(Dated: January 26, 2024)

Recently, Hall effect measurements are done on Lanthanum doped Strontium Iridate $Sr_{2-x}La_xIrO_4$ which is 5d analogue of cuprates [1]. Hall effect measurements show that the effective carrier density n_H exhibits a crossover from $n_H \sim x$ to $n_H \sim 1 + x$ near $x \simeq 0.16$. This is very similar to that found in cuprates around $p \simeq 0.19$. It is proposed that a pseudogap (PG) state in $Sr_{2-x}La_xIrO_4$ exists and is ending at $x \simeq 0.16$ [1]. However, PG boundary (in doping-temperature phase diagram) remains unknown. In this work, we apply a very successful the Gor'kov-Teitel'baum Thermal Activation (GTTA) model to $Sr_{2-x}La_xIrO_4$ and obtain its PG phase boundary and draw an updated phase diagram. Our results agree with previously known signatures of PG phase in this system [2, 3]. Using results from GTTA model we also obtain the evolution of "Fermi arcs" in this system as a function temperature for doping concentration $x \simeq 0.08$ which are in qualitative agreement with the reported results.

I. INTRODUCTION

The transition-metal oxides have gained considerable attention in the last few decades because of their diverse physical properties including high- T_c superconductivity [4–12]. The 3d transition metal copper oxides are the most extensively studied materials in which high- T_c superconductivity is realized by hole/electron doping of the Mott insulator Another striking characteristic of these hole-doped cuprates is the presence of a "Pseudogap (PG)" phase in the underdoped regime at normal temperature (much higher than T_c) [13–17]. The PG phase boundary (more precisely a crossover) starts at a very high temperature (~ 1000 K) near the Mott insulating phase and decreases linearly with increasing doping. It closes at a critical doping of $p* \simeq 0.19$, just above optimal doping regime [18–23].

Strontium Iridate Sr_2IrO_4 is a spin-orbit coupled 5d Mott insulator which shows similarities with cuprates. From simple valence counting arguments, strontium has valency: $[Kr]5s^2$, iridium has valency: $[Xe]4f^{14}5d^76s^2$ and oxygen has valency: $[He]2s^22p^4$. In the ionic case scenario, the nominal valency state of Ir^{4+} can be estimated from $+2 \times 2 + x - 2 \times 4 = 0$ i.e. x = +4, as nominal valence of Sr and O will be Sr^{2+} and O^{2-} respectively. I^{4+} has the configuration $[Xe]5d^5$. Thus, out of 5 electrons one electron remains unpaired in the 5d shell, which exhibits magnetism and Mott insulation [24]. A Canted AntiFerroMagnetic phase (C-AFM) is observed in the material below 230 K [25]. Under electron doping emergence of pseudogap and "Fermi arcs" are observed in the compound, resembling the hole-doped cuprates [24].

Several experimental studies have been reported in literature for electron doped Sr_2IrO_4 to understand the character of the electronic phases of this material. In 2014, Kim et al used a surface doping technique for deposition of potassium atoms on Sr_2IrO_4 and studied the evolution of the phenomenon of "Fermi arcs" with varying surface coverage and temperature [26]. A decrease in the anti-nodal gap and an increase in "Fermi arc" lengths was seen with the increase in the surface coverage. A similar Angle-resolved photo-emission spectroscopy (ARPES) analysis for 7% electron doped Sr_2IrO_4 has been reported, wherein the variation of PG magnitude with temperature is studied [27]. Electron doping in Sr_2IrO_4 can also be done by substituting Sr^{2+} by La^{3+} in the parent material. An evidence of a pseudogap was observed for $Sr_{2-x}La_xIrO_4$ with x = 0.10 from the ARPES measurements [3]. Li et al performed ARPES and in-plane resistivity analysis for $Sr_{2-0.30}La_{0.30}IrO_4$ thin films where they observed that although the system was insulating, the resistivity was suppressed for the doped material [28]. The electronic response of IrO_2 plane for $Sr_{2-0.134}La_{0.134}IrO_4$ using infrared spectroscopy revealed a PG of magnitude $\sim 17 \text{meV}$ [2].

