#### Abstract

Wrinkling instabilities of thin elastic sheets can be used to generate periodic structures over a wide range of length scales. Viscosity of the thin elastic sheet or its surrounding medium has been shown to be responsible for dynamic processes. While this has been explored for solid as well as liquid thin elastic sheets we here consider wrinkling of fluid deformable surfaces, which show a solid-fluid duality and have been established as model systems for biomembranes and cellular sheets. We use this hydrodynamic theory and numerically explore the formation of wrinkles and their coarsening, either by a continuous reduction of the enclosed volume or the continuous increase of the surface area. Both lead to almost identical results for wrinkle formation and the coarsening process, for which a universal scaling law for the wavenumber is obtained for a broad range of surface viscosity and rate of change of volume or area. However, for large Reynolds numbers and small changes in volume or area wrinkling can be suppressed and surface hydrodynamics allows for global shape changes following the minimal energy configurations of the Helfrich energy for corresponding reduced volumes.

## 1 Introduction

Thin elastic sheets that resist bending, are ubiquitous in nature and man-made systems and their mechanical properties enable countless applications. At a critical compression such sheets wrinkle. Thereby wrinkles emerge with a wavelength which balances the resistance to bending of the sheet and the stiffness that resists out-of-plane deformations. This might lead to the formation of periodic structures with regular spacing. The required compression can be induced by different approaches. Recent studies have focused on understanding the bending deformations that occur when solid thin elastic sheets are stretched [15, 8, 25], poked [45, 46], or wrapped around a curved object [18, 16]. Under suitable conditions, wrinkles can also be dynamic, with a tunable wavelength [5]. This can be realized if the solid thin elastic sheet is floating on a liquidair interface. Wrinkles are no longer static, they coarsen and thereby change wavelength and amplitude. The coarsening of the wrinkles has been associated with the inertial response of the underlying liquid. In contrast to these results for solid thin elastic sheets, wrinkling instabilities have also been observed in liquid thin elastic sheets. Besides wrinkling at the collapse of a viscous bubble film upon rupture [9, 39, 37, 23, 29], they can also form in a controlled manner [29]. As bending forces are no longer present, such sheets buckle when the rate of compression is faster than the smoothing effect of surface tension and wrinkling is associated with the viscosity of the film. While the mechanisms for wrinkling of solid and liquid thin elastic sheets significantly differ, both dynamics are associated with viscosity.

Various theories have been developed to model solid thin elastic sheets. Among them the Föppl-von Kármán equation is a popular approach [8, 31, 13, 41]. For a mathematical approach, which interprets wrinkling of solid sheets as a geometrical problem and determines the wrinkling patterns as configurations with the least possible energy, we refer to [42]. In contrast with this, approaches for liquid thin elastic sheets are rare. In [29] a dynamic version of the Föppl-von Kármán equation is used. Even, if argued in [29] that inertia plays a critical role in determining the number of wrinkles, hydrodynamic theories have not been considered in this context. This also holds for theoretical approaches for the dynamic wrinkling considered in [5].

We provide such a hydrodynamic approach and focus on fluid deformable surfaces. Such surfaces can be seen as thin elastic sheets with solid and liquid properties and have been established as model systems for biomembranes [2, 43]. They exhibit a solid-fluid duality, while they store elastic energy when stretched or bent, as solid thin elastic sheets, they flow as viscous two-dimensional fluids under in-plane shear. With these properties, fluid deformable surfaces can be seen as a hybrid between solid and liquid thin elastic sheets. Depending on the material properties, solid-like behaviour (large viscosity) or liquid-like behaviour (low bending rigidity) can be achieved. The solid-fluid duality has several consequences: it establishes a tight interplay between tangential flow and surface deformation. In the presence of curvature, any shape change is accompanied by a tangential flow and, vice-versa, the surface deforms due to tangential flow. Wrinkling of lipidic membranes have, e.g., been observed in [22]. Besides biomembranes, fluid deformable surfaces are also appropriate to model the complex deformations in embryonic epithelia. These cellular sheets are fluid-like to enable morphogenetic flows, e.g. measured during vertebrate body axis elongation [24], and wrinkling is an essential process in morphogenetic tissue deformations.

