Department of Applied Physics, Aalto University, FI-00076 Aalto, Finland

The doped Hubbard model is one of the paradigmatic platforms to engineer exotic quantum manybody states, including charge-ordered states, strange metals and unconventional superconductors. While undoped and doped correlated phases have been experimentally realized in a variety of twisted van der Waals materials, experiments in monolayer materials, and in particular 1T transition metal dichalcogenides, have solely reached the conventional insulating undoped regime. Correlated phases in monolayer two-dimensional materials have much higher associated energy scales than their twisted counterparts, making doped correlated monolayers an attractive platform for high temperature correlated quantum matter. Here, we demonstrate the realization of a doped Mott phase in a van der Waals dichalcogenide 1T-NbSe₂ monolayer. The system is electron doped due to electron transfer from a monolayer van der Waals substrate via proximity, leading to a correlated triangular lattice with both half-filled and fully-filled sites. We analyze the distribution of the half-filled and filled sites and show the arrangement is unlikely to be controlled by disorder alone, and we show that the presence of competing non-local many-body correlations would account for the charge correlations found experimentally. Our results establish 1T-NbSe₂ as a potential monolayer platform to explore correlated doped Mott physics in a frustrated lattice.

Mott insulators and the Hubbard model [1, 2] are one of the paradigmatic platforms to engineer exotic quantum many-body states. Doped Mott physics is known to lead to a variety of unconventional strongly correlated phenomena [3, 4], and represent a key physical regime leading to high- T_C superconductivity. Conventional doped Mott systems such as cuprates [5] feature square lattices and its phenomena may be impacted by disorder [6, 7], while more exotic phenomena can potentially appear in doped Mott systems lacking disorder and featuring geometrically frustrated lattices [8–11]. Van der Waals materials [12], including graphene and dichalcogenides, have risen as ideal materials systems for filling this gap. Electrostatic gating in these materials allows doping correlated systems without disorder effects [13], and their effective triangular lattices provide a complementary platform to explore the impact of geometric frustration [14, 15]. In particular, twisted van der Waals heterostructures have become the preferred system to emulate correlated states, ranging from conventional correlated insulators [16, 17], charge ordered states [18, 19] unconventional superconducting states [20, 21] and fractional topological states [22-24]. While the capability of doping van der Waals systems extends to monolayers, tunable correlated physics in monolayers have remained much less explored.

Monolayer dichalcogenides [25] can be used to realize different correlated states. Dichalcogenide materials have two typical different crystal structures (1H and 1T phases), with metallic dichalcogenides featuring charge density wave (CDW) orders in both phases. While monolayer 1H phases remain metallic and superconducting at lower temperatures [26–29], 1T phases develop a correlated insulating state [30–33] due to the superstructure generated by the charge density wave reconstruction [34]. Interestingly, the complex electronic structure of such a system can effectively result in a single orbital model in triangular lattice supercell [35, 36], leading to a strongly correlated state due to the reduced bandwidth. 1T dichalcogenides are well-known Mott insulators, and due to the geometric frustration, they have been proposed as quantum spin liquids [37, 38]. Their van der Waals nature turns them into ideal candidates to use as magnetic building block in van der Waals heterostructures [39–41]. Proximity effects can enable doping via charge transfer [42], turning them into an attractive system to explore doped Mott physics in a triangular lattice [43–47]. However, doped Mott phases featuring correlated order have remained unexplored experimentally in monolayer materials.

Here, we demonstrate the realization of a doped Mott phase in a van der Waals dichalcogenide monolayer. We show that, due to the charge reconstruction, an emergent correlated triangular lattice appears. The combination of local many-body correlations and charge transfer leads to a triangular lattice featuring both half-filled and fully-filled sites, realizing a deep doped Mott phase. We analyze the statistical distribution of half-filled and filled sites, showing that the arrangement is unlikely to be controlled by disorder alone but signaling the presence of underlying many-body non-local correlations. Our results establish 1T-NbSe₂ as a potential monolayer platform to explore correlated doped Mott physics in a frustrated lattice.

