January 30, 2024

Abstract

Designing lightweight yet stiff vibrating structures has been a long-standing objective in structural optimization. Here, we consider the optimization of a structural design subject to forces in the form of harmonic oscillations. We develop a unifying framework for the minimization of compliance and peak-power functions, while avoiding the assumptions of single-frequency and in-phase loads. We utilize the notion of semidefinite representable (SDr) functions and show that for compliance such a representation is immediate, while for peak power, the SDP representation is non-trivial. Subsequently, we propose convex relaxations of the minimization of an SDr function subject to the equilibrium equation as a constraint, and show promising computational results on well-known instances of Heidari et al. and others.

1 Introduction

The design of lightweight yet stiff vibrating structures has been a long-standing objective in structural optimization [KPA06]. Here, we consider the optimization of a structural design that is subject to forces in the form of harmonic oscillations, a topic of significance in a range of applications. These include rotating machinery in household appliances, construction machinery for cars and ships [LZG15a], and wind turbine support structures [LZG15b]. In this study, we focus on optimizing truss structures, leveraging their excellent stiffness-weight ratio [LYC08; Tyb+19].

Structural optimization was pioneered in Michell's seminal work [Mic04] in 1904, which demonstrated that the optimal material distribution for trusses, under a single loading condition, aligns with the principal stresses. Because the principal stresses are generally not straight, optimum designs may involve an infinite number of bars. To circumvent this, Dorn *et al.* [DGG64] discretized the design domain into the so-called ground structure, containing a fixed and finite number of optimized elements.

Relying on ground structure discretization, many theoretical and applied results have been presented in the literature. These include convex formulations for truss topology optimization under single [DGG64] or multiple [Ach+92; VB96; Lob+98; BN01] loading conditions, or possibly under worst-case loading [BN97]. In dynamics, it has been shown that the constraint for the lower bound on the fundamental free-vibration eigenfrequencies is convex [Ohs+99], also allowing for an efficient maximization of the fundamental free-vibration eigenfrequency [AK08].

*All authors are at the Czech Technical University.

In 2009, Heidari *et al.* [Hei+09] observed that, similar to the convex semidefinite programming formulation developed for the static setting [VB96], it is also possible to derive a convex semidefinite program for the peak-power minimization under harmonic oscillations. However, the reformulation requires that only a single-frequency in-phase load is present, with the driving frequency strictly below the lowest resonance frequency of the structure itself.

Surveying the more applied literature on continuum topology optimization under harmonic oscillations surprisingly reveals that the same restricting assumptions have been used in this community as well. In particular, the predominant objective is to minimize the dynamic compliance function [MKH93], which is physically meaningful only when the driving frequency of the load is below resonance [SNL19]. Otherwise, the optimization converges to a disconnected material distribution at anti-resonance. To the best of our knowledge, this issue has not yet been resolved.

The second typical assumption of single-frequency loads acting only in phase can be partially justified because it represents the worst-case situation [Hei+09]. On the other hand, such designs are hardly optimal for out-of-phase settings, such as unbalanced rotating loads. To the best of our knowledge, the only author who has explored this setting is Liu *et al.* [LZG15b], who considered minimization of the energy loss per cycle due to structural damping and minimization of the displacement amplitude. The latter case was handled by aggregating samples over the cycle, with the number of samples balancing computational efficiency with the accuracy of the approximation.

As was pointed out in [Ven16], real-world applications require multiple-frequency loads. In this direction, Liu *et al.* [LZG15a] minimized the integral of displacement amplitudes over a non-uniformly discretized frequency range, whereas Zhang *et al.* [ZK15] introduced an aggregation scheme to minimize the worst-case dynamic compliance for multiple frequencies. However, we are not aware of any publication that considers consider multiple-frequency harmonic loads acting on a structure concurrently.

1.1 Aims and contributions

Inspired by the initial results of Heidari *et al.* [Hei+09], in this study, we develop a unifying framework for the minimization of compliance and peak power functions, while avoiding the assumptions for single-frequency and in-phase loads.

Our procedure inherently relies on the notion of semidefinite representable (SDr) functions [BN01, Lecture 4.2], which are convex functions whose epigraph can be represented by the projection of a linear matrix inequality (LMI) feasibility set, the so-called LMI shadow. Minimization of such functions under linear constraints can be equivalently reformulated into linear semidefinite programming (SDP), and hence convex, problems.

We show that for compliance such representation is immediate due to the linearity. For the peak power, however, the SDP representation is not trivial; it relies on the positivity certificate of the trigonometric polynomials. Such certificates have already been extensively studied in the signal processing community for filter design [Dum17].

Using the notion of a SDr function, we propose convex relaxations of the minimization involving an SDr function and the equilibrium equation as a constraint. Minimization problems subject to an equilibrium equation are, in general, non-convex because of their complementarity nature. In compliance minimization, however, one can exploit the problem structure and eliminate state variables from the minimization in order to obtain a linear SDP problem. Because

this is not possible for peak power minimization in general, we propose a convex relaxation with penalization.

For this relaxation, we discuss its link to the Lagrange relaxation of the constrained minimization problem, showing that our convex relaxation corresponds to the Lagrange relaxation with a penalty coefficient equal to 0. Based on this observation, we adopt a convex relaxation with a non-zero penalty term to generate high-quality sub-optimal solutions.

First, we use the convex relaxation method for single-frequency harmonic loads. The inherent novelty there is allowing the forces to act out of phase. Numerical experiments show that although the relaxation alone is not tight, a penalization term added to the objective function secures convergence to a suboptimal solution that is a feasible point of the original problem. Subsequently, we study the peak power function under loads with multiple harmonics formulated as an SDr.

This article is structured as follows. In Section 2, we present the notation and definitions of terms used throughout the paper. In Section 3, we formalize the optimization problem and also present a relaxation procedure to solve the problem in Section 4. Section 5 then illustrates our method with five examples. Finally, Section 6 summarizes our developments and provides an outlook on related future research.

2 Notations

In this section, we introduce the necessary notation. In particular, \mathbb{R} and \mathbb{C} represent real and complex fields, respectively. \mathbb{T} denotes the set of complex numbers of modulus 1, that is, the set of all complex numbers $z = x + iy$ for which it holds that $|z| = \sqrt{x^2 + y^2} = 1$ and $i^2 = -1$. \mathbb{S}^N is the set of $N \times N$ symmetric or Hermitian matrices according to the context. For a complex number z , \bar{z} is its complex conjugate, while for a complex vector or matrix, $x^* = \bar{x}^T$ stands for the transpose conjugate.

We define the Frobenius scalar product $\langle A, B \rangle = \text{Tr}\{A^T B\}$, where $A, B \in \mathbb{S}^N$. When A, B are real, it holds that $\text{Tr}\{A^T B\} = \sum_{i,j} A_{i,j} B_{i,j}$, and $\text{Tr}\{A^T B\} = \sum_{i,j} \bar{A}_{i,j} B_{i,j}$ applies to the Hermitian case. Thus, the set \mathbb{S}^N with the Frobenius scalar product can be identified as a Euclidean vector space.

Let \mathbb{S}_+^N be the set of positive semidefinite (PSD) matrices and define the partial order $X \succeq 0 \iff X \in \mathbb{S}_+^N$. A real symmetric (resp. Hermitian) matrix A is PSD iff $x^T A x \geq 0, \forall x$ (resp. $x^* A x \geq 0$).

For a Hermitian matrix A , let $\Re A$ and $\Im A$ denote the matrices obtained by taking the real and imaginary part of A 's entries element-wise. Then,

$$A \succeq 0 \iff \begin{pmatrix} \Re A & -\Im A \\ \Im A & \Re A \end{pmatrix} \succeq 0. \quad (2.1)$$

The latter matrix is real PSD. Thus, any PSD Hermitian matrix is equivalent to a real symmetric PSD matrix of larger size.

Let F be an affine map from \mathbb{R}^n (or \mathbb{C}^n) to the set of real symmetric matrices \mathbb{S}^N , a linear matrix inequality (LMI) is defined as $F(x) \succeq 0$. The feasible set $\{x \mid F(x) \succeq 0\}$ of the LMI is called a spectrahedron and it is a convex and closed set; see, e.g., [BV04].

3 Optimization problem formulation

Here, we consider optimization problems occurring in the context of topology optimization of discrete structures with time-varying loads.