Models describing this interplay between curvature and surface flow have been introduced and numerically solved in [43, 33, 21, 3]. These numerical approaches provide the basis to explore the impact of surface viscosity and bending rigidity on the dynamics of wrinkles in biomembranes or epithelial tissue. However, instead of such concrete applications, we consider a systematic approach, where wrinkles form in a controlled manner and their dynamics can be analyzed. Similar to [29] we consider a closed surface with an embedded volume and either dynamically reduce the volume or increase the surface area to induce the required compression resulting in wrinkling. By considering a prolate geometry we further provide an axis of symmetry to induce wrinkling in a deterministic way. We also neglect the potential influence of the bulk fluid phases. This is justified if the Saffman-Delbrück number [34], which defines a hydrodynamic length relating the viscosity of the elastic sheet and the surrounding bulk fluid, is large. In this case, the hydrodynamics is effectively 2D on spatial scales smaller than the Saffman-Delbrück number [14]. Within this approach, we computationally study the effect of surface viscosity, respectively the Reynolds number, and the rate of volume reduction or area extension on the formation of wrinkles and their coarsening.

The remainder of this paper is structured as follows: In Section 2 we introduce the mathematical model and briefly describe its numerical solution. In Section 3 we describe the computational setup and vary parameters to explore the dynamics of wrinkling comparing the two different approaches of reducing the volume and increasing the surface area. This is considered within a geometric setting which allows for a controlled wrinkling instability. In Section 4 we discuss the results, demonstrate a universal scaling law for the wavenumber, generalize the setting to a less controlled situation and draw conclusions. Detailed computations and validations of the numerical approach are provided in Appendix A.

## 2 Methods

#### 2.1 Notation

We consider a time-dependent smooth domain  $\Omega = \Omega(t) \subset \mathbb{R}^3$  and its boundary  $\mathcal{S} = \mathcal{S}(t)$ , which is given by a parametrization X. Related to  $\mathcal{S}$  we denote the surface normal  $\nu$ , the shape operator  $B = -\nabla_P \nu$ , the mean curvature  $\mathcal{H} = \operatorname{tr} B$  and the surface projection  $P = I - \nu \otimes \nu$ , with tr the trace operator and I the identity. Let u be a continuously differentiable  $\mathbb{R}^3$ -vector field and  $\sigma$  a continuously differentiable  $\mathbb{R}^{3\times3}$ -tensor field defined on  $\mathcal{S}$ . As in [17, 27, 3] we define the surface tangential gradient  $\nabla_P u = P(\nabla u^e)_{|\mathcal{S}} P$  and the componentwise surface gradient  $\nabla_C \sigma = (\nabla \sigma^e)_{|\mathcal{S}} P$  where  $u^e$  and  $\sigma^e$  are arbitrary smooth extensions of u and  $\sigma$  in the normal direction and  $\nabla$  is the gradient of the embedding space  $\mathbb{R}^3$ . For the relation to the corresponding covariant derivative  $\nabla_{\mathcal{S}}$ , we refer to [3]. We define the corresponding divergence operators for a vector field u and a tensor field  $\sigma P$  by  $\operatorname{div}_P u = \operatorname{tr}(\nabla_P u)$  and  $\operatorname{div}_C(\sigma P) = \operatorname{tr}(\nabla_C \sigma)$ . With this definition  $\operatorname{div}_C \sigma$  leads to a non-tangential vector field even if  $\sigma$  is a tangential tensor field. By  $\Delta_C = \operatorname{div}_C \nabla_C$  we denote the componentwise Laplacian, with the Laplace-Beltrami operator  $\Delta_{\mathcal{S}} = \operatorname{div}_{\mathcal{S}} \nabla_{\mathcal{S}}$  acting on each component.

#### 2.2 Model

In [21] a model for fluid deformable surfaces with conserved enclosed volume is considered. Here, this model is modified by allowing for changes in volume and area, now reading

$$\partial_{t}\boldsymbol{u} + \nabla_{\boldsymbol{v}}\boldsymbol{u} = -\nabla_{S}p - p\mathcal{H}\boldsymbol{\nu} + \frac{2}{\operatorname{Re}}\operatorname{div}_{C}\boldsymbol{\sigma} - \gamma\boldsymbol{u} -\lambda\boldsymbol{\nu} + \mathbf{b} \operatorname{div}_{\boldsymbol{P}}\boldsymbol{u} = \delta_{A} \int_{S}\boldsymbol{u} \cdot \boldsymbol{\nu} = -\delta_{V}$$
(1)

