_{0,m} = \sum_{k} (ia_k^* \dot{a}_k - \omega_k a_k^* a_k).
$$
 (S54)

In a finite wire of length 2L, the general solution for a magnon of a given energy ω_k can be written as:

$$
\delta n(z,t) = \sum_{k>0} a_k(t) \Psi_k(z,t),
$$

$$
\Psi_k(z,t) = \alpha_k \psi_k(z,Z) + \beta_k \psi_{-k}(z,Z),
$$
\n(S55)

with the coefficients α_k and β_k determined from the assumption of vanishing spin current at the boundaries, $j_s(\pm L, t) = 0$. That is equivalent to imposing von Neumann boundary conditions, or

$$
\partial_z \delta n_{1,2}(z \to \pm L, t) = 0,\tag{S56}
$$

$$
(\alpha_k e^{\pm ikL} + \beta_k e^{\mp ikL}) \operatorname{sech}^2(\pm L - Z) + k \left[k(\alpha_k e^{\pm ikL} + \beta_k e^{\mp ikL}) + i(\alpha_k e^{\pm ikL} - \beta_k e^{\mp ikL}) \tanh(\pm L - Z) \right] = 0. \tag{S57}
$$

When $|Z| \ll L$, we can ignore the term proportional to sech²($\pm L - Z$), and the boundary conditions can be simplified to:

$$
\alpha_k(k+i)e^{ikL} + \beta_k(k-i)e^{-ikL} = 0,
$$

\n
$$
\alpha_k(k-i)e^{-ikL} + \beta_k(k+i)e^{ikL} = 0,
$$
\n(S58)

from which we can extract the allowed wave-vectors $k_n \equiv k(n)$ and the associated eigen-energies $\omega_n = \omega(k_n)$. Specifically, we find the following transcendental equation

$$
\tan(2k_n L) = \frac{2k_n}{1 - k_n^2},
$$
\n(S59)

which encodes two types of alternating solutions: $\tan(k_nL) = k_n$ and $\tan(k_nL) = -1/k_n$, that yields $\exp(2ik_nL) = \pm(i (k_n)/(i + k_n)$, respectively. Moreover, from

$$
\beta_n = \alpha_n \frac{i + k_n}{i - k_n} e^{ik_n L} \equiv \pm \alpha_n \tag{S60}
$$

we can write

$$
\Psi_n(z, Z) \approx C_n \left[\psi_{k_n}(z, Z) \pm \psi_{-k_n}(z, Z) \right] \equiv \pm \Psi_n^*(z, Z) \,, \tag{S61}
$$

where $C_n \approx 1/$ √ 2L is found from the normalization of the wave-functions. In the representation $\Psi_n(z, Z)$, the fluctuating magnonic fields can be formally written as:

$$
\delta n_1(z,t) = \frac{1}{2} \sum_n [\Psi_n(z,Z)a_n(t) + \Psi_n^*(z,Z)a_n^*(t)],
$$

$$
\delta n_2(z,t) = \frac{i}{2} \sum_n [\Psi_n(z,Z)a_n(t) - \Psi_n^*(z,Z)a_n^*(t)],
$$
 (S62)

where $a_n(t)$ are the amplitudes of the spin waves with the quantum number n. Consequently, the free magnon Lagrangian becomes identical to that in Eq. (S27), with $k \to n$, with the corresponding Hamiltonian

$$
H_{0,m} = \sum_{n} \omega_n a_n^* a_n . \tag{S63}
$$

Let us briefly discuss the approximate spectrum at small momenta $k_n \ll 1$ (that is, for wavelengths much larger than the DW size λ). In that case, we can write $\tan(2k_nL) \sim 2k_n$ and, together with $\tan(\theta + n\pi) = \tan(\theta)$, $n \in \mathcal{N}$, allows us to write $k_n = (r + n\pi/2)/L$, or

$$
\tan(2r) \sim 2r = 2k. \tag{S64}
$$

Therefore, we find that the solutions are:

$$
k_n \approx \frac{\pi n}{2(L-1)},\tag{S65}
$$

with $n = 0, 1, 2, \ldots$. We can easily infer that $n = 2k$ $(n = 2k + 1)$, with $k = 0, 1, \ldots$ pertaining to the first (second) type of magnon solution.

B. Berry phase mediated interaction between the DW and magnons

In the preceding section, the wave-functions $\Psi_n(z, Z)$ form a complete basis and can therefore be utilized to represent the magnonic fields $\delta n_{1,2}(z, t)$ also when Z and Φ become time-dependent.

FIG. S2. The energies ω_n and the wave-functions $\Psi_n(z)$ of the first five magnonic modes $(n = 1, \ldots, 5)$ in the presence of a DW located at different positions Z_0 in the ferromagnetic wire of length $2L = 20$. The arrows depict the spin orientation in each of the wire segment. All energies are expressed in terms of the magnonic energy gap $\omega_0 = K_e/s$.

The Berry phase contribution to the Lagrangian is

$$
\mathcal{L}^B = -s \int_{-L}^{L} dz \frac{d \times n}{1 - n \cdot d} \dot{n}, \qquad (S66)
$$

where d is the (arbitrary) direction of the Dirac string. In the following, we choose $d = -e_z$, and expand \mathcal{L}_B to the second order in the fluctuations. Retaining only the terms that contain the magnons, we obtain $\mathcal{L}_{m}^B = \mathcal{L}_{m,1}^B + \mathcal{L}_{m,2}^B + \mathcal{L}_{int}^B$ with

$$
\mathcal{L}_{m,1}^{B} = s \int_{-L}^{L} dz \left(\delta n_1 \dot{\Phi} \sin \theta_0 + \delta n_2 \dot{Z} \partial_z \theta_0 \right),
$$
\n
$$
\mathcal{L}_{m,2}^{B} = -s \int_{-L}^{L} dz \delta n_2 \partial_t \delta n_1,
$$
\n
$$
\mathcal{L}_{int}^{B} = s \int_{-L}^{L} dz \left(-\dot{Z} \delta n_2 \partial_Z \delta n_1 + \frac{1}{2} (\delta n_1^2 + \delta n_2^2) \cos \theta_0 \dot{\Phi} \right) \equiv \dot{Z} P_m^Z + \dot{\Phi} P_m^{\Phi},
$$
\n(S67)

where

$$
P_{\rm m}^{Z} = -s \int_{-L}^{L} dz \delta n_2 \partial_Z \delta n_1 , \qquad (S68)
$$

$$
P_{\rm m}^{\Phi} = \frac{s}{2} \int_{-L}^{L} dz (\delta n_1^2 + \delta n_2^2) \cos \theta_0.
$$
 (S69)