Fig. 1a shows a schematic of our experimental system where we have grown heterostructures of 1Tand 1H-crystal polymorphs of monolayer NbSe₂ via molecular-beam epitaxy (MBE) on highly-oriented pyrolytic graphite (HOPG), see Supplementary Information (SI) for details of the sample growth. The growth yields a statistical distribution of different heterostuctures and we focus here on the 1T/1H-heterobilayers. The samples were investigated by low-temperature scanning tunneling

(f) All the dI/dV spectra taken at the centre of the star of David arranged monotonically with respect to the location of upper Hubbard band. The spectra are vertically offset for clarity.

microscopy (STM) at T = 350 mK and Fig. 1b shows an STM image of a typical heterostructure. We can identify the 1H and 1T-phases through atomic scale imaging [26, 34, 48]. In a zoomed-in image (Fig. 1c), the lattice set-up by the well-known star-of-David (SoD) CDW reconstruction in 1T-NbSe₂ is clearly visible. Similarly to 1T-TaSe₂ and 1T-TaS₂, each CDW unit cell hosts a single state close to the Fermi level and electron-electron interactions break these into lower and upper Hubbard bands (LHB and UHB). In contrast to well-studied 1T-TaS₂ and 1T-TaSe₂, the LHB in 1T-NbSe₂ has been reported to be located below the valence band, making the material a charge transfer insulator [34].

The doping of the CDW lattice is controlled by the substrate. Monolayer 1T-NbSe₂ grown on HOPG is undoped and each CDW unit cell hosts a single unpaired electron (see SI). In heterostructures with 1H-NbSe₂ the situation is drastically altered, and only about 30% of the CDW unit cells remain singly occupied. This is visualized in Fig. 1f, which shows dI/dV spectra recorded at the centers of the SoD unit cells over the area shown in Fig. 1c. The spectra are ordered in energy, their spatial pattern is complex and disordered (Fig. 1d,e, see below for details). On the lower end of the plot (indicated halffilled), there are roughly symmetric peaks around the Fermi level corresponding to the LHB and UHB. While monolayer 1T-NbSe₂ directly grown on HOPG is a charge transfer insulator, the 1T-monolayer on 1H-NbSe₂ shows the typical behaviour of a Mott insulator: as the doping is increased (moving up in Fig. 1f), the UHB moves towards the Fermi level until it crosses it, the LHB becomes

doubly filled and the spectral peak corresponding to the UHB disappears.

The complex spatial distribution of the half- and fullyfilled cells can be probed by STS experiments as shown in Fig. 1d and e. The half-filled unit cells are clearly visible in the dI/dV map shown in Fig. 1d. The energy of the highest occupied band extracted from grid spectroscopy data over the same area is shown in Fig. 1e. Surprisingly, there is obvious clustering of the half-filled sites, which we analyze more quantitatively below. This is unexpected as in the absence of disorder and interactions, the halffilled sites should be randomly distributed. On the other hand, charge interaction between neighboring SoD unit cells can give rise to ordered patterns of the half-filled and fully-filled unit cells.

The distribution of the half- and fully-filled unit cells can be quantified by calculating spatial correlators of the filled and half-filled cells. The local nearest-neighbor spatial correlation can be defined as $\mathcal{C} = \langle n_i n_j \rangle_{ij \in NN}$ - $\langle n_i \rangle \langle n_i \rangle$, where $n_i = 1, 2$ for a half-filled/fully-filled site i, $ij \in NN$ denotes nearest neighbor pairs in the SoD triangular superlattice and $\langle \rangle$ denotes the statistical average. For an infinitely large system with a random distribution of fillings, the previous correlators would be identically 0. The presence of a finite value of the correlator signals that interactions lead to a preference in the fillings between neighboring sites. We have converted the data in Fig. 1 into a binary filled/half-filled format (Fig. 2a). This is then used to calculate the first neighbor correlator yielding a value of C = 0.02 indicating significant positive correlations in finding half-filled unit cells next

Figure 2. Analysis of the charge distribution in doped 1T-NbSe₂. (a) Experimental distribution of half-filled and fully-filled sites. (b) Probability distribution $P(\mathcal{C})$ of the first neighbor correlator \mathcal{C} in the case the fillings of the different sites are purely random, compared with the correlator obtained experimentally. (c) Probability distribution $P(|\mathcal{C}| > C_0)$ that a purely random arrangement leads to a correlator bigger than a threshold C_0 , compared with the experimentally measured value.

to each other. For a finite system, statistical fluctuations can lead to different non-zero values of the correlators even if the distribution of fillings were purely random. Such a purely random doping distribution would arise if the distributions of fillings is dominated by the effect of impurities or defects in the underlying 1H-NbSe₂ substrate. To quantify the impact of finite size effects, we compare the value of the correlator to the results from a purely random distribution in the finite size geometry of our experiment (Fig. 2b and c), indicating that the probability of finding our experimental correlator or bigger in a random system is less than 10%. The previous phenomenology shows that our system presents correlations that are unlikely to stem from randomness alone, and signals the presence of a mechanism leading to finite interactions between the filling of the sites. In the following we present a mechanism that would account for these finite correlations.