where  $\boldsymbol{u}$  is the surface velocity, p is the surface pressure,  $\boldsymbol{\sigma} = \frac{1}{2}(\nabla_{\boldsymbol{P}}\boldsymbol{u} + \nabla_{\boldsymbol{P}}\boldsymbol{u}^T)$  is the rate of deformation tensor,  $\mathbf{b} = \frac{1}{Be}(-\Delta_{\mathcal{S}}\mathcal{H} - \mathcal{H}(\|\boldsymbol{B}\|^2 - \frac{1}{2}\operatorname{tr}(\boldsymbol{B})^2)\boldsymbol{\nu}$  is the bending force,  $\lambda$  is the Lagrange multiplier to ensure the volume constraint, and  $\boldsymbol{v} = \boldsymbol{u} - \partial_t \boldsymbol{X}$  is the relative material velocity. Re denotes the Reynolds number, Be is the bending capillary number and  $\gamma$  is a friction coefficient. In [21] the enclosed volume and the surface area are considered to be constant, thus  $\delta_V = \delta_A = 0$ . Here we consider these volume and surface area terms time-dependent and define

$$\delta_V(t) = P_V \cdot (1 + \tanh(\alpha(t - t_0))), \tag{2}$$

$$\delta_A(t) = P_A \cdot (1 + \tanh(\alpha(t - t_0))), \tag{3}$$

where  $t_0 > 0$  is a relaxation time,  $P_V$  is the volume reduction rate,  $P_A$  is the area growth rate and  $\alpha \gg 1$  is a parameter ensuring a smooth transition. Within the time interval  $0 < t < t_0$ this leads to  $\delta_V \approx 0$  and  $\delta_A \approx 0$  and for  $t > t_0$  we obtain  $\delta_V \approx P_V$  and  $\delta_A \approx P_A$ . This results in a change in volume  $\frac{d}{dt}|\Omega| = P_V$  and surface area  $\frac{d}{dt}|S| = P_A|S|$ , respectively. While a reduction in volume directly corresponds to the experiments in [29], growth in surface area introduces a new mechanism. In the context of fluid deformable surfaces it has been introduced in [44]. In this context,  $\delta_A$  considers a mass production term. It allows to model growth or swelling of the surface.

We will relate  $\delta_A$  and  $\delta_V$  to ensure the same reduced volume. The reduced volume is defined as the scaled quotient of volume and surface area by

$$V_r = 6\sqrt{\pi} \frac{|\Omega|}{|\mathcal{S}|^{\frac{3}{2}}},\tag{4}$$

see [38]. For  $P_A = \frac{2}{3} P_V / |\Omega|$  we thus obtain the same reduced volume  $V_r$ , see Appendix A for the detailed computation.

We thus obtain a model for a fluid deformable surface with dynamic change of the reduced volume, either by reducing the enclosed volume or by increasing the surface area.

#### 2.3 Numerics

For the numerical discretization, we follow the concept of [21] and consider an Eulerian-Lagrangian approach. Lagrangian in normal directions with

$$\partial_t \boldsymbol{X} \cdot \boldsymbol{\nu} = \boldsymbol{u} \cdot \boldsymbol{\nu} \tag{5}$$

and Eulerian in tangential direction. To deal with potential mesh distortions we combine equations 1 and 5 with the mesh redistribution approach introduced in [4], considering

$$\mathcal{H}\boldsymbol{\nu} = \Delta_C \boldsymbol{X} \tag{6}$$

which in addition provides a representation of the mean curvature  $\mathcal{H}$ .

We approximate the surface S by a third-order polynomial surface  $S_h$ . The equations 1-6 and all geometrical quantities like the normal vector  $\boldsymbol{\nu}_h$  and the shape operator  $\boldsymbol{B}_h$  are formulated with respect to  $S_h$ . To solve the equations numerically, we discretize the system in time by a semi-implicit Euler method and in space by a surface finite element (SFEM) approach [10, 26]. For the pair of velocity and pressure, we use the Taylor-Hood element (third-order velocity  $\boldsymbol{u}_h$  and second-order pressure  $p_h$ ) and also consider a third-order approximation for the mean curvature  $\mathcal{H}_h$ . For a parallel efficient treatment of  $\lambda_h$ , we refer to [21]. The discrete equations