Variables of the optimization problem We can distinguish two types of variables:

- The *design variables* $a \in \mathbb{R}^m$ represent the vector of parameters of the structure, e.g., cross-section areas, (pseudo)densities, etc.
- The *state variables* $u \in \mathbb{R}^n$ describe the physics, e.g., displacements, velocities, temperature, etc.

Periodic time varying loads Let f represent the load of the structure. We assume here that the time-varying load f contains N harmonic components of base angular frequency ω , described by a sequence of complex vector-valued Fourier coefficients $c_k(f) \in \mathbb{C}^d, \forall k = -N, \dots, N$. f is thus a periodic function:

$$f(t) = \sum_{k=-N}^N c_k(f) e^{ik\omega t}. \quad (3.1)$$

f is real-valued, implying that the complex Fourier coefficients of f satisfy the symmetric condition $c_{-k}(f) = \overline{c_k(f)}$, where the complex conjugation is taken entry-wise. We also assume that there is no constant component in the load, thus $c_0(f) = 0$.

Equilibrium equation By the finite element discretization, the nodal velocity v is the solution of the ordinary differential equation (ODE)

$$M(a)\ddot{v} + K(a)v = \dot{f}. \quad (3.2)$$

Define the ordinary differential operator $L(a)$ as

$$L(a)v := M(a)\ddot{v} + K(a)v. \quad (3.3)$$

We shall refer to the equation $L(a)v = \dot{f}$ as the equilibrium equation.

The steady-state solution of the ODE is a periodic function with N harmonic components as well, satisfying

$$(-k^2\omega^2 M(a) + K(a))c_k(v) = ik\omega c_k(f), \forall k. \quad (3.4)$$

The equilibrium equation relates the state variables and design variables:

$$L(a)v = \dot{f} \iff (-k^2\omega^2 M(a) + K(a))c_k(v) = ik\omega c_k(f), \forall k. \quad (3.5)$$

Using the equilibrium equation as a constraint in the minimization (3.10), we automatically eliminate the values of a for which the design does not allow carrying the load, i.e. $f \notin \text{Range } L(a)$.

The matrix $M(a)$ and $K(a)$ are called the mass and the stiffness matrix. They depend linearly on the design variables a in the current study,

$$\begin{aligned} M(a) &= \sum_{i=1}^m a_i M_i, \\ K(a) &= \sum_{i=1}^m a_i K_i, \end{aligned} \quad (3.6)$$

where M_i and K_i are PSD mass and stiffness matrices of individual finite elements.

We assume that the highest harmonic frequency $N\omega$ is less than or equal to the smallest non-singular free-vibration angular eigenfrequency. It is shown in [AK08] that this is equivalent to

$$-N^2\omega^2M(a) + K(a) \succeq 0. \quad (3.7)$$

Further constraints on design variables With $a \in \mathbb{R}^m$ representing the vector of the cross-section areas of individual truss elements, we collect a number of constraints on the design variables a :

- $a_i \geq 0, \forall i = 1, \dots, m$, securing non-negative cross-section areas,
- $m - q^T a \geq 0$, providing an upper bound for structural mass, with $q \in \mathbb{R}^m$ being the constant vector of the element weight contributions,
- $-\lambda^2 M(a) + K(a) \succeq 0$, ensuring that the smallest non-singular free-vibration angular eigenfrequency is at least λ , see, e.g., [AK08].

Objective function In this study, we consider the peak power $p[u]$ as an objective function. It is the maximum value of the instant power delivered to the structure by the load $f(t)$, i.e.,

$$p[c(v)] = \max_{t \in [0, \frac{2\pi}{\omega}]} \{|f(t)^T v(t)|\}. \quad (3.8)$$

Peak power minimization To summarize, we aim at solving the following minimization problem:

$$\begin{aligned} \min_{a, c(v)} \quad & p[c(v)] \\ \text{s.t.} \quad & \begin{cases} a_i \geq 0, a^T q \leq m, -N^2\omega^2M(a) + K(a) \succeq 0 \\ (-k^2\omega^2M(a) + K(a))c_k(v) = ik\omega c_k(f), \forall k = -N, \dots, N \end{cases} \end{aligned} \quad (3.9)$$

This is a particular instance of a broader class of problems

$$\begin{aligned} \min_{a, u} \quad & p[u] \\ \text{s.t.} \quad & \begin{cases} G(a) \succeq 0 \\ L(a)u = f \end{cases} \end{aligned} \quad (3.10)$$

that build a unifying framework for compliance and peak power minimizations, namely, the minimization of a semi-definite representable (SDr) function under the equilibrium condition. By the equilibrium condition, we understand that the state variable u and design variable a are involved in the optimization problem and are constrained by the equilibrium equation $L(a)u = f$.

4 Minimization of SDr function under equilibrium

Let us develop the framework of minimization of a semidefinite representable (SDr) function under the equilibrium condition in more detail.

4.1 Schur's complement Lemma

Schur's complement of a block matrix is an essential tool to transform the non-linear constraints of a special structure into LMI constraints. Let us consider a block matrix $M = \begin{pmatrix} A & B^T \\ B & C \end{pmatrix}$. Schur's complement Lemma relates the positive (semi)definiteness of M to the positive (semi)definiteness of its blocks. Let us first assume that the block C is invertible.

Lemma 4.1 (Schur's complement Lemma with C invertible [Wol+00]) *Consider the block matrix M as defined above with the matrix C invertible. Then, $M \succeq 0$ if and only if the following two conditions hold:*

$$\begin{cases} C \succeq 0, \\ A - B^T C^{-1} B \succeq 0. \end{cases} \quad (4.1)$$

In the case when C is not invertible, we can use the Moore-Penrose pseudo-inverse instead of the inverse. However, additional conditions for B are now required, see [BV04, Appendix A.5].

Lemma 4.2 (Generalized Schur's complement Lemma [BV04]) *Consider a block matrix M . $M \succeq 0$ iff the following conditions hold:*

$$\begin{cases} C \succeq 0, \\ (I - CC^\dagger)B = 0, \\ A - B^T C^\dagger B \succeq 0. \end{cases} \quad (4.2)$$

The second condition $(I - CC^\dagger)B = 0$ means that all the column vectors of B are in the range space of C . The use of Schur's complement Lemma is essential for obtaining equivalent (convex) reformulations of problems under the equilibrium equation $L(a)u = f$, see [Tyb+21], for example. The Generalized Schur's complement Lemma also allows us to conclude that B 's columns are in the range space of C , once there exists indeed a matrix A of an appropriate dimension such that

$$\begin{pmatrix} A & B^T \\ B & C \end{pmatrix} \succeq 0. \quad (4.3)$$

The (Generalized) Schur complement Lemma still holds whenever A and C are Hermitian and B^T is replaced by B^* , this property is used to construct the constraints for peak power minimization since we use complex Fourier coefficients.

4.2 Semidefinite representable function

In (3.10), we deal with the case where p is a semidefinite representable function.

Definition 4.1 (SDr function, [BN01, Lecture 4.2]) *Let p be a convex function; it is semidefinite representable (SDr) if and only if its epigraph is an LMI shadow. Namely, there are linear matrix-valued functions P_j , $j \in \{0, 1, 2\}$, such that*

$$\forall \theta \in \mathbb{R}, \forall u \in \mathbb{R}^n, \theta \geq p[u] \iff \exists w \in \mathbb{R}^m, P_0(\theta) + P_1(u) + P_2(w) \succeq 0. \quad (4.4)$$

Alternatively, a second type of semidefinite representation can be used. A function whose epigraph admits a semidefinite representation of the second type is also called the SDr function in this work.