Recently, Hsu et al carried out Hall-effect and specific heat analysis for $Sr_{2-x}La_xIrO_4$ at several dopings [1]. They report variation in the Hall-coefficients of $Sr_{2-x}La_xIrO_4$ for 0 < x < 0.20 as a function of temperature (T). The variation of C/T (C=specific heat) as a function of T^2 is also reported. A dramatic change in the carrier density at around $x \simeq 0.16$ and a divergence in the extrapolated (T=0K) heat capacity indicates the presence of critical doping for PG opening below $x \le 0.16$. Measured Hall number density indicates a "sudden" increase in carrier density from $n_H \sim x$ to $n_H \sim 1 + x$ around that doping. Nevertheless, PG boundary is still unknown, which is addressed in this work.

The Gorkov-Teitelbaum Thermal Activation (GTTA) model was introduced by Lev P. Gor'kov and Gregory B. Teitel'baum in 2006 [29]. It is a phenomenological model for number of charge carriers which was derived from the Hall effect data of $La_{2-x}Sr_xCuO_4$ [29]. The experimental Hall effect data of $La_{2-x}Sr_xCuO_4$ can be rationalized by the GTTA model as follows:

$$R_H = \frac{1}{n_{Hall}e} \tag{1}$$

$$n_{Hall}(x,T) = n_0(x) + n_1(x)e^{[-\Delta(x)/T]}$$
 (2)

The first term $n_0(x)$, is the temperature independent term which incorporates the carrier density due to external hole doping. The second term is temperature dependent term which can be interpreted as thermal activation contribution of carriers above the gap. $n_0(x)$ varies linearly with x for low doping (up to x = 0.07). For x > 0.07, $n_0(x)$ evolves non-linearly with x. $n_1(x) \simeq 2.8$ (roughly constant) for doping concentrations (x < 0.19) and drops abruptly for doping concentrations (x > 0.19). $\Delta(x)$ is referred as the activation energy and corresponds to the energy difference between the "Fermi arc" and the band bottom for $La_{2-x}Sr_xCuO_4$ [29]. The extracted $\Delta(x)$ decreases linearly with increase in x till x = 0.20. The $\Delta(x)$ values are in agreement with ARPES results.

We applied this very successful model (GTTA) to $Sr_{2-x}La_xIrO_4$ and we have drawn an updated phase diagram (refer to Section 4) for the system. Reasons behind applying GTTA to $Sr_{2-x}La_xIrO_4$ are given in section 2. We observe that at x=0.036, $\Delta \simeq 1200$ K, then it linearly decreases with increasing doping and ends at $x \simeq 0.16$. This is quite similar to that found in cuprates. Using the carrier density obtained from GTTA model, the evolution of the "Fermi arcs" for doping concentration $x \simeq 0.08$ at temperature 70K and 100K is also obtained (refer to section 3).

This paper is organized as follows: In section 2 we present our analysis of the Hall effect data using the GTTA model. In section 3 we present the development "Fermi arcs" with increasing temperature and for a given doping concentration ($x \simeq 0.08$) for which the data is available. We conclude all our findings in the section 4.

II. ANALYZING THE HALL EFFECT DATA USING THE GTTA MODEL

As discussed in the previous section, GTTA model is proven to be very successful for $La_{2-x}Sr_xCuO_4$ system [29]. Gor'kov and Teitel'baum calculated the doping dependent parameters viz. $n_0(x), n_1$ and $\Delta(x)$ in Eq.2 using the experimental Hall effect data available in the literature [30, 31]. The calculated $\Delta(x)$ agreed well with the ARPES experiments [32, 33].

The crystal structure as well as the electronic structure (one unpaired electron in d orbitals) of Sr_2IrO_4 compound is similar to that of La_2CuO_4 . Signatures of PG in $Sr_{2-x}La_xIrO_4$ for some doping concentrations have been observed by ARPES measurements [3, 27] similar to $La_{2-x}Sr_xCuO_4$. The temperature dependence of the Hall coefficient for $Sr_{2-x}La_xIrO_4$ is also similar to that of $La_{2-x}Sr_xCuO_4$. Keeping in mind these strong similarities it is reasonable to apply the GTTA model to $Sr_{2-x}La_xIrO_4$ system. We also obtain a-posteriori justification of the application of GTTA model as extracted PG agrees reasonably well with some pre-existing experimental data [2, 3].