Above, P_m^Z and P_m^{Φ} represent the pressure of the magnons on the DW along the Z and Φ directions, respectively [\[20\]](#page-4-12). These terms occur because the basis states become time-dependent: sliding and rotating along with the DW, respectively. The last term, in particular, pertain to a fictitious magnetic field Φ along the wire axis, which in the case of a uniform magnet does not have any physical effects (it shifts the zero of energy by $\dot{\Phi}$). However, as demonstrated later, it can cause physical effects when the wire contains DW(s). Importantly, the linear coupling terms vanish due to the orthogonality of the magnon modes with the DW zero modes encoded by $\{Z, \Phi\}.$

Writing explicitly the expressions for the magnonic fields we find for the second term:

$$
P_{\rm m}^{\Phi} = \frac{s}{8} \sum_{n,m} \int_{-L}^{L} dz \left([\Psi_n(z, Z) a_n(t) + \Psi_n^*(z, Z) a_n^*(t) | [\Psi_m(z, Z) a_m(t) + \Psi_m^*(z, Z) a_m^*(t)] - [\Psi_n(z, Z) a_n(t) - \Psi_n^*(z, Z) a_n^*(t) | [\Psi_m(z, Z) a_m(t) - \Psi_m^*(z, Z) a_m^*(t)] \right) \cos(\theta_0) \approx \sum_{n,m} P_{nm}^{\Phi} a_n^*(t) a_m(t), \tag{S70}
$$

$$
P_{nm}^{\Phi} = \frac{s}{2} \int_{-L}^{L} dz \Psi_n^*(z, Z) \Psi_m(z, Z) \cos(\theta_0).
$$
 (S71)

In the last line, we disregard the terms $\propto a_n(t)a_m(t)$ and $\propto a_n^*(t)a_m^*(t)$ as they relate to high-energy processes that are not effective in the low-energy theory describing the DW. Of particular importance in our work are the diagonal terms, that is

$$
P_{nn}^{\Phi} \equiv P_n(Z_0) = \frac{s}{2} \int_{-L}^{L} dz \Psi_n^*(z, Z) \Psi_n(z, Z) \cos(\theta_0), \qquad (S72)
$$

which will be discussed in more detail in the following sections.

C. Equations of motion in the presence of magnons

The equation of motion for the magnon field $a_n(t)$ reads (neglecting the Hamiltonian terms because they scale as $1/L$, as discussed later):

$$
i\dot{a}_n = \omega_n a_n - \sum_m (\dot{Z}P_{nm}^Z + \dot{\Phi}P_{nm}^\Phi) a_m , \qquad (S73)
$$

while the DW dynamics in the absence of Gilbert damping becomes:

$$
\partial_{\Phi} U(\Phi) - 2s\dot{Z} + \dot{P}_{\text{m}}^{\Phi} = 0,
$$

$$
2s\dot{\Phi} + \frac{\partial V_{\text{pin}}(Z)}{\partial Z} + \dot{P}_{\text{m}}^Z = 0.
$$
 (S74)

Eliminating \dot{Z} from the above equations:

$$
\dot{Z} = \frac{1}{2s} \left(\partial_{\Phi} U(\Phi) + \dot{P}_{\rm m}^{\Phi} \right), \tag{S75}
$$

we obtain

$$
M_{\Phi}\ddot{\Phi} + \partial_{\Phi}U(\Phi) + \dot{P}_{\mathbf{m}}^{\Phi} + \frac{M_{\Phi}}{2SN_{dw}}\ddot{P}_{\mathbf{m}}^{Z} \approx M_{\Phi}\ddot{\Phi} + \partial_{\Phi}U(\Phi) + \dot{P}_{\mathbf{m}}^{\Phi} = 0,
$$
\n(S76)

where in the last line we neglected the P_m^Z terms which become irrelevant for large wires and strongly pinned DW. This in turn pertains to the total Lagrangian:

$$
\mathcal{L}_{\text{tot}} = \frac{M_{\Phi}\dot{\Phi}^2}{2} - U(\Phi) + \sum_{n} (ia_n^* \dot{a}_n - \omega_n a_n^* a_n) + \dot{\Phi} P_{\text{m}}^{\Phi}.
$$
 (S77)

Dropping the Φ index from P_m^{Φ} from here on and utilizing $P_{\Phi} = \partial_{\dot{\Phi}} \mathcal{L}_{\text{tot}} = M_{\Phi} \dot{\Phi} + P_m$, we can readily obtain the corresponding (quantum) Hamiltonian:

$$
H_{\text{tot}} = \frac{(P_{\Phi} - P_{\text{m}})^2}{2M_{\Phi}} + \sum_{n} \omega_n a_n^{\dagger} a_n + U(\Phi), \qquad (S78)
$$

which is the DW-magnon Hamiltonian displayed in the main text.

D. Uniform ferromagnetic lead coupled to the magnetic cavity

In a fixed frame, the magnetic lead is described by the Lagrangian

$$
\mathcal{L}_l = -\frac{1}{2} \int dz \left[2s \delta n_{l,1} \partial_t \delta n_{l,2} + \delta n_{l,1} \mathcal{H}_l \delta n_{l,1} + \delta n_{l,2} \mathcal{H}_l \delta n_{l,2} \right],\tag{S79}
$$

where $n_{l,1(2)}$ are the amplitudes along the two orthogonal directions. More generally, the magnetization fluctuations read:

$$
\mathbf{n}_l(z) = \mathbf{e}_{1,l} n_{1,l}(z) + \mathbf{e}_{2,l} n_{l,2}(z), \qquad (S80)
$$

where

$$
e_{1,l} = (-1,0,0); e_{2,l} = (0,1,0).
$$
 (S81)