Definition 4.2 (SDr function, second representation) Let p be a convex function; it is semidefinite representable (SDr) if and only if there exists $a \in \mathbb{R}^m$, together with $g_k \in \mathbb{R}^n$ and $A_k \in \mathbb{S}^N$ for $k = 1, \dots, m$, such that $\forall \theta \in \mathbb{R}, \forall u \in \mathbb{R}^n$:

$$\theta \geq p[u] \iff \exists Q \in \mathbb{S}_+^N, a_k \theta + g_k^T u = \text{Tr}\{A_k^T Q\}. \quad (4.5)$$

Whenever p is SDr, the minimization problem (3.10) is, after adding the variables θ and w , equivalent to

$$\begin{aligned} & \min_{a, u, \theta, w} \theta \\ & \text{s.t.} \begin{cases} a_i \geq 0, m - q^T a \geq 0, L(a) \succeq 0, \\ L(a)u = f, \\ P_0(\theta) + P_1(u) + P_2(w) \succeq 0. \end{cases} \end{aligned} \quad (4.6)$$

If the semidefinite representation of the second type is used, then we obtain the following equivalent optimization problem:

$$\begin{aligned} & \min_{a, u, \theta, Q} \theta \\ & \text{s.t.} \begin{cases} a_i \geq 0, m - q^T a \geq 0, L(a) \succeq 0, \\ L(a)u = f, \\ a_k \theta + g_k^T u = \text{Tr}\{A_k^T Q\}, \forall k \in \{1, \dots, m\}, \\ Q \succeq 0. \end{cases} \end{aligned} \quad (4.7)$$

Example 4.1 (Compliance minimization) Compliance minimization is formulated as

$$\begin{aligned} & \min_{a, u} f^T u \\ & \text{s.t.} \begin{cases} a_i \geq 0, q^T a \leq m, K(a) \succeq 0, \\ K(a)u = f. \end{cases} \end{aligned} \quad (\mathcal{P}_{\text{compl}})$$

The compliance $u \mapsto f^T u$ is SDr, as it is linear in u . $\theta \geq f^T u$ is already an LMI, with a one-dimensional matrix. Thus $(\mathcal{P}_{\text{compl}})$ is equivalent to

$$\begin{aligned} & \min_{a, u, \theta} \theta \\ & \text{s.t.} \begin{cases} a_i \geq 0, q^T a \leq m, K(a) \succeq 0, \\ K(a)u = f, \\ \theta \geq f^T u. \end{cases} \end{aligned} \quad (4.8)$$

Example 4.2 (Peak power minimization under single harmonic load [Hei+09]) Assume for now that the time-varying load has one frequency component $f(t) = \cos(\omega t)f_R + \sin(\omega t)f_I$. The nodal velocities $v(t) = \cos(\omega t)v_R + \sin(\omega t)v_I$ satisfy the ODE

$$M(a)\ddot{v} + K(a)v = \dot{f} \quad (4.9)$$

and at the steady state v_R and v_I satisfy

$$\begin{cases} (-\omega^2 M(a) + K(a))v_R = \omega f_I, \\ (-\omega^2 M(a) + K(a))v_I = -\omega f_R. \end{cases} \quad (4.10)$$

It has been shown in [Hei+09] that

$$f(t)^T v(t) = \frac{1}{4} [(f_R^T v_R - f_I^T v_I) - i(f_R^T v_I + f_I^T v_R)] e^{i2\omega t} + \frac{1}{4} [(f_R^T v_R - f_I^T v_I) + i(f_R^T v_I + f_I^T v_R)] e^{-i2\omega t}. \quad (4.11)$$

Consider (θ, v) in the epigraph of the peak power function $\theta \geq \max_t |f(t)^T v(t)|$. Then, letting $z = e^{i\omega t}$, we can write $f^T v$ as a trigonometric polynomial in z . The epigraph condition is equivalent to the nonnegativity of polynomials $\theta \pm f^T v$. By Theorem A.2, iff $\exists Q^0 \in \mathbb{S}_+^3, Q^1 \in \mathbb{S}_+^3$:

$$\begin{aligned} \theta &= \text{Tr}\{\Lambda_0 Q^0\}, \\ 0 &= \text{Tr}\{\Lambda_{-1} Q^0\}, \\ \frac{1}{4}((f_R^T v_R - f_I^T v_I) - i(f_R^T v_I + f_I^T v_R)) &= \text{Tr}\{\Lambda_{-2} Q^0\} \end{aligned} \quad (4.12)$$

and

$$\begin{aligned} -\theta &= \text{Tr}\{\Lambda_0 Q^1\}, \\ 0 &= \text{Tr}\{\Lambda_{-1} Q^1\}, \\ -\frac{1}{4}((f_R^T v_R - f_I^T v_I) - i(f_R^T v_I + f_I^T v_R)) &= \text{Tr}\{\Lambda_{-2} Q^1\}, \end{aligned} \quad (4.13)$$

where Λ_0 is the 3 by 3 identity matrix, $\Lambda_{-1} = \begin{pmatrix} 0 & 0 & 0 \\ 1 & 0 & 0 \\ 0 & 1 & 0 \end{pmatrix}$ and $\Lambda_{-2} = \begin{pmatrix} 0 & 0 & 0 \\ 0 & 0 & 0 \\ 1 & 0 & 0 \end{pmatrix}$. Consequently, the minimization of the peak power under a single harmonic load reads as

$$\begin{aligned} \min_{a, v_R, v_I, \theta, Q^0, Q^1} \quad & \theta \\ \text{s.t.} \quad & \begin{cases} a_i \geq 0, q^T a \leq m, (-\omega^2 M(a) + K(a)) \succeq 0, \\ (-\omega^2 M(a) + K(a)) v_R = \omega f_I, \\ (-\omega^2 M(a) + K(a)) v_I = -\omega f_R, \\ \text{the equality constraints (4.12) and (4.13),} \\ Q^0, Q^1 \succeq 0. \end{cases} \end{aligned} \quad (4.14)$$

Example 4.3 (Peak power minimization) The peak power minimization problem is formalized as

$$\begin{aligned} \min_{a, c(v)} \quad & p[c(v)] \\ \text{s.t.} \quad & \begin{cases} a_i \geq 0, a^T q \leq m, -N^2 \omega^2 M(a) + K(a) \succeq 0, \\ (-k^2 \omega^2 M(a) + K(a)) c_k(v) = ik\omega c_k(f), \forall k = -N, \dots, N. \end{cases} \end{aligned} \quad (4.15)$$

The peak power $p[c(v)] = \max_{t \in [0, \frac{2\pi}{\omega}]} \{|f(t)^T v(t)|\}$ is SDr thanks to the semidefinite certificate of nonnegativity of trigonometric polynomials, which follows from Theorem A.2 in Appendix A.

The peak power minimization is, therefore, equivalent to

$$\begin{aligned} & \min_{a, c(v), \theta, Q^0, Q^1} \theta \\ & \text{s.t.} \begin{cases} a_i \geq 0, a^T q \leq m, -N^2 \omega^2 M(a) + K(a) \succeq 0, \\ (-k^2 \omega^2 M(a) + K(a)) c_k(v) = ik\omega c_k(f), \forall k = -N, \dots, N, \\ \text{the equality constraints (A.17),} \\ Q^0, Q^1 \succeq 0. \end{cases} \end{aligned} \quad (\mathcal{P}_{\text{pp}})$$

The difficulty of the minimization problem of the form (3.10) is now concentrated in the equilibrium equation constraint. All other constraints can be treated efficiently using existing SDP solvers.

For the next developments, we define a so-called ‘‘physical’’ feasible point of the equilibrium equation and focus on the first type of semidefinite representation, Definition 4.1. For the semidefinite representation of the second type, Definition 4.2, we can easily adapt the results that will be presented now, and we will treat them in the end of this subsection.

We start by noting that if a particular pair of variables (a, u) is feasible for the constraint $L(a)u = f$, then f is in the range of $L(a)$, and u must be of the form $u = L(a)^\dagger f + u_0$, where $L(a)^\dagger$ is the Moore-Penrose pseudoinverse of $L(a)$ and u_0 is in the null space of $L(a)$. We call $L(a)^\dagger f$ (resp. u_0) the physical (resp. nonphysical) part of u . Note that since f is in the range of $L(a)$, $(a, L(a)^\dagger f)$ is feasible for the equilibrium condition. Thus, we make the following assumption.