Figure 1: Wrinkling obtained by volume reduction with  $P_V = 0.02$  and Re = 0.025. (a) Snapshots for t = 0.0, 0.4, 0.6, 1.2 colour coded by mean curvature  $\mathcal{H}$ . The wrinkles are analysed along the equator denoted by the white line. (b) Minima and maxima of wrinkle profile along the rotational angle of the equator over time. (c) Mean curvature  $\mathcal{H}$  of wrinkle profile along the rotational angle of the equator over time.

are implemented in the finite element toolbox AMDiS [47, 48] which is based on DUNE [36, 1]. For the surface approximation, we used the Dune-CurvedGrid library [30]. For a straightforward mesh parallelization and multiple processor computation, we use the PETSc library and solve the linear system by a direct solver. Pre- and postprocessing are done in Paraview and Python.

For validation of the numerical model for  $\delta_V = \delta_A = 0$  we refer to [21]. Additional validation for  $\delta_V \neq 0$  and  $\delta_A \neq 0$  are considered in Appendix A.

### 3 Results

We consider a prolate geometry with volume  $|\Omega| = 4.19$  and surface area  $|\mathcal{S}| = 12.73$ , slightly perturbed (see Appendix A), without flow  $\boldsymbol{u} = \boldsymbol{0}$ , as initial condition. This setting leads to a reduced volume  $V_r = 0.98$ . The minimal energy configuration of the Helfrich energy corresponds to a dumbbell shape and remains within this regime during the time evolution with reducing volume or increasing surface area [38]. Figure 1 (a) shows a typical evolution. It is obtained by volume reduction with  $P_V = 0.02$  and Reynolds number Re = 0.025. Wrinkles form around

Figure 2: Number of wrinkles  $N_w$  over time for continuous volume reduction. (a) Considered for different Reynolds number Re (for  $P_V = 0.02$ ) and (b) for different volume reduction rates  $P_V$  (for Re = 0.016).

the equator of the prolate and are oriented in direction of the smaller principal curvature of the surface. They are regularly arranged during formation and relax over time. Figure 1 (b), (c) visualize the coarsening process by considering the wrinkle profile along the equator, indicated by the white line in Figure 1 (a).

We will explore these dynamics by varying the Reynolds number Re and the volume reduction rate  $P_V$  or the area growth rate  $P_A$ . We consider low Reynolds numbers Re  $\leq 1$  in a range which can be related to the experiments in [29, 39]. Instead of an instantaneous compression, as, e.g., considered in [5, 19] we consider finite rates of volume reduction and area increase. We are especially interested in the formation of wrinkles and their coarsening and will therefore analyze the number of wrinkles and their wavelength over time. All other parameters remain constant. We consider Be = 0.01,  $\gamma = 0.0$ ,  $\alpha = 50$  and  $t_0 = 0.1$ .

#### 3.1 Wrinkling by volume reduction

We consider  $\delta_A = 0$ . In Figure 2 (a) we show the number of wrinkles  $N_w$  over time for  $P_V = 0.02$ and different Reynolds numbers Re. Depending on Re a threshold of compression has to be overcome before wrinkles form. If this threshold is reached the maximal number of wrinkles  $N_{max} = \max N_w(t)$  forms almost instantaneously. The time instances at which the maximal number of wrinkles  $N_{max}$  forms are highlighted in Figure 2 (a). The time of wrinkle formation  $\tau_0 = \operatorname{argmin}\{t|N_w(t) > 0\}$  increases with increasing Re. This increase is associated with a decrease of  $N_{max}$ . For Re = 1, no wrinkling occurs. In this situation tangential flow is sufficient to globally deform S to suppress wrinkling. After wrinkles are formed they coarsen. The coarsening process is almost independent on Re, the curves for different Re in Figure 2 (a) essentially lye on top of each other.

We now vary  $P_V$  and keep Re = 0.016. The corresponding results for the number of wrinkles  $N_w$  are shown in Figure 2 (b). We again mark the time instances of wrinkle formation  $\tau_0$ . For low volume reduction rates, no wrinkling occurs. Again in this situation, tangential flow is sufficient to globally deform S to suppress wrinkling. If wrinkling occurs, qualitatively the dependency on  $P_V$  is similar to the dependency on 1/Re. The wrinkle formation for a faster

Figure 3: Number of wrinkles  $N_w$  over time for continuous area increase. (a) Considered for different Reynolds number Re (for  $P_A$  corresponding to  $P_V = 0.02$ ) and (b) for different increasing area rates  $P_A$  (for Re = 0.016). Instead of  $P_A$ , we indicate the corresponding values for  $P_V$  for better comparison.