Consequently, the lead can be aligned either ferro- or anti-ferromagnetically with the cavity. The magnonic fields read (assuming Neumann boundary conditions at the interface with the cavity):

$$
\delta n_l = \sum_{k \ge 0} \sqrt{\frac{2}{L_l}} \cos\left[k(z+L)\right] b_k, \qquad (S82)
$$

where b_k are the amplitudes of the magnons with momentum $k \ge 0$ and L_l the size of the lead. The exchange coupling between the magnetic cavity and the lead at position $z = -L$ reads:

$$
H_{\rm c} = \mathcal{T}\mathbf{n}_l(-L)\cdot\mathbf{n}(-L) \approx \mathcal{T}(\mathbf{e}_{1,l}\delta n_{1,l} + \mathbf{e}_{2,l}\delta n_{2,l})(\mathbf{e}_1\delta n_1 + \mathbf{e}_2\delta n_2) = \frac{\mathcal{T}}{2}\left(\delta n_l^*\delta n e^{-i\Phi} + \delta n_l \delta n^* e^{i\Phi}\right),\tag{S83}
$$

where T is the coupling strength, which we assumed to be isotropic, while $\delta n = \delta n_1 + i \delta n_2$ (and similarly for the lead). Above, we kept only the leading-order contributions in the magnonic fields (the coupling along the z direction only renormalizes the magnonic Hamiltonian for each ferromagnetic side with opposite signs for the two alignments). Performing the substitution:

$$
\delta n \to \delta n e^{i\Phi} \,,\tag{S84}
$$

the tunneling Hamiltonian becomes independent on Φ , but it affects the effective magnetic field felt by the magnons, $P_n = \Phi P_m$, which now becomes:

$$
P_{\rm m} = \frac{s}{2} \int_{-L}^{L} dz (\cos \theta_0 + 1)(\delta n_1^2 + \delta n_2^2).
$$
 (S85)

This leads to the modified total Hamiltonian, including the lead:

$$
H_{\text{tot}} = \frac{(P_{\Phi} - P_{\text{m}})^2}{2M_{\Phi}} + \sum_{n} \omega_n a_n^{\dagger} a_n + U(\Phi) + \sum_{k,n} \mathcal{T}_{kn}(b_k^{\dagger} a_n + \text{h.c.}) + \sum_{k} \omega_k b_k^{\dagger} b_k,
$$
(S86)

and in the following, we retain only the Berry phase mediated interactions between the DW and the magnons (since the Hamiltonian terms scale as $1/L$ and are negligible for a large cavity). If we focus on the dynamics around one of the cavity modes, ω_n , then $P_m \approx P_n a_n^{\dagger} a_n$, with $P_n \equiv P_n(Z_0)$ being the result of integration for a given position Z_0 of the DW in the wire.

In Figs. $S3(a)$ $S3(a)$ and (b) we show P_n as a function of Z_0 and L, respectively, for the first five magnonic modes. We see that the qualitative behavior follows:

$$
P_n(Z_0) \approx 1 + Z_0/L \,,\tag{S87}
$$

up to corrections due to interference effects associated with the standing waves. However, this expression becomes exact for magnons that satisfy $k_n L \gg 1$.

The Hamiltonian part of the Lagrangian can be found similarly, by expanding again up to second order in the fluctuations $\delta n_{1,2}$. Retaining only the second order corrections in the magnonic fields (since the first order correspond to high-energy processes), the interaction with the DW becomes:

$$
\mathcal{L}_{int}^{H} = \frac{1}{2} \int_{-L}^{L} dz \left(\delta n_1 V_1 \delta n_1 + \delta n_2 V_2 \delta n_2 + \delta n_1 V_3 \delta n_2 \right),
$$

\n
$$
V_1 = K_h \cos(2\theta_0) \sin^2 \Phi - \frac{b}{2} \sin \theta_0 \sin \Phi,
$$

\n
$$
V_2 = K_h (\cos^2 \Phi - \sin^2 \theta_0 \sin^2 \Phi) - \frac{b}{2} \sin \theta_0 \sin \Phi,
$$

\n
$$
V_3 = K_h \cos \theta_0 \sin(2\Phi).
$$
 (S88)

We can further write:

$$
\mathcal{L}_{int}^{H} \approx \frac{1}{4} \sum_{n,m} \int_{-L}^{L} dz \Psi_{n}^{*}(z, Z) \Psi_{m}(z, Z) (V_{1} + V_{2}) a_{n}^{*} a_{m}
$$

$$
\equiv \sum_{n,m} (K_{h} J_{nm} \sin^{2} \Phi + b F_{nm} \sin \Phi) a_{n}^{*} a_{m},
$$
(S89)
$$
J_{nm} \equiv J_{nm}(Z_{0}) = -\frac{3}{4} \int_{-L}^{L} dz \Psi_{n}^{*}(z, Z) \Psi_{m}(z, Z) \sin^{2} \theta_{0},
$$

$$
F_{nm} \equiv F_{nm}(Z_{0}) = \frac{1}{8} \int_{-L}^{L} dz \Psi_{n}^{*}(z, Z) \Psi_{m}(z, Z) \sin \theta_{0},
$$

where we disregarded terms containing $a_n^* a_m^*$ and $a_n a_m$ as they do not conserve the number of magnons and correspond to high energy process (note that V_3 only contains such types of process, and therefore does not contribute to the low-energy theory). Furthermore, we also disregarded the terms that only affect the magnons independently on the DW degrees of freedom.

In Figs. [S3\(](#page-18-0)c)-(f) we show the dependence of the diagonal terms $J_{nn} \equiv J_n(L, Z_0)$ and $F_{nn} \equiv F_n(L, Z_0)$ on both the position of the DW (Z_0) and the size of the wire (L). We see that both $J_n(L, Z_0), F_n(L, Z_0) \propto 1/L$, and thus become negligible for $L \gg 1$ compared to the Berry phase contribution.