The strongly interacting model realized in 1T-NbSe_2 is expected not only to feature local electronic repulsion, but also finite interactions between SoD sites may be present. In general, the interacting model can be written as extended Hubbard model in the triangular lattice [8, 9] of the form

$$\mathcal{H} = \sum_{i,j,s} t_{i,j} \hat{c}_{i,s}^{\dagger} \hat{c}_{j,s} + U \sum_{i} \left(\hat{n}_{i,\uparrow} - \frac{1}{2} \right) \left(\hat{n}_{i,\downarrow} - \frac{1}{2} \right) + \sum_{i,s} \mu_{i} \hat{c}_{i,s}^{\dagger} \hat{c}_{i,s} + \sum_{i,j,s,s'} V_{i,j} \hat{n}_{i,s} \hat{n}_{j,s'}$$
(1)

where $V_{i,j}$ parametrizes the nearest neighbors interactions and $\hat{n}_{i,s} = \hat{c}_{i,s}^{\dagger} \hat{c}_{i,s}$ is the number operator for spin s in site i. The hoppings $t_{i,j}$ account for the finite dispersion of the SoD band, U accounts for the local electrostatic repulsion. Local disorder stemming from the stacking or defects is included in μ_i , where $\mu_i \in [-W, W]$ are random values with W parametrizing the strength of disorder. The extended electrostatic interactions $V_{i,j}$ are instrumental to give rise to nearest neighbor correlations in the fillings compatible with the experimental findings. The previous model can be solved using a mean field decoupling using a self-consistent procedure [49], which allows us to simultaneously capture the impact of local interactions, non-local interactions, charge transfer, kinetic energy and disorder. Calculations are performed at the electrostatic filling found experimentally, and we take $U = 2.2\beta$, with β the bandwidth of the SoD flat band leading to a deep Mott state, and $V_2 = 0.2U$. During the minimization domains and topological defects may appear, which are directly accounted by the self-consistent solution of the interacting problem.

Let us first consider the minimal case where only local interaction U and nearest neighbor repulsion V_1 are present. In this situation, charges are expected to repel each other and give rise to a negative first neighbor correlation \mathcal{C} . For more complex interactions, positive correlations can be found. We show in Fig. 3 two minimal models consistent with the experiment, a model with competing attractive and repulsive interaction $V_1 - V_2$, where the nearest neighbor attraction V_1 can stem from SoD polarons [50–53] (Figs. 3a,c,e,g), and a model with purely repulsive $V_1 - V_2 - V_3$ interactions [36, 54] (Fig. 3b,d,f,h). For both models, the self-consistent charge arrangement shows distributions comparable to the experimental ones (Fig. 3a,b) featuring small clusters. The combination of the local disorder and the mean-field interactions gives rise to a locally modulated self-consistent electrostatic potential (Fig. 3c,d), yielding a spatially dependent density of states in the system (Fig. 3e,f). The density of states features both half-filled and fully-filled sites (Fig. 3) consistent with experimental results.

Due to the inherent frustration of the lattice and interactions the ground state may be multiply degenerate, and most importantly depends on the disorder configuration considered. To account for this variability and show the robustness of this phenomenology we have performed a statistical analysis of the nearest neighbor correlator by

Figure 3. Self-consistent solution of an interacting long-range doped Hubbard model with disorder. Panels (a,c,e,g) correspond to a model with competing attractive and repulsive interactions $V_1 = -0.5V_2$, $V_2 > 0$ and (b,d,f,h) to a model with only repulsive interactions with $V_1 = 0.3V_2$, $V_3 = V_2$. Both models give rise to a charge arrangement with positive first neighbor correlator C > 0 as found experimentally (a,b), featuring a combination of disorder and many-body interactions giving rise to a fluctuating local potential (c,d). The density of states is strongly site dependent, giving rise to half-filled sites with a Mott gap and fully filled sites (e,f) Panels (g,h) show the statistical distribution of the correlators for different disorder realizations, featuring an overall positive correlation both for attractive and repulsive models. We took disorder $W = 5V_2$ in (a,c,e,g) and $W = 3V_2$ (b,d,f,h).