Assumption 4.1 *Assume that for any feasible (a, u) of the constraint $L(a)u = f$, $p[u]$ is independent of the nonphysical part of u , i.e., $p[u] = p[L(a)^\dagger f]$.*

Example 4.4 *For compliance minimization, this assumption is satisfied by the symmetry of $K(a)$. If f is in the range of $K(a)$ then f is orthogonal to u_0 , and thus, $p[u] = f^T u = f^T K(a)^\dagger f$. We can reformulate the compliance minimization as a linear SDP problem*

$$\begin{aligned} & \min_{a, \theta} \theta \\ & \text{s.t.} \begin{cases} a_i \geq 0, q^T a \leq m, \\ \begin{pmatrix} \theta & f^T \\ f & K(a) \end{pmatrix} \succeq 0 \end{cases} \end{aligned} \quad (4.16)$$

thanks to generalized Schur’s complement Lemma,

$$\begin{cases} K(a) \succeq 0, \\ f \in \text{Range } K(a), \\ \theta \geq f^T K(a)^\dagger f, \end{cases} \iff \begin{pmatrix} \theta & f^T \\ f & K(a) \end{pmatrix} \succeq 0. \quad (4.17)$$

Because p is independent of the nonphysical solution, its epigraph is also independent of the nonphysical solution for any feasible (a, u) . By the SDP representability of p , the LMI representation of the epigraph should also be independent of the nonphysical solution. We recall that from Definition 4.1 we have

$$\theta \geq p[u] \iff \exists w, P_0(\theta) + P_1(u) + P_2(w) \succeq 0. \quad (4.18)$$

Then, we can express the linear matrix function $P_1(u)$ as

$$P_1(u) = \sum_j (g_j^T u) \tilde{P}_j \quad (4.19)$$

with a family of vectors g_j and matrices \tilde{P}_j of an appropriate size. We assume that the following condition holds:

Assumption 4.2 *Assume that g_j is in the range of $L(a)$ whenever f is in the range of $L(a)$.*

Lemma 4.3 *Assumption 4.2 is sufficient for Assumption 4.1.*

Proof. Let p be an SDr function such that Assumption 4.2 holds. Then for any (a, u) feasible for $L(a)u = f$, by the symmetry of $L(a)$, if g_j is in the range of $L(a)$ then u_0 is orthogonal to g_j and thus

$$P_1(u) = \sum_j (g_j^T L(a)^\dagger f) \tilde{P}_j. \quad (4.20)$$

Thus, the LMI representation of p is independent of the non-physical solution, which implies that p is independent of the nonphysical solution. ■

Returning to the peak power minimization problem, by a careful study of the generalized eigenvalue problem of free vibrations [AK08], we can show that the peak power function is indeed independent of the nonphysical part of $(a, c(v))$ whenever it is feasible and whenever the highest driving frequency of the load is below the smallest non-singular free-vibration eigenfrequency of the structure, i.e., $-N^2\omega^2M(a) + K(a) \succeq 0$. For the proof, we refer the reader to Lemma B.1 of Appendix B.

Assumptions 4.1 and 4.2 are not restrictive, since it would be questionable to optimize an objective function that depends on the nonphysical part of the solution of $L(a)u = f$. In the context of topology optimization of discrete structures, the non-physical part of $L(a)u = f$ would consist of the displacements or the velocities of nodes without any attached member.

To check Assumption 4.2 for objective functionx with the second SDP representation, we recall that if the objective function $p[u]$ has the second type SDP representation then there exists $a_k \in \mathbb{R}$, g_k and A_k of fixed dimension for $k = 1, \dots, m$ such that $\theta \geq p[u] \iff a_k\theta + g_k^T u = \text{Tr}\{A_k^T Q\}$ where $Q \succeq 0$. p satisfies the assumption 4.2 iff the g_k 's of the SDP representation are in the range of $L(a)$ whenever f is in the range of $L(a)$.

4.3 Convex relaxation

Let us now consider a SDr function and a minimization problem of the form (3.10). Furthermore, let Assumptions 4.1 and 4.2 hold. In what follows, we propose a convex relaxation of (3.10). For brevity, we only present the strategy for the first-type representation, Definition 4.1. Adaptation of the results of this subsection to Definition 4.2 is straightforward.

First, by the semidefinite representability of the objective function, we introduce slack variables θ and w and rewrite (3.10) as

$$\begin{aligned} \min_{a, u, \theta, w} \quad & \theta \\ \text{s.t.} \quad & \begin{cases} a_i \geq 0, m - q^T a \geq 0, L(a) \succeq 0, \\ L(a)u = f, \\ P_0(\theta) + P_1(u) + P_2(w) \succeq 0. \end{cases} \end{aligned} \quad (4.21)$$

Due to Assumption 4.1, we can remove u from the set of optimization variables, since only the physical part of the equation $L(a)u = f$ matters. However, we need to keep in mind that f must be in the range of $L(a)$,

$$\begin{aligned} & \min_{a, \theta, w} \theta \\ & \text{s.t.} \begin{cases} a_i \geq 0, m - q^T a \geq 0, L(a) \succeq 0, \\ f \in \text{Range } L(a), \\ P_0(\theta) + P_1(L(a)^\dagger f) + P_2(w) \succeq 0. \end{cases} \end{aligned} \quad (4.22)$$

After exploiting Assumption 4.2, we observe that the linear matrix function P_2 evaluated at $L(a)^\dagger f$ is

$$P_1(L(a)^\dagger f) = \sum_j (g_j^T L(a)^\dagger f) \tilde{P}_j. \quad (4.23)$$

Furthermore, we consider a matrix $F = (f \ g_j)$ whose column vectors are f and v_j for all (finitely many) j . Then, there exist constant matrices C_j such that $g_j^T L(a)^\dagger f = \text{Tr}\{C_j^T (F^T L(a)^\dagger F)\}$. To derive C_j , we note that

$$v_j^T L(a)^\dagger f = (F e_{j+1})^T L(a)^\dagger (F e_0) = \text{Tr} \left\{ e_0^T e_{j+1} F^T L(a)^\dagger F \right\} \quad (4.24)$$

with e_i denoting vectors of the canonical basis. Consequently, we can symmetrize the last expression and obtain C_j . After introducing a variable X and a constraint $X = F^T L(a)^\dagger F$, we obtain the optimization problem

$$\begin{aligned} & \min_{a, \theta, w, X} \theta \\ & \text{s.t.} \begin{cases} a_i \geq 0, m - q^T a \geq 0, L(a) \succeq 0, \\ f \in \text{Range } L(a), \\ X = F^T L(a)^\dagger F, \\ P_0(\theta) + \sum_j \text{Tr}\{C_j^T X\} \tilde{P}_j + P_3(w) \succeq 0. \end{cases} \end{aligned} \quad (4.25)$$

The range constraint can now be replaced because $X = F^T L(a)^\dagger F$ is equivalent to

$$X = F^T L(a)^\dagger F \iff \begin{cases} X \preceq F^T L(a)^\dagger F \\ X \succeq F^T L(a)^\dagger F \end{cases}, \quad (4.26)$$

by splitting matrix equality into two semidefinite inequalities. Combined with Assumption 4.2 and thanks to Schur's complement Lemma, we have the equivalent formulation

$$\begin{aligned} & \min_{a, \theta, w, X} \theta \\ & \text{s.t.} \begin{cases} a_i \geq 0, m - q^T a \geq 0, \\ \begin{pmatrix} X & F^T \\ F & L(a) \end{pmatrix} \succeq 0, \\ X \preceq F^T L(a)^\dagger F, \\ P_0(\theta) + \sum_j \text{Tr}\{C_j^T X\} \tilde{P}_j + P_3(w) \succeq 0. \end{cases} \end{aligned} \quad (4.27)$$

For any X and a such that $\begin{pmatrix} X & F^T \\ F & L(a) \end{pmatrix} \succeq 0$, there is the trace inequality $\text{Tr}\{X - F^T L(a)^\dagger F\} \geq 0$.

The trace equality $\text{Tr}\{X - F^T L(a)^\dagger F\} = 0$ is thus sufficient and necessary for the satisfaction of $X \preceq F^T L(a)^\dagger F$. Consequently, we can replace $X \preceq F^T L(a)^\dagger F$ by $\text{Tr}\{X - F^T L(a)^\dagger F\} = 0$.