Figure 4: Phase diagram of the maximal number of wrinkles  $N_{max}$  over the Reynolds number Re and the volume reduction rate  $P_V$  (a) and the area increase rate  $P_A$  (b). Instead of  $P_A$  we indicate  $\frac{3}{2}|\Omega|P_A$ , which are the corresponding values for  $P_V$ , for better comparison. The black dots highlight values of Re and  $P_V$  shown in Figures 2 or 3, respectively.

volume reduction corresponds to that of a lower Reynolds number.

Due to the continuous reduction of volume, the surface does not relax to the corresponding equilibrium shape associated with the reduced volume (dumbbell shape) [38] if the Reynolds number Re is too small or the volume reduction rate too large. The induced wrinkling along the short axis of the prolate and their subsequent coarsening lead to an energy path towards a local minimum, similar to the one shown in Figure 1 (a) at t = 1.2. Decreasing the volume further can easily be realized by deepening the remaining valleys. This further increases the energy barriers, which need to be overcome to escape this local minimum. While the kinetic energy globally in time decreases during the coarsening process, with only local in time increasing periods, which are associated with coarsening events, the Helfrich energy strongly increases for all Re with only small perturbations associated with the coarsening events, see Figure 7 (a) and (c) in Appendix A, respectively. However, for Re = 1 or above and small volume reduction rates the tangential flow allows for global shape changes continuously sampling shapes close to the

Figure 5: Coarsening of wrinkles analysed by the wavenumber  $\tilde{\nu}$  as a function of time. (a) Considered for different Reynolds numbers Re and  $P_V = 0.02$  (solid lines) and corresponding  $P_A$  (dashed line). (b) Considered for different volume reduction rates  $P_V$  (solid lines) and corresponding area increase rates  $P_A$  (dashed lines) and Re = 0.016. The data correspond to Figures 2 and 3, but only those values which lead to wrinkling are considered. Both indicate a scaling law of  $t^{-1/2}$  indicated by the black lines.

equilibrium dumbbell shapes [38], see Figure 7 (a) in Appendix A. This corresponds to previous results on enhanced convergence towards equilibrium shapes due to surface viscosity [20]. The equilibrium shapes are computed by minimizing the Helfrich energy under the constraints of volume and global area conservation following [20, 28, 3]. Additional qualitative differences can also be seen in the tangential flow field, which is plotted for different Reynolds numbers Re in Figure 8 in Appendix A. While wrinkles induce perturbations of the flow field around the equator, for Re = 1 tangential flow is only used for mass transport to globally deform the surface towards a more elongated dumbbell shape.

#### 3.2 Wrinkling by area increase

We next ask if the behaviour changes if instead of a volume reduction the surface area is increased. In analogy to Figure 2 (a) and (b) we show in Figure 3 (a) and (b) the number of wrinkles over time for different Reynolds number Re (for  $\frac{3}{2}|\Omega|P_A = 0.02$ ) and for different area increasing rates  $P_A$  (Re = 0.016). The results are very similar to the corresponding plots in Figure 2.

#### 3.3 Phase diagram

In Figure 4 the maximal number of wrinkles  $N_{max}$  is shown with respect to the Reynolds number Re and the volume reduction rate  $P_V$  or the corresponding rescaled area increasing rate  $P_A$ . The qualitative behaviour of the dynamics is the same as in Figures 2 (a) and (b) and 3 (a) and (b), we therefore only focus on  $N_{max}$ . The specific values from Figures 2 (a) and (b) and 3 (a) and (b) are marked for comparison. While slight quantitative differences can be observed, the qualitative behaviour remains and does not depend on the realization of the reduced volume by volume reduction or area increase.