FIG. 1: The activation energy $\Delta(x)$ obtained by fitting Eq. 2 [29] to the experimental Hall coefficient data for $Sr_{2-x}La_xIrO_4$ for different doping concentrations extracted from Fig.1 of [1] and by private communications with the authors of [1]. Red solid circles represents experimental PG values obtained in [2, 3].

The Hall-effect data for the system was measured very recently by Hsu et al [1]. The evolution of Hall-coefficient R_H with temperature for doping concentrations 0.122, 0.124, 0.138, 0.174, 0.186 and 0.196 is reported. From Fig.1 of [1], a qualitative change in the $R_H(T)$ is observed for x > 0.14 indicating some sort of a crossover. We have extracted the data for of the R_H from Fig.1 of [1] to investigate the nature of PG phase crossover for different La-doping concentrations. Since a crossover is observed near doping $x \sim 0.16$ only the data for x < 0.16is considered for the present analysis. $n_{Hall}(x,T)$ is calculated from the extracted $R_H(T)$ data [34]. Using Eq. 2 the values of $n_0(x), n_1$ and $\Delta(x)$ for the mentioned doping concentrations are obtained. The doping dependence $\Delta(x)$ is displayed in Fig. 1, which is the central result of this work. The $R_H(T)$ data for doping concentrations 0.036, 0.08 and 0.10 are obtained via personal communication with the authors of [1]. The GTTA fitted model along with the reported experimental values of $R_H(T)$ for x=0.036 is shown in Fig. 2(a) for a representation purpose. It is clear that the GTTA model fits exceptionally well for T > 100K as for low temperatures, weak localization effects comes into picture. For this doping concentration, the value of $\Delta(x)$ reaches ~ 1200K, very similar to that observed in $La_{2-x}Sr_xCuO_4$. Fig. 2(b) shows the plot of Hall coefficients vs temperature obtained from the GTTA model for an intermediate doping (x = 0.124). For x=0.124, $\Delta(x)$ is 300 K. The temperature dependence of the Hall-coefficients obtained from GTTA model for all the other doping concentrations are included in the supplementary information. An excellent fitting of GTTA model to the experimental Hall-effect

data is seen.

FIG. 2: The temperature dependence of Hall coefficients of $Sr_{2-x}La_xIrO_4$ for doping concentrations (a) x = 0.036 and (b) x = 0.124 from the GTTA model (red line) along with experimental $R_H(T)$ from [1].

Fig. 3 shows the doping dependence of $n_0(x)$. $n_0(x)$ increases with increase in doping concentration. The $n_0(x)$ value for x = 0.036 falls near the $n_0(x) \simeq x$ line. For larger x (x > 0.036), $n_0(x)$ deviates considerably from linear behaviour $n_0(x) = x$ and shoots up for larger x ($x \simeq 0.14$) which is the signature of $n_h \sim x$ to $n_h \sim 1 + x$ transition. This transition is discussed in detail in [1]. The doping dependence of $(n_0(x))$ for $Sr_{2-x}La_xIrO_4$ is similar to that observed for $La_{2-x}Sr_xCuO_4$ [35]. n_1 is roughly constant ($n_1 \sim 3.8$) for low doping (till x = 0.10) after which it abruptly decreases.

FIG. 3: Plot of $n_0(x)$ as a function of doping calculated from GTTA model using the experimental Hall effect data [1] for $Sr_{2-x}La_xIrO_4$.