The only non-convex and non-linear constraint is now $\text{Tr}\{X - F^T L(a)^\dagger F\} = 0$. A convex relaxation consists of removing the trace equality constraint,

$$\begin{aligned} & \min_{a, \theta, w, X} \theta \\ & \text{s.t.} \begin{cases} a_i \geq 0, m - q^T a \geq 0, \\ \begin{pmatrix} X & F^T \\ F & L(a) \end{pmatrix} \succeq 0, \\ P_0(\theta) + \sum_j \text{Tr}\{C_j^T X\} \tilde{P}_j + P_3(w) \succeq 0. \end{cases} \end{aligned} \quad (4.28)$$

Remark 4.1 *We observe that:*

- *The relaxation does not require linearity of $L(a)$, i.e., it applies to both truss and frame settings. The relaxation requires only that $L(a) \succeq 0$. Under the assumption of linearity of $L(a)$, the relaxation is indeed a convex SDP problem, and thus can be solved efficiently by existing software.*
- *The feasible points of the relaxation are statically admissible designs, i.e., cross-section areas that carry the structural loads, which holds because the second LMI constraint secures that f is in the range of $L(a)$.*
- *If $X = F^T L(a)^\dagger F$ holds at the optimal solution of the convex relaxation, then we can extract the optimal solution of (3.10) from the convex relaxation.*

4.4 Link between the convex relaxation and Lagrange relaxation

Let us now take another look at the equivalent formulation with trace equality:

$$\begin{aligned} & \min_{a, \theta, w, X} \theta \\ & \text{s.t.} \begin{cases} a_i \geq 0, m - q^T a \geq 0, \\ \begin{pmatrix} X & F^T \\ F & L(a) \end{pmatrix} \succeq 0, \\ \text{Tr}\{X - F^T L(a)^\dagger F\} = 0, \\ P_0(\theta) + \sum_j \text{Tr}\{C_j^T X\} \tilde{P}_j + P_3(w) \succeq 0. \end{cases} \end{aligned} \quad (4.29)$$

Considering the second LMI, if a and X are feasible, it must hold that

$$\text{Tr}\{X - F^T L(a)^\dagger F\} \geq 0. \quad (4.30)$$

Hence, we can replace the equality by $\text{Tr}\{X - F^T L(a)^\dagger F\} \leq 0$ and the following optimization stays equivalent to (3.10):

$$\begin{aligned} & \min_{a, \theta, w, X} \theta \\ & \text{s.t.} \begin{cases} a_i \geq 0, m - q^T a \geq 0, \\ \begin{pmatrix} X & F^T \\ F & L(a) \end{pmatrix} \succeq 0, \\ \text{Tr}\{X - F^T L(a)^\dagger F\} \leq 0, \\ P_0(\theta) + \sum_j \text{Tr}\{C_j^T X\} \tilde{P}_j + P_3(w) \succeq 0. \end{cases} \end{aligned} \quad (4.31)$$

The Lagrange relaxation consists of moving the inequality constraint into the objective and penalizing it with a positive weight η , leading to

$$\begin{aligned} \min_{a, \theta, w, X} \quad & \theta + \eta \operatorname{Tr}\{X - F^T L(a)^\dagger F\} \\ \text{s.t.} \quad & \begin{cases} a_i \geq 0, m - q^T a \geq 0, \\ \begin{pmatrix} X & F^T \\ F & L(a) \end{pmatrix} \succeq 0, \\ P_0(\theta) + \sum_j \operatorname{Tr}\{C_j^T X\} \tilde{P}_j + P_3(w) \succeq 0, \end{cases} \end{aligned} \quad (4.32)$$

where the penalty factor η is increased until the original constraint $\operatorname{Tr}\{X - F^T L(a)^\dagger F\} \leq 0$ becomes feasible. Let us denote by $L(\eta)$ the optimal value depending on η . For one η^* , suppose that $(a^*, \theta^*, w^*, X^*)$ is the corresponding solution, then for any (a, θ, w, X) satisfying the constraint of (4.31), we have

$$\theta \geq \theta + \underbrace{\eta^* \operatorname{Tr}\{X - F^T L(a)^\dagger F\}}_{\leq 0} \geq \theta^* + \eta^* \operatorname{Tr}\{X^* - F^T L(a^*)^\dagger F\}. \quad (4.33)$$

Therefore, $\max_{\eta \geq 0} L(\eta)$ provides a lower bound of the problem (4.31).

We note that the convex relaxation (4.28) corresponds to the Lagrange relaxation with weight $\eta = 0$. However, the Lagrange relaxation remains a difficult problem due to the presence of $\operatorname{Tr}\{F^T L(a)^\dagger F\}$. We propose to solve the following relaxation, by removing $\operatorname{Tr}\{F^T L(a)^\dagger F\}$ from the objective function:

$$\begin{aligned} \min_{a, \theta, w, X} \quad & \theta + \eta \operatorname{Tr}\{X\} \\ \text{s.t.} \quad & \begin{cases} a_i \geq 0, m - q^T a \geq 0, \\ \begin{pmatrix} X & F^T \\ F & L(a) \end{pmatrix} \succeq 0, \\ P_0(\theta) + \sum_j \operatorname{Tr}\{C_j^T X\} \tilde{P}_j + P_3(w) \succeq 0, \end{cases} \end{aligned} \quad (4.34)$$

which is a linear SDP, and hence convex, problem.

5 Numerical examples

This section illustrates the theoretical developments of Section 4 by means of numerical experiments. The construction of the SDP problems is detailed in Appendix C. Specifically, we solve a problem introduced in [Hei+09], showing that our approach not only reaches the optimal solution for the in-phase setting, but also provides a better design for the out-of-phase scenario. Our second example 5.2 illustrates the applicability of the method to larger problems. The third 5.3 and fourth 5.4 examples illustrate the influence of multiple harmonics on design.

All numerical examples presented in this section were implemented in a Python code available at https://gitlab.com/ma.shenyuan/truss_exp, with the optimization programs modeled in CVXPY [DB16], a Python interface for modeling optimization problems, and providing an interface to the optimizer MOSEK [ApS23] that we used to solve the resulting SDP problems. The optimization problems were solved on a standard laptop, equipped with the 6 AMD Ryzen 5 4500U processors and 16 GB of RAM.

5.1 21-element problem by Heidari *et al.*

As the first illustration, we consider the problem introduced in [Hei+09]: a ground structure containing 21 finite elements and 12 nodes, see Fig. 1. In this problem, all horizontal and vertical bars share a length of 1, whereas the diagonal ones are $\sqrt{2}$ long. All elements are made of the same material, with the Young modulus $E = 25,000$ and density $\rho = 1.0$. Furthermore, we bound the total structural weight from above by $m = 1$.

Figure 1: Boundary conditions and ground structure of the 21-element truss structure introduced in [Hei+09].

Kinematic boundary conditions consist of fixed supports at the top nodes, preventing their horizontal and vertical movements. For dynamic loads, we consider them acting at the bottom nodes, with the horizontal forces (denoted in green color in Fig. 1) $f_I(t) = \frac{1}{2} \sin(\omega t)$ and the vertical forces (drawn in orange in Fig. 1) being $f_R(t) = \frac{1}{2} \cos(\omega t)$. For both these loading functions, we assume the same angular frequency $\omega = 15$. The time-dependent force magnitudes appear visualized in Fig. 2a. Notice that the resultant of the components f_R and f_I is always a force of magnitude $1/2$, thus modeling an unbalanced rotating load with the period of $T = \frac{2\pi}{15} \approx 0.42$. Under this setting, the time varying load has one Fourier component $c_1(f)$ such that the last four values are

$$c_1(f) = \begin{pmatrix} \vdots \\ i/4 \\ 1/4 \\ -i/4 \\ 1/4 \end{pmatrix}. \quad (5.1)$$

5.1.1 In-phase loads

First, we optimize the peak power of the loads $f_R(t)$ and $f_I(t)$ independently. For this setting, the relaxation with penalty (4.34) is exact, as was shown in [Hei+09]. Thus, globally optimal