F. Effect of the pinning potential on the magnons

Here we scrutinize the effect of the pinning potential on the magnons. Assuming that the DW is strongly pinned at Z_0 , the scattering of the magnons can be extracted by solving the pinning potential at position Z_0 . That is, we need to solve the following Schrodinger equation:

$$
[\mathcal{H}_0 + V_0 \delta(z - Z_0)] \Psi_n(z, Z_0) = \omega_n \Psi_n(z, Z_0), \qquad (S90)
$$

where the (dimensionless) scattering strength is $V_0 = \delta K_e/(2K_e)$, and the wave-function is subject to the boundary conditions $\partial_z \Psi_n(z = \pm L) = 0$ (vanishing spin current). We seek for solutions of the form:

$$
\Psi_n(z) = \begin{cases} \alpha_{L,k}\psi_k(z,Z_0) + \beta_{L,k}\psi_{-k}(z,Z_0) & -L < z < Z_0, \\ \alpha_{R,k}\psi_k(z,Z_0) + \beta_{R,k}\psi_{-k}(z,Z_0) & Z_0 < z < L, \end{cases}
$$
\n
$$
(S91)
$$

so that the connection between the two across the scatterer reads:

$$
-[\Psi'_n(Z_0^+, Z_0) - \Psi'_n(Z_0^-, Z_0)] + V_0\Psi_n(Z_0, Z_0) = 0,
$$
\n(S92)

FIG. S3. (a) The Berry phase accumulated by the first five magnon modes for $L = 10$ as a function of the DW position Z_0 (b) Same, as a function of L for $Z_0 = 1$. The black, red, blue, brown, and green curves correspond, in the increasing order, to the $n = 1$ (uniform mode) to $n = 5$ magnonic modes in the wire. They all exhibit the same behavior: the Berry phase is maximum (minimum) at $Z_0 = -L (Z_0 = L)$, while away from $Z_0 = 0$ they show oscillations due to interference effects. (c)–(d) The Hamiltonian terms J_n and F_n as a function of Z_0 and L, respectively.

as well as $\Psi_n(Z_0^+, Z_0) = \Psi_n(Z_0^-, Z_0)$, stemming from the continuity of the wave-function. Hence, the equations determining the spectrum and the wave-functions, respectively, read:

$$
\alpha_{k,R}(k+i)e^{ikL} + \beta_{k,R}(k-i)e^{-ikL} = 0,
$$
\n
$$
\alpha_{k,L}(k-i)e^{-ikL} + \beta_{k,L}(k+i)e^{ikL} = 0,
$$
\n
$$
(\alpha_{k,L} - \alpha_{k,R})e^{ikZ_0} - (\beta_{k,L} - \beta_{k,R})e^{-ikZ_0} = 0,
$$
\n
$$
(\alpha_{k,L} - \alpha_{k,R})e^{ikZ_0} + (\beta_{k,L} - \beta_{k,R})e^{-ikZ_0} + \frac{ikV_0}{1+k^2}(\alpha_{L,k}e^{ikZ_0} - \beta_{L,k}e^{-ikZ_0}) = 0.
$$
\n(S93)

The resulting eigen-momentum equation becomes:

$$
2(1+k^2)\left[2k\cos(2kL) - (1-k^2)\sin(2kL)\right] - kV_0\left[(1-k^2)\cos(2kL) + 2k\sin(2kL) - (1+k^2)\cos(2kZ_0)\right] = 0. \tag{S94}
$$

Although we cannot find an exact solution for k_n analytically, we can determine approximate solutions in the limit $L \to \infty$. We can write

$$
k_n \approx \frac{1}{L} \left(\frac{n\pi}{2} + a_n \right) , \tag{S95}
$$

with $n = 0, 1, \ldots$, and a_n needs to be found perturbatively. In doing so, we find:

$$
a_n = \frac{n\pi}{8L} [4 - V_0 (1 + (-1)^n \cos(\pi n Z_0/L)].
$$
\n(S96)

Hence, we can deduce that magnons experience minimal scattering at low k_n values, and the impact of potential pinning can be safely ignored.

III. DERIVATION OF THE REDUCED DENSITY MATRIX DESCRIBING THE DW EVOLUTION

In this section, we provide additional information regarding the dynamics of the domain wall (DW) in the presence of driven magnons in the finite magnetic wire system.

A. Linearised wire Hamiltonian in the original frame

We assume that the magnetic cavity is driven at a frequency $\Omega_n \sim \omega_n$. In a frame rotating at this frequency, the total Hamiltonian reads:

$$
H_{\text{tot}} = \frac{(P_{\Phi} - P_n a_n^{\dagger} a_n)^2}{2M_{\Phi}} + U(\Phi) + \Delta_n a_n^{\dagger} a_n + h_n(a_n^{\dagger} + a_n), \qquad (S97)
$$

where $\Delta_n = \omega_n - \Omega_n$ and $h_n = \sqrt{W_n \kappa_{n,ex}/\omega_n}$ is the amplitude of the ac magnetic field driving the mode n from the left port, with $\kappa_{n,ex}$ being the corresponding decay rate and W_n the injected power. Note that here we disregarded the other (non-driven) magnonic modes, as they are not resonant with the DW states and therefore do not participate in the dynamics. The evolution of the combined system density matrix ρ_S can be captured by the following Lindblad equation:

$$
\dot{\rho}_{\rm S} = -i[H_{\rm tot}, \rho_{\rm S}] + \kappa_n \mathcal{D}(a_n)\rho_{\rm S} + \sum_{j,k} \gamma_{jk} \mathcal{D}(A_{jk})\rho_{\rm S} , \qquad (S98)
$$

where we recall that $A_{jk} = |j\rangle\langle k|$. Next, we can expand the magnonic cavity field operators around their steady-state value, α_n , that is, $a_n \to \alpha_n + a_n$. The average value α_n is found by requiring that the linear terms in a_n and a_n^{\dagger} that do not involve DW operators vanish, leading to the following equation

$$
h_n = \alpha_n \left[i\kappa_n - \left(\Delta_n + \frac{P_n^2 |\alpha_n|^2}{M_{\Phi}} \right) \right].
$$
 (S99)

The resulting density matrix equation is the same as above, but the unitary part is described by the Hamiltonian

$$
H_{\rm tot} = \frac{(P_{\Phi} - P_n |\alpha_n|^2)^2}{2M_{\Phi}} - \frac{P_n P_{\Phi} (\alpha_n a_n^{\dagger} + \alpha_n^* a_n)}{M_{\Phi}} + \underbrace{\left(\Delta_n - \frac{P_n^2 |\alpha_n|^2}{M_{\Phi}}\right)}_{\Delta'_n} a_n^{\dagger} a_n + U(\Phi), \tag{S100}
$$

In the limit of small power, or $|\alpha_n| \ll 1$, we can disregard all terms $\propto |\alpha_n|^2$ above, which results in the Hamiltonian in Eq. (3) in the main text.