Coming back to Fig. 1, $\Delta(x)$ starts at a very high temperature (~ 1200K) near the Mott insulating phase for low doping ($x \simeq 0.036$) after which it decreases roughly linearly with increase in electron doping concentration. $\Delta(x)$ decreases to ~ 300K at $x \simeq 0.14$ which is near the predicted quantum critical doping concentration. Data between x = 0.14 and x = 0.16 is not available. Regarding the physical meaning of $\Delta(x)$, Gor'kov and Teitel'baum suggested that these thermal activation contributions to the charge carriers come from the activation of electrons from the states near the anti-nodal region $(0,\pm\pi)$ to the nodal (π,π) region which are separated by an effective energy gap $\Delta(x)$ [29]. They validated this interpretation of $\Delta(x)$ by comparing their values with ARPES results showing a strong agreement [32]. Thus, we compare values of $\Delta(x)$ with the PG values of $Sr_{2-x}La_x IrO_4$ reported in literature (displayed in Fig.1) obtained by different experimental techniques. In Fig.1 we display two points representing the magnitude of PG for $x \simeq 0.10$ and $x \simeq 0.134$ (red solid circles). The point with $x \simeq 0.10$ corresponds to the PG magnitude along the anti-nodal point obtained through ARPES measurements. The PG magnitude, $(2\Delta_{PG} \simeq 50meV)$ was extracted from Fig. 3e of [3]. The other point corresponds to the PG magnitude $2\Delta_{PG} \sim 17 meV$ for doping concentration $x \simeq 0.134$ measured by Seo et al. using infrared spectroscopy [2]. Thus, the extracted values of $\Delta(x)$ from the Hall effect data using GTTA model are in agreement with the PG signatures already reported in literature for $Sr_{2-x}La_x IrO_4$. It would be better if more such experiments are done for the low doping regime so as to more precisely determine the PG boundary.

The pseudogap data points at low doping such as at x = 0.04 actually corresponds to a special phase of underdoped $Sr_{2-x}La_xIrO_4$. In reference[36] it is found that underdoped phase of this system consists of an inhomogeneous and phase separated state, more precisely, puddles of pseudogap phase nucleates around dopant atoms forming an inhomogeneous mixture. In other words Mott state and PG state coexist on a mesoscopic length scale. Thus the PG obtained from GTTA analysis in the underdoped regime should be thought of as an average gap.

III. FERMI ARCS

The phenomenon of "Fermi arcs" is observed in cuprates [37]. It is also observed in this iridate system [38]. In cuprates at very low doping PG is of d-wave symmetry which depects a node near (π, π) direction. At higher dopings and higher temperatures these nodes extend to form an arc lie feature in ARPES spectra around the nodal direction [37]. These features are called "Fermi arcs".

Using the free electron model for 2-dimensional materials (similar to the approach used by Gor'kov and Teitel'baum [39]), the relation between number of charge carriers per unit area (N) and the arclength of Fermi arc measured in terms of arc angle $\Delta \phi$ is,

$$N = \frac{1}{2\pi^2} \int_0^{\Delta\phi} d\theta \int_0^{k_F} k \, dk. \tag{3}$$

Thus,

$$N = \frac{k_F^2}{4\pi^2} \Delta \phi, \tag{4}$$

where, k_F is the magnitude of Fermi wave vector (in x-y plane). N can be calculated from carrier density (n_{Hall}) of the material. Thus Eq. 4 can be rewritten as follows:

$$\Delta \phi = \frac{4\pi^2 (n_{Hall}c)}{nk_F^2},\tag{5}$$

where, c is the lattice constant along the Ir-O-Sr direction i.e. 25.96Å [40] and n is the number of Ir-O planes in a unit cell of Sr_2IrO4 . Since only one quadrant of Brillouin zone is usually displayed reporting ARPES measurements, we divide $\Delta\phi$ calculated from Eq. 5 by 4 to represent the "Fermi arcs".