finding the ground state of the interacting model over 10^5 different disorder configurations. The calculations of the nearest neighbor correlator can be directly performed with a downfolded model that integrates out charge fluctuations. In the absence of charge fluctuations the long-range interacting model can be mapped to a gas-lattice model of the form $H = \sum V_{ij} \tilde{n}_i \tilde{n}_j$ where $\tilde{n}_i = 1, 2$ are the classical occupations of the sites, whose lowest energy configuration can be obtained by a Markov chain Monte Carlo minimization. This classical limit allows us to effectively sample over many disordered configurations, demonstrating that generic disorder configurations feature a positive correlation driven by interactions as shown in Fig. 3g,h. A more detailed analysis of the model can be found in the SI.

Having analyzed the spatial distribution of filled and half-filled sites, we now focus on the low energy spectroscopic response of the system. Half-filled sites host a local S = 1/2. In the presence of antiferromagnetic coupling with the 1H substrate, this is expected to give rise to a Kondo peak. $1T/1H-TaS_2$ and $1T/1H-TaS_2$ heterostructures realize half-filled Kondo lattices, where the coupling of the localized moments of 1T-layer and the conduction electrons in the 1H-layer result in heavyfermion insulator or magnetically ordered states [39– 41]. In contrast, the $1T/1H-NbSe_2$ heterostructure of our experiment has a large charge transfer leading to a strongly doped regime of the correlated lattice [42], pushing our system towards the Kondo charge depletion found in 4Hb-TaS₂ [55, 56]. We observe that only $\sim 6\%$ of half-filled sites have a pronounced Kondo peak (Fig. 4b), whereas most of the unit cells do not show clear Kondo signature (Fig. 4a). These different phenomenologies may stem from some half filled sites having antiferromagnetic Kondo coupling $J_K > 0$, whereas others having ferromagnetic one $J_K < 0$. Local stacking is known to greatly impact the interlayer exchange coupling in van der Waals materials [57–59], so that the different exchange couplings can naturally arise due to the different registry of 1T SoD and the 3×3 CDW of the underlying 1H-NbSe₂. The 3×3 CDW has been shown to strongly modulate the Yu-Shiba-Rusinov states of magnetic metal atoms on bulk 2H-NbSe₂ [60], motivating this as a possible cause for our observations. Finally, it is unlikely that the absence of the Kondo features could be explained arising solely from impurities in 1H, given that the impurity density present in 1H is much lower that the one required to suppress Kondo in 94% of the half filled sites.

In addition to the zero-magnetic field spectroscopy show in Fig. 4a, we have investigated the evolution of the spectroscopy with out-of-plane magnetic field of ± 10

Figure 4. Magnetic field dependence of the half-filled sites with and without Kondo peak. Panel (a) shows half-filled site (large bias spectra shown in inset) without a Kondo peak. Panel (b) shows half-filled site (large bias spectra shown in inset) having Kondo peak. Panel (c, d) shows magnetic field dependence of sites shown in panel (a, b), respectively.

T. The results are shown in Figs. 4c and d for the halffilled sites without and with Kondo features, respectively. Both sets of spectra feature a noticeable magnetic field dependence. Spectra corresponding to half-filled site with Kondo signature splits with magnetic field as expected. The low bias signature in half-filled site without Kondo also have a magnetic field dependent splitting. This response is very similar to the behaviour

found on fully-filled sites (where Kondo related phenomena are not expected to occur, see SI) and could indicate that it would be associated with pseudogap enhancement of the underlying 1H-NbSe₂ substrate with applied field [27, 48].

To summarize, we have shown that monolayer 1T-NbSe₂ develops a doped Mott insulating state due to charge transfer from the substrate. We have identified the appearance of both half-filled and fully-filled sites, showing that this material provides a paradigmatic platform to emulate doped Hubbard physics in a triangular lattice. Based on the statistical distribution of halfand fully-filled sites, we have found signatures of underlying correlations, signaling that non-local correlations contribute to the charge distribution of the doped Mott insulating monolayer. From the perspective of strongly correlated phase diagram, our experiment is likely to be in the overdoped regime, and the emergence of superconducting state at lower dopings would represent an open question. Our results establish a new platform to emulate doped Hubbard physics in a monolayer van der Waals material, providing a starting point to explore correlated phases of matter in geometrically frustrated, tunable quantum materials.