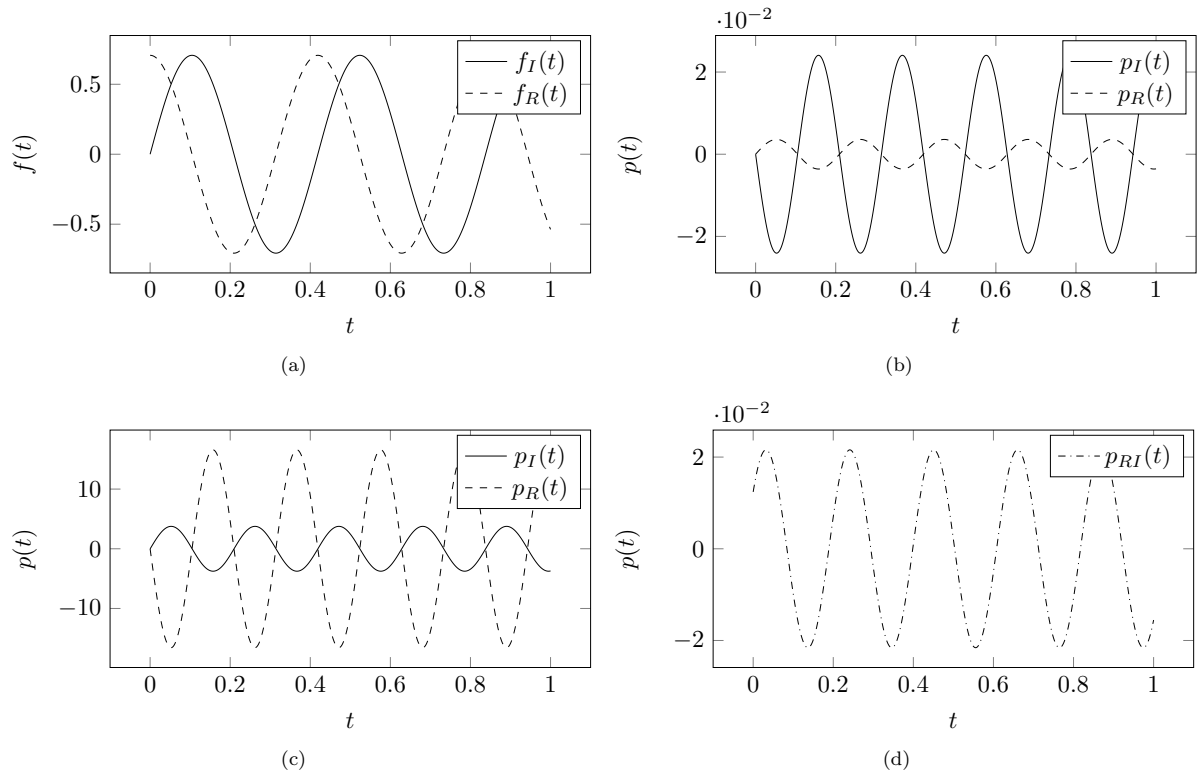

Figure 2: (a) Time-varying loads $f_R(t)$ and $f_I(t)$ and the powers associated with the (b) optimal designs under in-phase loads, and (c) the same designs under out-of-phase loads. Figure (d) shows the power of a design optimized for out-of-phase loads.

solutions can be found by solving a single SDP problem; see Figs. 3(a) and 3(b) for their topology and Fig. 2b for the optimal time-varying powers $p_R(t)$ and $p_I(t)$. The corresponding optimal peak powers are 0.0036 and 0.0241, respectively.

Figure 3: Optimized topology for the (a) in-phase loads f_R , (b) in-phase loads f_I , and (c) out-of-phase loads f_R and f_I acting according to Fig. 1.

5.1.2 Out-of-phase loads

Next, we consider the setting of the loads $f_I(t)$ and $f_R(t)$ that act simultaneously. The first, naive option, would be to investigate the performance of structures designed for in-phase loads $f_R(t)$ or $f_I(t)$ only. Not surprisingly, the performance of these designs is far from optimal because they do not suppress power by exploiting the interaction between the loads; see Fig. 2c. A similar situation also appears for the worst-case peak power minimization by Heidari *et al.* [Hei+09], in which a solution is searched for the worst-case of all unit forces, i.e., the loads acting in phase. As shown in Fig. 2d, the peak power for the out-of-phase configuration can be considerably reduced by enabling this interaction.

To achieve this, we apply the convex relaxation introduced in Section 4. The optimal value of the objective function is equal to 1.203×10^{-11} , which is a lower bound for the minimal peak power. However, the actual peak power of the design given by the convex relaxation is equal to 0.0831. For the relaxed solution, we also observe that the total mass constraint is not active: The total mass for the relaxation solution is only 0.40, which means that we have used 40% of the available mass. Also, the optimal X is different from $F^*L_{1,\omega}(a)^\dagger F$ at the optimal solution. The trace difference is evaluated as $\text{Tr}\{X - F^*L_{1,\omega}(a)^\dagger F\} = 1508.038$, which is far from zero.

Furthermore, we implement the penalized relaxation (4.34) with $\eta = 10$, chosen large enough for the equality $\text{Tr}\{X - F^*L_{1,\omega}(a)^\dagger F\} = 0$ to hold, and also render the mass bound active. We numerically confirm that θ is indeed equal to the peak power 0.0216, and there is a trace equality $X = F^T K_\omega(a)^\dagger F$. The optimized design a is shown in Figure 4, with the line widths illustrating the actual value of a .

Figure 4: Optimal solutions of convex relaxation with penalty parameter $\eta = 10$.

As we can see in the above optimization, a large enough η results in trace equality. It remains to investigate the effect of η on the peak power performance of the optimal solution. To this end, we solved the SDP relaxation for 80 different values of η ranging from 10^{-9} to 10. We collected the trace differences, total masses and optimal θ of the solutions of the SDP relaxations. In addition, we also plot the actual peak power of the optimal design in an orange color, see Figure 5.

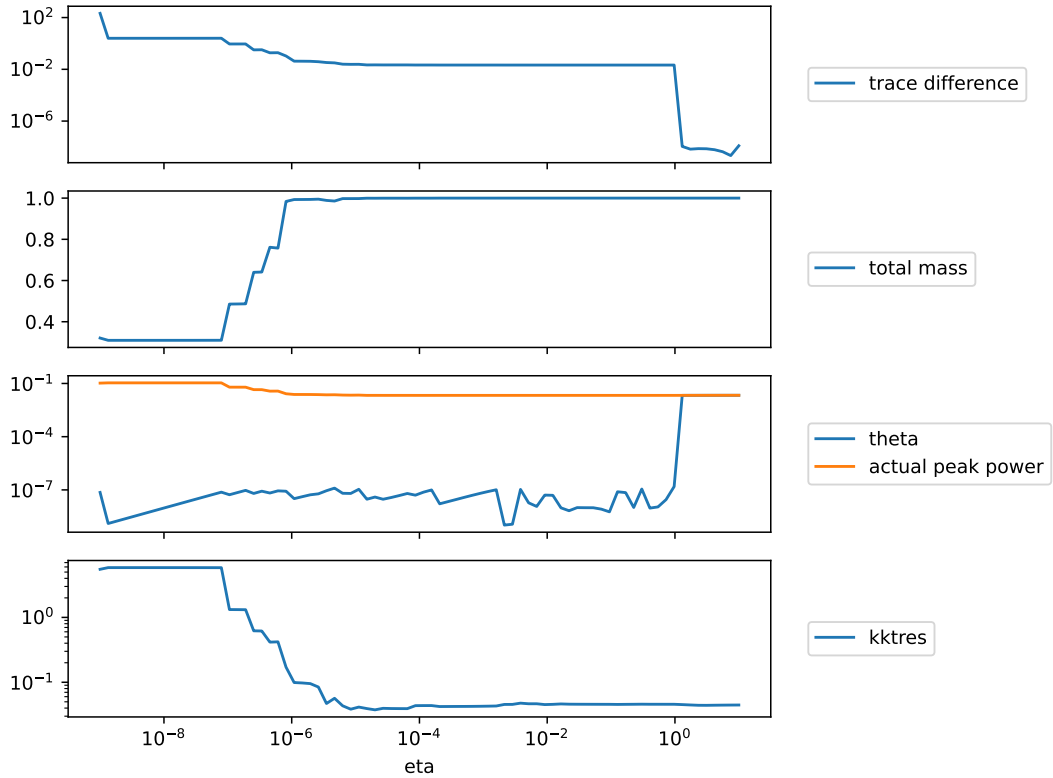

Figure 5: SDP relaxation with 80 different values of η for the Heidari truss with not-in-phase single harmonic load

For small values of η , Figure 5 reveals that there is a nonzero trace difference at the optimal solution and the total mass constraint is not active. As a result, we observe in the early part of the graphs that the actual peak power of the optimal design is higher than that of the optimal design obtained for large η . With η increasing, the trace equality becomes satisfied and the total mass constraint becomes active. The optimal value of θ then agrees with the actual peak power. However, the actual peak power does not improve further when the trace equality reaches 0.