### 4 Discussion

Fluid deformable surfaces with an enclosed volume and a continuous reduction of volume or a continuous increase in surface area can undergo a wrinkling instability. Only for large Reynolds numbers Re = 1 or above and for small changes in volume  $\delta_V$  or area  $\delta_A$  this instability can be suppressed. In these cases, surface viscosity allows to globally deform the surface to adapt to the changing reduced volume  $V_r$ . The emerging dynamic shapes are close to the equilibrium shapes of the Helfrich energy [38]. Surface hydrodynamics has been shown to support convergence towards these shapes if the volume and area remain constant,  $\delta_V = \delta_A = 0$ , see [21]. This result is extended towards small changes in volume or area. Also under these circumstances surface hydrodynamics allows for global shape adaptation and continuously sampling the equilibrium shapes or at least shapes which are close to them. The evolution of the energies, the kinetic energy  $E_{kin}$  and the Helfrich energy  $E_H$  is shown in Figure 7 (a) and (c) in Appendix A, respectively. The reference values for  $E_H$  correspond to the equilibrium shapes for the reduced volume  $V_r$ . This shows a remarkable difference to the theory in [42]. Under the presence of viscosity the configuration with the least possible energy does not contain wrinkles. Within the considered geometrical setting the least possible energy corresponds to the equilibrium (dumbbell) shape of the Helfrich energy [38]. Wrinkling under the influence of viscosity only leads to local energy minima.

The evolution after winkles have formed is characterized by coarsening. This has been qualitatively addressed in Figures 1, 2 and 3. The coarsening process seems to be independent on Re and also, with slightly larger error bars, variations in  $\delta_V$  and  $\delta_A$  lead to similar coarsening. We now quantify this. Instead of the number of wrinkles  $N_w$  we therefor consider the surface wavenumber

$$\tilde{\nu} = \frac{N_w}{l} \tag{7}$$

where l is the geodesic length of the curve along which we measure the wrinkles. This curve is highlighted by the white line in Figure 1 (a). The corresponding results to Figures 2 and 3 are shown in Figure 5 (a) and (b), respectively. They indicate a coarsening rate  $t^{-1/2}$ . This scaling behaviour is independent on Re and  $P_V$  or  $P_A$ . This further highlights that wrinkling only depends on the change in the relation of enclosed volume and surface area. The same effect can be achieved by reducing the volume or by growing the surface. This might explain the similar wrinkling pattern found in nature and man-made systems. Within morphogenetic tissue deformations actually both, volume changes and surface growth might be essential.

A theoretical foundation of the obtained scaling law and also an experimental validation of the influence of viscosity in the proposed model currently have to remain open issues. The considered geometric setting was chosen to initiate wrinkles in a controlled manner. However, the numerical approach also works for other settings. On a sphere the emerging wrinkling patterns are less controlled due to the missing prefered symmetry axis. Considering a spherical domain with significantly larger growth rates leads to symmetry breaking and more irregular surface patterns, see Figure 6. The results correspond to Reynolds number Re = 0.016 and  $P_A = 1$ . All other parameters are as before. Shown are time instances of the evolution, the color coding corresponds to the mean curvature  $\mathcal{H}$ . A corresponding movie of the evolution is provided

Figure 6: Wrinkling instability and subsequent coarsening on the unit sphere for Re = 0.016 and  $P_A = 1.0$ . Time instances are shown for t = 0.0, 0.1, 0.2, 0.4, 0.6, from left to right. The color coding corresponds to the mean curvature  $\mathcal{H}$ . A corresponding video of the evolution is provided in the Electronic Supplement.

in the Electronic Supplement. The emerging wrinkling morphology is reminiscent to wrinkle patterns in swelling films on spherical substrates [7], which were computational reproduced in [40] using a phenomenological pattern formation model. Even if dynamics is not considered in these studies, the observed hexagonal wrinkles can also be found in the dynamic patterns under the influence of surface viscosity, see Figure 6. This provides additional similarities between wrinkling patterns in solid and liquid thin elastic sheets and asks for experimental validation in the context of biomembranes or epithelial tissue.

## A Appendix

### A.1 Computations on the reduced volume

According to the definition of the reduced volume in eq. (4) we obtain

$$\frac{\mathrm{d}}{\mathrm{d}t}V_r = \frac{6\sqrt{\pi}}{|\mathcal{S}|^{\frac{3}{2}}}\frac{\mathrm{d}}{\mathrm{d}t}|\Omega| - \frac{9|\Omega|\sqrt{\pi}}{|\mathcal{S}|^{\frac{5}{2}}}\frac{\mathrm{d}}{\mathrm{d}t}|\mathcal{S}| = \frac{6\sqrt{\pi}}{|\mathcal{S}|^{\frac{3}{2}}}\delta_V - \frac{9|\Omega|\sqrt{\pi}}{|\mathcal{S}|^{\frac{3}{2}}}\delta_A.$$

To fulfill  $\frac{\mathrm{d}}{\mathrm{d}t}V_r = 0$  thus requires the chose  $P_A = \frac{2}{3}P_V/|\Omega|$ .