B. Total wire Hamiltonian in the rotated frame

The gauge field introduced by the magnons can be removed by a unitary transformation $U(\Phi) = e^{iP_n\Phi}$, so that the total Hamiltonian becomes:

$$
\widetilde{H}_{\text{tot}} \equiv \mathcal{U}^{\dagger}(\Phi) H_{\text{tot}} \mathcal{U}(\Phi) = \frac{P_{\Phi}^2}{2M_{\Phi}} + U(\Phi) + \Delta_n a_n^{\dagger} a_n + h_n (a_n^{\dagger} e^{-iP_n \Phi} + a_n e^{iP_n \Phi}), \tag{S101}
$$

which shows that the entire effect of the coupling is lumped into the driving term. Note that in effect this transformation also alters the DW dissipator. However, since the rates are already small compared to the level spacing, we disregard any such modifications induced by this transformation. We can further displace the magnons by a quantity that, in turn, removes the linear terms that are independent of Φ. That is:

$$
\widetilde{H}_{\text{tot}} = \frac{P_{\Phi}^2}{2M_{\Phi}} + U'(\Phi) + \Delta_n a_n^{\dagger} a_n + h_n \left[a_n^{\dagger} (e^{-iP_n\Phi} - 1) + a_n (e^{iP_n\Phi} - 1) \right],
$$

\n
$$
U'(\Phi) = U(\Phi) + h_n \left[a_n^*(e^{-iP_n\Phi} - 1) + \alpha_n (e^{iP_n\Phi} - 1) \right].
$$
\n(S102)

In the limit $\kappa_n \ll \Delta_n$ (which is needed for efficient cooling), we can approximate $h_n \approx -\alpha_n \Delta_n$, so that:

$$
\widetilde{H}_{\text{tot}} = \frac{P_{\Phi}^2}{2M_{\Phi}} + U'(\Phi) + \Delta_n a_n^{\dagger} a_n - \alpha_n \Delta_n \left[a_n^{\dagger} (e^{-iP_n \Phi} - 1) + a_n (e^{iP_n \Phi} - 1) \right],
$$
\n
$$
U'(\Phi) = U(\Phi) - 2\bar{n}\Delta_n \left[\cos(P_n \Phi) - 1 \right],
$$
\n(S103)

where $\bar{n} = |\alpha_n|^2$ is the average number of magnons in mode ω_n . As in the previous subsection, if $|\alpha_n| \ll 1$, we can disregard the modifications of the potential $U(\Phi)$ by the magnons.

C. Effective DW density matrix evolution

The total density matrix evolution of the combined system in the lab frame is described by the following Liouville equation:

$$
\dot{\rho}_{\rm S} = (\mathcal{L}_{\rm m} + \mathcal{L}_{\Phi} + \mathcal{L}_{\Phi - \rm m})\rho_{\rm S} \,,\tag{S104}
$$

with

$$
\mathcal{L}_{\text{m}}\rho_{\text{S}} = -i\Delta_{n}[a_{n}^{\dagger}a_{n}, \rho_{\text{S}}] + \kappa_{n}\mathcal{D}(a_{n})\rho_{\text{S}},
$$
\n
$$
\mathcal{L}_{\Phi}\rho_{\text{S}} = -i[H_{\Phi}, \rho_{\text{S}}] + \sum_{j,k} \gamma_{jk}\mathcal{D}(A_{jk})\rho_{\text{S}},
$$
\n
$$
\mathcal{L}_{\Phi-\text{m}}\rho_{\text{S}} = -ig_{n}[P_{\Phi}X_{n}, \rho_{\text{S}}],
$$
\n(S105)

where $X_n = (\alpha_n a_n^{\dagger} + \alpha_n^* a_n)/|\alpha_n|$ and we recall that $g_n = |\alpha_n| P_n(Z_0)/M_{\Phi}$. Let us define $\rho_{\Phi}(t) = \text{Tr}_{m}[\rho_{\mathcal{S}}(t)]$ as the reduced density matrix that describes the dynamics of the DW only, and adiabatically eliminate the magnons. Then, in the interaction picture and within the Born-Markov approximation we obtain [\[31\]](#page-5-9):

$$
\dot{\rho}_{\Phi}(t) = -g_n^2 \int_0^{\infty} d\tau \text{Tr}_m\{ [P_{\Phi}(t)X_n(t), [P_{\Phi}(t-\tau)X_n(t-\tau), \rho_{\Phi}(t) \otimes \rho_m]] \}
$$

\n
$$
= -g_n^2 \left(\int_0^{\infty} d\tau \langle X_n(t)X_n(t-\tau) \rangle [P_{\Phi}(t), [P_{\Phi}(t-\tau), \rho_{\Phi}(t)]] + \int_0^{\infty} d\tau \langle [X_n(t), X_n(t-\tau)] \rangle [P_{\Phi}(t), \rho_{\Phi}(t)P_{\Phi}(t-\tau)] \rangle \right)
$$
\n(S106)

where $P_{\Phi}(t) = \sum_{j,k} \langle j | P_{\Phi} | k \rangle e^{i(\epsilon_j - \epsilon_k)t} A_{jk}$, and [\[31\]](#page-5-9)

$$
\langle X_n(t)X_n(t-\tau) \rangle = \text{Tr}_m[X_n e^{\mathcal{L}_m \tau} X_n \rho_m(t)] \equiv \langle a_n^{\dagger}(t) a_n(t-\tau) \rangle + \langle a_n(t) a_n^{\dagger}(t-\tau) \rangle,
$$

$$
\langle [X_n(t), X_n(t-\tau)] \rangle = \text{Tr}_m[X_n e^{\mathcal{L}_m \tau} [X_n, \rho_m(t)]] \equiv \langle [a_n^{\dagger}(t), a_n(t-\tau)] \rangle + \langle [a_n(t), a_n^{\dagger}(t-\tau)] \rangle,
$$
 (S107)

with ρ_m being the (thermal) density matrix describing the magnons in mode ω_n around the steady state solution α_n . The correlators above can be evaluated by employing the quantum regression theorem [\[31\]](#page-5-9), which gives:

$$
\langle a_n^{\dagger}(t)a_n(t-\tau) \rangle = e^{-(-i\Delta_n + \kappa_n/2)\tau} \langle a_n^{\dagger}(t)a_n(t) \rangle = e^{-(-i\Delta_n + \kappa_n/2)\tau} n_B(\omega_n),
$$