FIG. 4: Evolution of "Fermi arcs" with doping concentration x = 0.08 at temperatures (a) 80K and (b) 200K

The evolution of the "Fermi arcs" $\Delta \phi$ with respect to temperature is obtained from Eq. 5 and their schematic plots are displayed in Fig. 4. The magnitude of Fermi wave vector k_F is extracted from Fig-1 of [27]. The values of $n_{Hall}(x,T)$ obtained from the GTTA model are used in Eq. 6 to obtain $\Delta \phi$. The "Fermi arcs", for a given doping concentration expands, i.e. $\Delta \phi$ increases, as the temperature increases. Thus with increase in temperature the extension of the gap observed at the anti-nodal region is suppressed for a given doping. Kim et al have reported the "Fermi arcs" obtained by ARPES analysis corresponding to 7% electron-doped Sr_2IrO4 in Fig 1 of [27] for temperatures 10K and 70K. From Fig 1 of [27], the "Fermi arc" length $\Delta \phi$ for 7% electron-doping at 70K is $\Delta \phi \sim 36^{\circ}$ (by taking the angle between points having intensity half to that at nodal point). For doping concentration x = 0.08 (for which we have the data, and which is close to 7 percent electron doping), the calculated Fermi arc length $\Delta \phi$ at temperature 80K is $\Delta \phi \simeq 30^{\circ}$ (Fig. 4). Thus, there is a qualitative agreement between "Fermi arcs" $\Delta \phi$ calculated using Eq. 5, wherein $n_{Hall}(x,T)$ values are computed using GTTA model, and the reported results [27].

IV. CONCLUSIONS

We have applied the very successful GTTA model to $Sr_{2-x}La_x IrO_4$ system and extracted its PG boundary (crossover) using the Hall-effect data [1]. It is observed that PG opens at very high temperatures (~ 1200 K) near low doping ($x \simeq 0.036$) and then it decreases approximately linearly as doping is increased. As displayed in Fig. 1, the PG boundary when extrapolated vanishes at around $(x \simeq 0.16)$ which is the critical doping for the pseudogap opening as discovered in [1]. Our results also agree with some experimental data for PG previously reported in this system [2, 3]. We note that this doping dependence of PG boundary is very similar to that found in cuprates. We also schematically show the evolution of the "Fermi arcs" using the carrier density calculated from the GTTA model at temperatures 80K and 200K for a given doping concentration ($x \simeq 0.08$) which are in qualitative agreement with the reported results [27]. We also draw an updated phase diagram for $Sr_{2-x}La_xIrO_4$ in Fig. 5. The magnetic phase diagram of the material is redrawn using the extracted data from Fig. 12 of [25]. On top of the previously known magnetic phase, we find a region of the PG phase boundary for $Sr_{2-x}La_xIrO_4$ in Fig. 5. This PG phase boundary should be refined through future experiments and analysis of $Sr_{2-x}La_x IrO_4$ system.

FIG. 5: Updated phase diagram of $Sr_{2-x}La_xIrO_4$. The black solid square denotes $\Delta(x)$ obtained from the GTTA model in this work. All the points corresponding to C-AFM transitions is extracted from Fig. 12 of [25]. The boundaries between long-range and short-range C-AFM order as suggested in [25] is shown with long-range C-AFM order extending upto x = 0.08 (purple). The proposed region of PG phase boundary for $Sr_{2-x}La_xIrO_4$ is marked (in grey). Future experiments and analysis will refine this PG phase boundary.

- [34] Before we apply GTTA model to $Sr_{2-x}La_xIrO_4$, we reproduce their results [29] for cuprates. From the Halleffect data for $La_{2-x}Sr_xCuO_4$ [30, 31], the carrier density n_{hall} is calculated using the relation $R_H = \frac{1}{n_{Hall}e}$. The extracted values of $n_0(x)$, n_1 and $\Delta(x)$ thus obtained are in agreement with values reported by Gor'kov and Teitel'baum. $n_0(x)$, for very low doping (x < 0.07) increases as $n_0(x) \simeq x$ and then non-linearly increases for larger doping x values as shown in supplementary infor-

mation. $n_1(x)$ is almost constant ($\simeq 2.8$) and abruptly decreases for large doping (x > 0.18). Doping dependence of $\Delta(x)$ is also shown in the supplementary information. $\Delta(x)$ decreases approximately linearly from $\sim 1000K$ at around $x \simeq 0.04$ to $\sim 100K$ at $x \simeq 0.20$. Our results agree with the results obtained by Gor'kov and Teitel'baum [29]. Thus it benchmarks (or validates) our numerical method.