Finally, we try to estimate the optimality of the design obtained by SDP relaxations. The peak power of the truss under harmonic loads is a differentiable function of a and the gradient can be obtained by sensitivity analysis as shown in Appendix D, suggesting that it might also be possible to implement the gradient-based method to minimize the peak power. Without any additional variables, the peak power minimization can be expressed as

$$\begin{aligned} \min_{a \in \mathbb{R}^n} \quad & p(a) \\ \text{s.t.} \quad & a_i \geq 0, a^T q \leq m, \end{aligned} \tag{5.2}$$

where p is the function of the peak power evaluated at a .

The formulation (5.2) makes peak power minimization a nonlinear optimization problem with linear inequality constraints. As a result, the linear constraint qualification (LCQ) holds, which implies that the Karush–Kuhn–Tucker conditions (KKT) are necessary for any local minimizer of the peak power minimization. In other words, if \bar{a} is a local minimizer of the peak power

minimization, then there exists a unique vector of Lagrange multipliers $\gamma \in \mathbb{R}^n$ and $\Gamma \in \mathbb{R}$ such that the following KKT system is satisfied:

$$\begin{cases} \nabla p(\bar{a}) - \gamma + \Gamma q = 0, \\ \gamma_i \geq 0, \bar{a}_i \geq 0, \gamma_i \bar{a}_i = 0, \forall i, \\ \Gamma \geq 0, m - \bar{a}^T q \geq 0, \Gamma(m - \bar{a}^T q) = 0. \end{cases} \quad (5.3)$$

For any feasible a , we define the KKT residual at a as the solution of the linear programming problem

$$\begin{aligned} \min_{\gamma \in \mathbb{R}^n, \Gamma \in \mathbb{R}} \quad & a^T \gamma + \Gamma(m - a^T q) \\ \text{s.t.} \quad & \begin{cases} \nabla p(a) - \gamma + \Gamma q = 0, \\ \gamma_i \geq 0, \forall i, \\ \Gamma \geq 0. \end{cases} \end{aligned} \quad (5.4)$$

By the necessary condition of optimality, if \bar{a} is a local minimizer of (5.2), then the solution of the linear programming problem (5.4) is a unique vector of Lagrange multipliers, and the optimal value is zero. If a design a is suboptimal but in the vicinity of a local optimal solution, then we expect a low value of the KKT residual. The KKT residual can thus be used as an approximate optimality certificate even though it is not sufficient for non-convex problems.

For the illustrative problem considered in this section, we observe that the KKT residual is approximately 0.045 for a sufficiently large η . Moreover, the KKT residual decreases with increasing η , as shown in the last subplot of Figure 5. This analysis suggests that the optimal solution with a sufficiently large η might be close to a local optimum of the peak power minimization problem (5.2).

5.2 Cantilever beam problem

Next, we consider a cantilever beam under a rotating tip load; see Figure 6(a). The design domain of the outer dimensions 2×1 is discretized into a uniform grid of 4×7 nodes, with the left edge of the domain fixed. We connect each pair of the nodes by a bar element, resulting in 378 elements in total. The rotating out-of-phase load is applied in the upper right corner of the beam. The components of this load act at the angular frequency of 15 and

$$c_1(f) = - \begin{pmatrix} 0 \\ \vdots \\ i \\ 1 \\ \vdots \\ 0 \end{pmatrix} / \sqrt{2}.$$

The non-zeros components of $c_1(f)$ correspond to the loaded degrees of freedom as shown in Figure 6(a) and the load has an amplitude of $\|c_1(f)\| = 1$.

The truss members are made of a material with Young's modulus $E = 25,000$ and density $\rho = 1$. The total mass is bounded from above by 10. In what follows, we consider convex relaxation with the penalty coefficient $\eta = 10$, for which the minimization converges to the design shown in Figure 6(b). This design contains 40 finite elements and possesses the peak

power of 0.147 and the lowest angular eigenfrequency of 18.97 which is strictly larger than the driving frequency of the loads 15.

The optimization problem contained 389 scalar design variables. The compiled problem instance had 3 additional matrix variables containing 5295 scalar variables, and there were 406 constraints in total. The solution of the problem took 0.76 seconds, suggesting a relatively good scalability of the method.

Figure 6: Cantilever beam problem: (a) fully connected ground structure, and (b) optimal design for the penalized relaxation with $\eta = 10$.

Figure 7: SDP relaxation with 80 different values of η for the cantilever problem

As in the previous example, we consider 80 values of η ranging from 10^{-9} to 10^1 to visualize the effect of η on the performance of the optimal design, see Figure 7. From this figure we observe that the satisfaction of the trace difference becomes zero when η is larger than 1, and as a result, the optimal value of θ agrees with the actual value of the peak power. However, the mass bound is always active for each value of η in this example. The KKT residual is reduced by the 2 orders of magnitude as η increases.

5.3 Peak power minimization under multifrequency rotating loads

Optimizing structures under rotating loads is valuable for industrial applications. Here, we again consider the Heidari *et al.* [Hei+09] truss structure subjected to two rotating loads with different angular frequencies ω_1 and ω_2 simultaneously and the mass bound equal to 1, Figure 8. These loads are applied to the bottom nodes of the truss and share the same constant amplitude 1. Their relative angle to the horizontal axis is a function of time and is equal to $\omega_1 t + \phi_1$ and $\omega_2 t + \phi_2$, respectively.

Figure 8: A truss subjected to two rotational loads of different angular frequencies ω_1 and ω_2 .

In the context of the current method, we have to assume that two frequencies ω_1 and ω_2 are harmonic to each other, which implies that there is a basic frequency ω_0 such that $\omega_1 = n_1\omega_0$ and $\omega_2 = n_2\omega_0$ are integer multiples of the basic frequency ω_0 . We assume without loss of generality that $n_2 \geq n_1$, so that the time-varying load f has n_2 Fourier components. To apply the SDP relaxation method we set the Fourier components of the load f to

$$\forall n \geq 1, c_n(f) = \frac{\delta_{n=n_1} e^{i\phi_1}}{2} \begin{pmatrix} 0 \\ \vdots \\ 0 \\ \frac{1}{2} \\ \frac{1}{2i} \\ 0 \\ 0 \end{pmatrix} + \frac{\delta_{n=n_2} e^{i\phi_2}}{2} \begin{pmatrix} 0 \\ \vdots \\ 0 \\ 0 \\ 0 \\ 0 \\ \frac{1}{2} \\ \frac{1}{2i} \end{pmatrix}, \quad (5.5)$$

where $\delta_{n=k}$ is the Kronecker delta notation such that $\delta_{n=k}$ is equal to one if and only if $n = k$.

For numerical experiments, we set $\phi_1 = \frac{\pi}{2}$ and $\phi_2 = -\frac{\pi}{2}$ and consider different values of ω_1 and ω_2 , see Table 1. For each instance, we solve the resulting SDP relaxation with the penalty coefficient $\eta = 10$ to make the trace difference approximately zero in the optimal solution.

ω_1	ω_2	ω_0	n_1	n_2	$p[c(v)]$	$\tilde{\omega}_1$	KKT residual
7.5	15	7.5	1	2	0.0334	18.611	0.1448
10	15	5	2	3	0.0377	19.224	0.1630
12.5	15	2.5	5	6	0.0421	20.146	0.1815
13.125	15	1.875	7	8	0.0432	20.436	0.1882

Table 1: Peak power minimization under multifrequency rotating loads. Parameters of the rotating loads and performance of the optimal design of the SDP relaxation with penalty. ω_1 and ω_2 denote the angular driving frequencies of the load and ω_0 is the basic frequency such that $\omega_1 = n_1\omega_0$ and $\omega_2 = n_2\omega_0$. In addition, $p[c(v)]$ denotes the peak power, and $\tilde{\omega}_1$ stands for the lowest resonance eigenfrequency.

In each instance, we reached a sub-optimal solution with non zero KKT residual of the peak power and the mass bound was active. Because there is no comparable design available in the literature, we further compare the objective function value with that of the common initial point, the uniform truss design. Compared to this case, each of our optimized designs provides approximately 50% improvement in terms of peak power. Each of the optimized designs also has its first resonance frequency strictly higher than the driving frequency 15. The optimal designs for $n_2 = 2$ and $n_2 = 8$ are shown in Figures 9(a) and 9(b).