\n
$$
\langle a_n(t)a_n^{\dagger}(t-\tau) \rangle = e^{-(i\Delta_n + \kappa_n/2)\tau} \langle a_n(t)a_n^{\dagger}(t) \rangle = e^{-(i\Delta_n + \kappa_n/2)\tau} [1 + n_B(\omega_n)],
$$

\n
$$
\langle a_n(t-\tau)a_n^{\dagger}(t) \rangle = e^{-(-i\Delta_n + \kappa_n/2)\tau} \langle a_n(t)a_n^{\dagger}(t) \rangle = e^{-(-i\Delta_n + \kappa_n/2)\tau} [1 + n_B(\omega_n)],
$$

\n
$$
\langle a_n^{\dagger}(t-\tau)a_n(t) \rangle = e^{-(i\Delta_n + \kappa_n/2)\tau} \langle a_n^{\dagger}(t)a_n(t) \rangle = e^{-(i\Delta_n + \kappa_n/2)\tau} n_B(\omega_n).
$$
\n(S108)

Therefore:

$$
\langle X_n(t)X_n(t-\tau) \rangle = \left[e^{-i\Delta_n \tau} (1 + n_B(\omega_n)) + e^{i\Delta_n \tau} n_B(\omega_n) \right] e^{-\kappa_n \tau/2},
$$

$$
\langle [X_n(t), X_n(t-\tau)] \rangle = \left(e^{i\Delta_n \tau} - e^{-i\Delta_n \tau} \right) e^{-\kappa_n \tau/2}.
$$
 (S109)

We can insert the above equations in the expression for the density matrix evolution to obtain

$$
\dot{\rho}_{\Phi}(t) = -g_n^2 \sum_{j,k} |\langle j|P_{\Phi}|k\rangle|^2 \left(\int_0^{\infty} d\tau e^{-i(\epsilon_j - \epsilon_k)\tau} \left[e^{-i\Delta_n \tau} (1 + n_B(\omega_n)) + e^{i\Delta_n \tau} n_B(\omega_n) \right] e^{-\kappa_n \tau/2} [A_{jk}, [A_{jk}^{\dagger}, \rho_{\Phi}(t)]]
$$
\n
$$
+ \int_0^{\infty} d\tau e^{-i(\epsilon_j - \epsilon_k)\tau} \left(e^{-i\Delta_n \tau} - e^{i\Delta_n \tau} \right) e^{-\kappa_n \tau/2} [A_{jk}, \rho_{\Phi}(t) A_{jk}^{\dagger}] \right)
$$
\n
$$
= g_n^2 \sum_{j,k} |\langle j|P_{\Phi}|k\rangle|^2 \left(\frac{\kappa_n}{2} \left[\frac{1 + n_B(\omega_n)}{(\epsilon_k - \epsilon_j - \Delta_n)^2 + (\kappa_n/2)^2} + \frac{n_B(\omega_n)}{(\epsilon_k - \epsilon_j + \Delta_n)^2 + (\kappa_n/2)^2} \right] \mathcal{D}[A_{jk}] \rho_{\Phi}(t) \right)
$$
\n
$$
+ i \left[\frac{(1 + n_B(\omega_n))(\epsilon_k - \epsilon_j - \Delta_n)}{(\epsilon_k - \epsilon_j - \Delta_n)^2 + (\kappa_n/2)^2} + \frac{n_B(\omega_n)(\epsilon_k - \epsilon_j + \Delta_n)}{(\epsilon_k - \epsilon_j + \Delta_n)^2 + (\kappa_n/2)^2} \right] [A_{jk}^{\dagger} A_{jk}, \rho_{\Phi}(t)] \right)
$$
\n
$$
\equiv i \sum_j (\epsilon_j + \delta \epsilon_j) [A_{jk}^{\dagger} A_{jk}, \rho_{\Phi}(t)] + \sum_{j,k} (\Gamma_{jk}^n + \gamma_{jk}) \mathcal{D}[A_{jk}] \rho_{\Phi}(t), \qquad (S110)
$$

where

$$
\Gamma_{jk}^{n} = \frac{g_n^2 \langle j|P_{\Phi}|k\rangle|^2 \kappa_n}{2} \left[\frac{1 + n_B(\omega_n)}{(\epsilon_k - \epsilon_j - \Delta_n)^2 + (\kappa_n/2)^2} + \frac{n_B(\omega_n)}{(\epsilon_k - \epsilon_j + \Delta_n)^2 + (\kappa_n/2)^2} \right] \approx \frac{1}{2} \frac{g_n^2 |\langle j|P_{\Phi}|k\rangle|^2 \kappa_n}{(\epsilon_k - \epsilon_j - \Delta_n)^2 + (\kappa_n/2)^2},
$$
\n(5111)
\n
$$
\delta \epsilon_j^n = g_n^2 \sum_k |\langle j|P_{\Phi}|k\rangle|^2 \left[\frac{(1 + n_B(\omega_n))(\Delta_n - \epsilon_k + \epsilon_j)}{(\epsilon_k - \epsilon_j - \Delta_n)^2 + (\kappa_n/2)^2} + \frac{n_B(\omega_n)(\Delta_n + \epsilon_k - \epsilon_j)}{(\epsilon_j - \epsilon_k + \Delta_n)^2 + (\kappa_n/2)^2} \right]
$$
\n
$$
\approx \sum_k \frac{g_n^2 |\langle j|P_{\Phi}|k\rangle|^2 (\Delta_n - \epsilon_k + \epsilon_j)}{(\epsilon_k - \epsilon_j - \Delta_n)^2 + (\kappa_n/2)^2}.
$$
\n(5112)

In the last lines of each above equation, we assumed $k_BT \ll \omega_n$ such that $n_B(\omega_n) \approx 0$. Note that $\delta \epsilon_j$ is the Lamb shift of the DW levels due to interaction with the magnons. We can now establish the stationary density matrix pertaining to the DW, that is, $\dot{\rho}_{\Phi} = 0$, and $\rho_{\Phi} = \sum_j p_j |j\rangle\langle j|$, with p_j the (out-of-equilibrium) occupation probability of the DW state of energy ϵ_j . They obey the following detailed balance equation:

$$
p_j \sum_{k \neq j} \underbrace{(\gamma_{kj} + \Gamma_{kj}^n)}_{\Gamma_{kj}^{\text{tot}}} - \sum_{k \neq j} p_k \underbrace{(\gamma_{jk} + \Gamma_{jk}^n)}_{\Gamma_{jk}^{\text{tot}}} = 0, \tag{S113}
$$

and subject to the normalization condition $\sum_j p_j = 1$. In the main text, we find p_j numerically by including the first 20 DW levels in the above equation.