#### A.2 Construction of the surface

Let X be a parametrization of the unit sphere. We define the parametrization of the prolate by

$$\boldsymbol{X}_{r,a} = r((1+a)^{-\frac{1}{2}}X_0, (1+a)^{-\frac{1}{2}}X_1, (1+a)X_2).$$

The elongation is determined by a, which is chosen as a = 0.2. The radius is chosen by  $r = 1 + \epsilon r_0(\mathbf{x})$  where  $\epsilon > 0$  and  $r_0$  is a Gaussian random field

$$r_0(oldsymbol{x}) = \sum_{i=0}^N lpha_i e^{-eta_i \|oldsymbol{x} - oldsymbol{x}_i\|^2}$$

Figure 7: Evolution of the Helfrich energy  $E_H$  and the kinetic energy  $E_{kin}$  for different Reynolds numbers Re. (a) and (c) for decreasing volume with  $P_V = 0.002$  and (b) and (d) for increasing surface area with  $P_A = \frac{3}{2} |\Omega| P_V$ . The corresponding plots are almost identical. As a reference, we plotted the minimal Helfrich energy for the corresponding reduced volume (dashed green line).

with uniformly distributed variables  $\{\alpha_i\}_i^N \subset [-10^{-6}, 10^{-6}]$ ,  $\{\beta_i\}_i^N \subset [100, 1000]$  and  $\{x_i\}_i^N \subset S$ , see [35]. This initial surface guarantees a surface distortion independent of the discretization. For the spherical surface we set a = 0.

#### A.3 Energies

Throughout the paper, we consider the non-dimensional energies

$$E_H = \frac{1}{\text{Be}} \int_{\mathcal{S}} \frac{1}{2} \mathcal{H}^2, \quad E_{kin} = \int_{\mathcal{S}} \frac{1}{2} \|\boldsymbol{u}\|^2,$$

denoting the Helfrich energy and the kinetic energy, respectively.

The evolution of these energies corresponding to the simulations shown in Figures 2 and 3 are shown in Figure 7 (a) and (b), respectively. They indicate a stronger increase in  $E_H$  for lower Reynolds numbers Re and an increase of  $E_{kin}$  until the wrinkling instability is followed by a decay which is interrupted by coarsening events.

Figure 8: Visualization of the tangential fluid flow by the surface LIC filter. The colour demonstrates the magnitude of the tangential velocity. The plots correspond to the time instants of the maximal number of wrinkles highlighted in Figure 2 (a) for  $P_V = 0.02$  and different Reynolds number (a) Re = 0.016, (b) Re = 0.025, (c) Re = 0.05, (d) Re = 0.1, (e) Re = 1.0.

#### A.4 Numerical validation

Numerical analysis results for these types of problems exist only for Stokes flow on stationary surfaces [11, 12, 32]. The proposed optimal orders of convergence have been confirmed numerically in [6] and have also been obtained for fluid deformable surfaces [20, 3]. In [20] it is shown that the additional volume constraint does not alter the convergence properties. We reproduce the results for the volume reduction case. As before we reduce the time step width with the grid size by  $\tau \sim h^3$  and consider the inextensibility error  $e = \|\operatorname{div}_{\mathbf{P}} \boldsymbol{u}_h\|_{L^{\infty}(L^2)}$ . As in [20] we observe roughly third-order convergence for e with respect to h and first-order with respect to  $\tau$ . According to [11, 12, 32] these are the optimal rates, to be expected for the considered setting. In addition, we consider the number of wrinkles  $N_w(t)$  and at least qualitatively obtain the wrinkle instability and the coarsening process to be independent of the discretization, see Figure 9.

Figure 9: Convergence study for continuous volume reduction. The considered parameters are Re = 0.05 and  $P_V = 0.02$ . *h* denotes the mesh size. (a) Inextensibility error *e* indicates third-order convergence in space and first-order convergence in time. (b) Number of wrinkles over time. The time wrinkling occurs and the coarsening process are almost indistinguishable for fine mesh sizes.