D. Wigner function (or quasi-probability distribution)

The Wigner function is defined as [\[26\]](#page-5-4):

$$
W(\Phi, P_{\Phi}) = \frac{1}{\pi} \int d\Phi' \langle \Phi - \Phi' | \rho_{\Phi} | \Phi + \Phi' \rangle e^{2i P_{\Phi} \Phi'} , \qquad (S114)
$$

and it contains all possible information about the DW state. The density operator ρ_{Φ} can be deduced from it and hence the expectation value of all the possible DW observables. Its physical interpretation can be traced back to the expectation values of the operators. Let A be an operator in the phase space $\Phi - P_{\Phi}$. Then, its expectation value reads:

$$
\langle A \rangle = \int \int d\Phi dP_{\Phi} W(\Phi, P_{\Phi}) A. \tag{S115}
$$

Although naively one could interpret $W(\Phi, P_{\Phi})$ as a probability distribution in the phase space, this is not, in fact, a classical probability distribution. A feature that distinguishes the Wigner function from a classical probability distribution is the fact that the former can take negative values. Generally, negativities in the Wigner function are a good indication of the nonclassical nature of a quantum state [\[26\]](#page-5-4).

At the origin, i.e. $\Phi = P_{\Phi} = 0$, we find:

$$
W(0,0) = \frac{1}{\pi} \int d\Phi' \langle -\Phi' | \rho_{\Phi} | \Phi' \rangle = \frac{1}{\pi} \sum_{j} p_{j} \int d\Phi' \Psi_{j}^{*} (-\Phi') \Psi_{j} (\Phi') \equiv \frac{1}{\pi} \sum_{j} (-1)^{j+1} p_{j}, \qquad (S116)
$$

which is the expression employed in the main text.

E. Detection of the DW levels occupation from the emitted power spectrum

In experimental settings, the population of the DW levels can be determined by examining the power spectrum of the magnons that are emitted. This involves applying a separate laser, which is weakly driven, to the magnetic cavity at one of the ports. This laser is tuned to resonate with one of the magnonic modes, denoted as ω_p (distinct from the laser used to manipulate occupations). The resulting magnonic radiation is subsequently analyzed.

Let us establish the equations of motion for the quantum fluctuations of the cavity operators a_p s around the average value α_p :

$$
\dot{a}_p = -\frac{\kappa_p}{2} a_p - i \frac{P_n(Z_0)}{M_{\Phi}} P_{\Phi}(a_p + \alpha_p) + \sqrt{\kappa_{p,ex}} a_{p,\text{in}}(t) + \sqrt{(\kappa_p - \kappa_{p,ex})} b_{p,\text{in}}(t) ,\tag{S117}
$$

where κ_p and $\kappa_{p,ex}$ are the total decay rate and the decay rate associated with the vacuum noise of the laser field, respectively. Note that we can write the input contribution as $a_{p,in}(t) \to h_p(t) + a_{p,in}$, which is the sum of the coherent part of the input and fluctuations, respectively. The output power spectrum associated with a mode driven by the laser frequency $\omega_L = \omega_p$ is given by [\[24\]](#page-5-2):

$$
S_p(\omega) = \frac{1}{2\pi} \int_{-\infty}^{\infty} d\tau e^{-i(\omega - \omega_L)\tau} \langle a_{p,\text{out}}^\dagger(t + \tau) a_{p,\text{out}}(t) \rangle , \qquad (S118)
$$

where the output field, $a_{p,out}(t)$, is related to the input one, $a_{p,in}(t)$, via the input-output relations:

$$
a_{p,\text{out}}(t) = \sqrt{\kappa_{p,\text{ex}}}[a_p(t) + \alpha_p] + h_p(t) + a_{p,\text{in}}(t),
$$
\n(S119)

and $\langle \ldots \rangle$ represents the expectation value over the stationary state. We are hence left with finding the cavity field evolution, which can be formally integrated as:

$$
a_p(t) = a_{p,0}(t) + i \frac{P_n(Z_0)}{M_{\Phi}} \int_0^t d\tau e^{-\kappa_p (t-\tau)/2} P_{\Phi}(\tau) [a_p(\tau) + \alpha_p]
$$

\n
$$
\approx a_{p,0}(t) + i \frac{P_n(Z_0)}{M_{\Phi}} \sum_{j,k} \langle j | P_{\Phi} | k \rangle \int_0^t d\tau e^{-\kappa_p (t-\tau)/2} e^{-i(\epsilon_j - \epsilon_k)(t-\tau)} A_{jk}(t) [a_p(\tau) + \alpha_p]
$$

\n
$$
\approx a_{p,0}(t) - \frac{\alpha_p P_n(Z_0)}{M_{\Phi}} \sum_{j,k} \frac{\langle j | P_{\Phi} | k \rangle}{\epsilon_j - \epsilon_k - i\kappa_p/2} A_{jk}(t),
$$
\n(S120)

where $a_{p,0}(t)$ is the solution in the absence of the coupling to the DW, i.e. for $P_n(Z_0) = 0$, and we kept the leading order terms in the Dyson series. Hence, the noise can be written as:

$$
S_p(\omega) = \frac{1}{2\pi} \int_{-\infty}^{\infty} d\tau e^{-i(\omega - \omega_L)\tau} \left\langle \left[\sqrt{\kappa_{p,ex}} a_p^{\dagger}(t+\tau) + a_{p,\text{in}}^{\dagger}(t+\tau) + \sqrt{\kappa_{p,ex}} \alpha_p^* - \frac{i h_p^*}{\sqrt{k_{p,ex}}} \right] \right\rangle
$$

$$
\times \left[\sqrt{\kappa_{p,ex}} a_p(t) + a_{p,\text{in}}(t) + \sqrt{\kappa_{p,ex}} \alpha_p + \frac{i h_p}{\sqrt{\kappa_{p,ex}}} \right] \right\rangle.
$$
 (S121)

This can be expressed as the sum of elastic scattering (which does not involve DW) and the inelastic contribution (or side-band transitions), that is, $S_p(\omega) \equiv S_{p,el}(\omega) + S_{p,in}(\omega)$. The former is given by:

$$
\mathcal{S}_{p,el}(\omega) \approx \frac{1}{2\pi} \int_{-\infty}^{\infty} d\tau e^{-i(\omega - \omega_L)\tau} \left[\frac{1}{\kappa_{p,ex}} |h_p|^2 + \kappa_{p,ex} |\alpha_p|^2 + i(\alpha_p^* h_p - \alpha_p h_p^*) \right]
$$

=
$$
\frac{|h_p|^2}{\pi \kappa_{p,ex}} \int_{-\infty}^{\infty} d\tau e^{-i(\omega - \omega_L)\tau} \left[1 + \frac{8\kappa_{p,ex}^2}{\kappa_p^2} - \frac{8\kappa_p \kappa_{p,ex}}{\kappa_p^2} \right] = \frac{W_p}{\omega_p} \left[1 - \frac{8\kappa_{p,ex} (\kappa_p - \kappa_{p,ex})}{\kappa_p^2} \right] \delta(\omega - \omega_L),
$$
(S122)

with the delta function highlighting the elastic processes. The second term, which takes on the behavior of the DW, is expressed as follows:

$$
S_{p,\text{in}}(\omega) = \frac{\kappa_{p,\text{ex}}}{2\pi} \int_{-\infty}^{\infty} d\tau e^{-i(\omega - \omega_L)\tau} \langle a_p^{\dagger}(t + \tau) a_p(t) \rangle = \frac{\kappa_{p,\text{ex}}}{2\pi} \mathcal{R}e \int_{0}^{\infty} d\tau e^{-i(\omega - \omega_L)\tau} \langle a_p^{\dagger}(t + \tau) a_p(t) \rangle
$$

\n
$$
= -\frac{\kappa_{p,\text{ex}}}{2\pi} g_p^2 \mathcal{R}e \int_{0}^{\infty} d\tau e^{-i(\omega - \omega_L)\tau} \langle \int_{0}^{t + \tau} d\tau_1 e^{-\kappa_p (t + \tau - \tau_1)/2} P_{\Phi}(\tau_1) \int_{0}^{t} d\tau_2 e^{-\kappa_p (t - \tau_2)/2} P_{\Phi}(\tau_2) \rangle
$$

\n
$$
\approx \frac{\kappa_{p,\text{ex}}}{2\pi} g_p^2 \mathcal{R}e \sum_{j,j';k,k'} |\langle j| P_{\Phi}|k \rangle|^2 \int_{0}^{\infty} d\tau e^{-i(\omega - \omega_L)\tau} \langle \int_{0}^{\infty} d\tau_1 e^{-\kappa_p \tau_1/2} e^{-i(\epsilon_j - \epsilon_k)\tau_1} A_{jk}(t + \tau)
$$

\n
$$
\times \int_{0}^{\infty} d\tau_2 e^{-\kappa_p \tau_2/2} e^{-i(\epsilon_j - \epsilon_{k'})\tau_2} A_{j'k'}(t) \rangle
$$

\n
$$
= \frac{\kappa_{p,\text{ex}}}{2\pi} g_p^2 \mathcal{R}e \int_{0}^{\infty} d\tau e^{-i(\omega - \omega_L)\tau} \sum_{j,k} \frac{|\langle j| P_{\Phi}|k \rangle|^2}{(\epsilon_j - \epsilon_k)^2 + (\kappa_p/2)^2} \langle A_{jk}(t + \tau) A_{kj}(t) \rangle
$$

\n
$$
= \frac{\kappa_{p,\text{ex}}}{2\pi} g_p^2 \mathcal{R}e \int_{0}^{\infty} d\tau e^{-i(\omega - \omega_L)\tau} \sum_{j,k} \frac{|\langle j| P_{\Phi}|k \rangle|^2}{(\epsilon_j - \epsilon_k)^2 + (\kappa_p/2)^2} e^{-M_{jk}\tau} p_j
$$

where $\Gamma_{jk}^{\text{eff}} = \mathcal{I}mM_{jk} = \sum_{p}(\Gamma_{pk}^{n} + \Gamma_{pj}^{n} + \gamma_{pk} + \gamma_{pj}) = \Gamma_{kj}^{\text{eff}}$, as demonstrated below. Therefore, for $\omega \neq \omega_L$, the total contribution to the noise is due to side-band transitions, as mentioned in the main text.

F. The DW correlators

Here, we provide the derivation of the evolution of the various expectation values and correlators utilized above. We start with

$$
\frac{d}{dt}\langle A_{jk}(t)\rangle = i(\epsilon_j - \epsilon_k)\langle A_{jk}(t)\rangle - \sum_{j',k'}(\Gamma_{j'k'}^n + \gamma_{j'k'})\text{Tr}\{A_{jk}(A_{k'j'}A_{j'k'}\rho_{\Phi} + \rho_{\Phi}A_{k'j'}A_{j'k'})\}\n+ 2\sum_{j',k'}(\Gamma_{j'k'}^n + \gamma_{j'k'})\text{Tr}\{A_{k'j'}A_{jk}A_{j'k'}\rho_{\Phi}\} = [i(\epsilon_j - \epsilon_k) - \underbrace{\sum_{p}(\Gamma_{pk}^n + \gamma_{pk} + \Gamma_{pj}^n + \gamma_{pj})}\langle A_{jk}(t)\rangle, \quad (S124)
$$

so that

 $\overline{\Gamma}$

$$
\langle A_{jk}(t) \rangle = e^{i(\epsilon_j - \epsilon_k)t} e^{-\Gamma_{jk}^{\text{eff}}t} \langle A_{jk}(0) \rangle. \tag{S125}
$$

Hence, we can use the quantum regression theorem [\[31\]](#page-5-9) to extract the correlators:

$$
\langle A_{jk}(t+\tau)A_{j'k'}(t)\rangle = e^{i(\epsilon_j - \epsilon_k)\tau}e^{-\Gamma_{jk}^{\text{eff}}\tau} \langle A_{jk}(t)A_{j'k'}(t)\rangle \equiv e^{i(\epsilon_j - \epsilon_k)\tau}e^{-\Gamma_{jk}^{\text{eff}}\tau}p_j,
$$
\n(S126)

where in the last line we assumed the long-time (or stationary) limit density matrix $\rho_{\Phi} = \sum_j p_j |j\rangle\langle j|$.