Figure 9: Peak power minimization under multifrequency rotating loads: (a) optimized design for $n_2 = 2$, and (b) for $n_2 = 8$.

ω_1	ω_2	ω_0	n_1	n_2	n_{var}	n_{constr}	t (s)
7.5	15	7.5	1	2	108	10	0.094
10	15	5	2	3	201	14	0.163
12.5	15	2.5	5	6	684	26	1.293
13.125	15	1.875	7	8	1176	34	2.567

Table 2: Problem sizes of the peak power minimization under multifrequency rotating loads. ω_1 and ω_2 denote the angular driving frequencies of the load and ω_0 is the basic frequency such that $\omega_1 = n_1\omega_0$ and $\omega_2 = n_2\omega_0$. In addition, n_{var} and n_{constr} denote the number of variables and constraints, respectively, and t stands for the solution time.

The size of the corresponding SDP problem for each instance is reported in Table 2, but the actual size of the solved problem may differ due to the remodeling done in the CVXPY package, which transforms the problem into a conic form accepted by MOSEK. This remodeling involves additional variables and constraints. For example, every LMI constraint $L(x) \succeq 0$ is converted to $L(x) = X$ and $X \succeq 0$ with a slack variable X that has the same size of the LMI $L(x)$ and additional linear equality constraints are introduced to ensure equality $L(x) = X$. Moreover, to convert a Hermitian PSD constraint into a real symmetric PSD constraint, one also needs to include additional variables and constraints.

As a result, even when the number of “active” Fourier components was the same throughout all test cases, the sizes of the problems were different. Typically, for the last instance where $n_2 = 8$, the constraint $\begin{pmatrix} X & F^* \\ F & L_{n_2, \omega_0}(a) \end{pmatrix} \succeq 0$ involves a LMI of the size $8 \times (21 + 3) = 192$. To transform it into the standard formulation of MOSEK, we need to include a 384 by 384 real symmetric matrix variable and additional linear equality constraints. From this we observe that it is definitely needed to exploit sparsity to solve for large instances of the peak power minimization using the proposed SDP method.

5.4 Peak power minimization under multiple frequency loads

The convex relaxation method is also capable of optimizing structural designs under periodic loads with multiple frequency components. The theoretical construction of the minimization problem remains the same as in the single-frequency situation and is summarized in Appendix C.

A finite energy (being L^2 function) periodic time-varying load f can be decomposed into its Fourier series. In theory, if we truncate the Fourier sequence of a periodic load f up to a finite number of Fourier coefficients and optimize the truss using the presented method with respect to the truncated load, it approximates the optimization with respect to the original periodic load. However, not every such periodic load is suitable for the method presented here.

For example, let us again consider the Heidari *et al.* [Hei+09] problem that we have already presented in Section 5.1, but with a modification of the dynamic loads. In particular, we apply the loads shown in Figure 10, where f_1 and f_2 are two periodic loads acting simultaneously.

Figure 10: Ground structure of the 21-element truss structure under multiple frequency loads f_1 and f_2 .

f_1 is a periodic function with period T and amplitude 1 such that

$$f_1(t) = \begin{cases} -1 & \text{if } -\frac{T}{2} < t \leq 0, \\ 1 & \text{if } 0 < t \leq \frac{T}{2}. \end{cases} \quad (5.6)$$

The periodic load f_2 has the same amplitude and period with a delay T_0 , so that $\forall t \in \mathbb{R}, f_2(t) = f_1(t - T_0)$. To approximate the nodal velocity $v(t)$ for a given vector of cross section areas a , we solve for the following linear equations up to a finite number N of Fourier coefficients:

$$(-k^2\omega^2 M(a) + K(a))c_k(f) = ik\omega c_k(f), \forall |k| \leq N. \quad (5.7)$$

Because the period is T , the lowest harmonic frequency is $\omega = \frac{2\pi}{T}$. We calculate the Fourier coefficients of f_1 as

$$c_k(f_1) = \begin{cases} 0 & \text{if } k = 0, \\ \frac{1}{T} \int_{-T/2}^{T/2} f_1(t) e^{-ik\omega t} dt = \frac{i}{\pi} \frac{(-1)^k - 1}{k} & \text{otherwise.} \end{cases} \quad (5.8)$$

Because f_2 is delayed in time, $\forall k, c_k(f_2) = e^{-ik\omega T_0} c_k(f_1)$. Finally, the overall Fourier coefficients of $f(t)$ read as

$$\forall k \neq 0, c_k(f) = (0 \quad \dots \quad c_k(f_1) \quad 0 \quad c_k(f_2) \quad 0)^T. \quad (5.9)$$

Let $T = 2(s)$ and $T_0 = 0.2(s)$ and consider a truss with uniform cross-section areas of the total mass $m = 1$. For this case, we calculate the power function with f using a truncated Fourier series. In Figure 11(a), we plot the instant power of the truss in time for different numbers of Fourier coefficients, observing that the power function requires at least 15 harmonics. Their spectrum in Figure 11(b) reveals that the coefficients must cover all resonance frequencies (drawn in red). For the adopted discretization, the maximum eigenfrequency is evaluated as

233 rad/s, so we need to include at least $\frac{233}{\omega} \approx 74$ Fourier components of f to cover the range of eigenfrequencies of the uniform truss.

Figure 11: Response of the Heidari *et al.* truss under time-varying load f : (a) Effect of truncations of the time-varying load on the instant power, and (b) norm of the Fourier coefficients of the nodal velocity up to some finite number of frequencies in logarithmic scale. The vertical red lines indicates the position of the eigenfrequencies of the specific design. It is observed that the Fourier components of the velocity start to converge only when all the eigenfrequencies are covered which shows that for the specific time varying load it is required to include a large number of Fourier components to compute an accurate response of the structure.

Because we have assumed that the maximum frequency of the load is less than the minimum resonance frequency $-N^2\omega^2 M(a) + K(a) \succeq 0$, and because the minimum resonance frequency of a truss under a mass constraint cannot be arbitrarily large, we can only consider small enough N . This limitation suggests that the current method of peak power minimization is suitable for time-varying loads of low frequencies whose Fourier components have a fast decreasing norm. This implies smooth-enough time-varying loads f . If the time-varying loads f are functions with C^k regularity (k times derivable and with a continuous k -th derivative), then the norm of $c_n(f)$ tends to zero at speed $\frac{1}{n^k}$. When f is smooth, we can expect that a few numbers of $c_n(f)$ suffice to approximate the original f . For the current example, since f is not smooth, it requires many Fourier components.

For the reasons outlined in the previous paragraph, in the remaining part of this section, we solve the peak power minimization problem while considering truncations of f up to the third Fourier coefficient, i.e.,

$$f(t) = \sum_{k=-3}^3 c_k(f) e^{ik\omega t}. \quad (5.10)$$

We lower its frequency, thus, we set $T = 2(s)$ for numerical reasons. The convex relaxation with

penalty of the corresponding peak power minimization writes as

$$\begin{aligned} \min_{a, X, \theta, Q_1, Q_2} \quad & \theta + \eta \operatorname{Tr}\{X\} \\ \text{s.t.} \quad & \begin{cases} a_i \geq 0, a^T q \leq m, -N^2 \omega^2 M(a) + K(a) \succeq 0, \\ \begin{pmatrix} X & F^* \\ F & L_{3, \omega}(a) \end{pmatrix} \succeq 0, \\ P_j(\theta, CX, Q_j) \succeq 0, \forall j \in \{1, 2\}, \end{cases} \end{aligned} \quad (5.11)$$

where $X \in \mathbb{S}^9$ and $Q_j \in \mathbb{S}^6$ are Hermitian matrices. Taking $\eta = 10$, set so that the mass constraint in relaxation (5.11) is active and the matrix inequality $X = F^* L_{3, \omega}(a)^\dagger F$ holds, the minimization converges to the design in Figure 12(a) that exhibits the instant power function shown in Figure 12(b). The peak power is improved by 40% compared to the uniform truss. The lowest resonance frequency of the optimal truss is evaluated as 13.062 rad/s , which is less than the highest frequency of the load $3\omega = \frac{3 \times 2\pi}{T} = 3\pi \text{ rad/s}$.

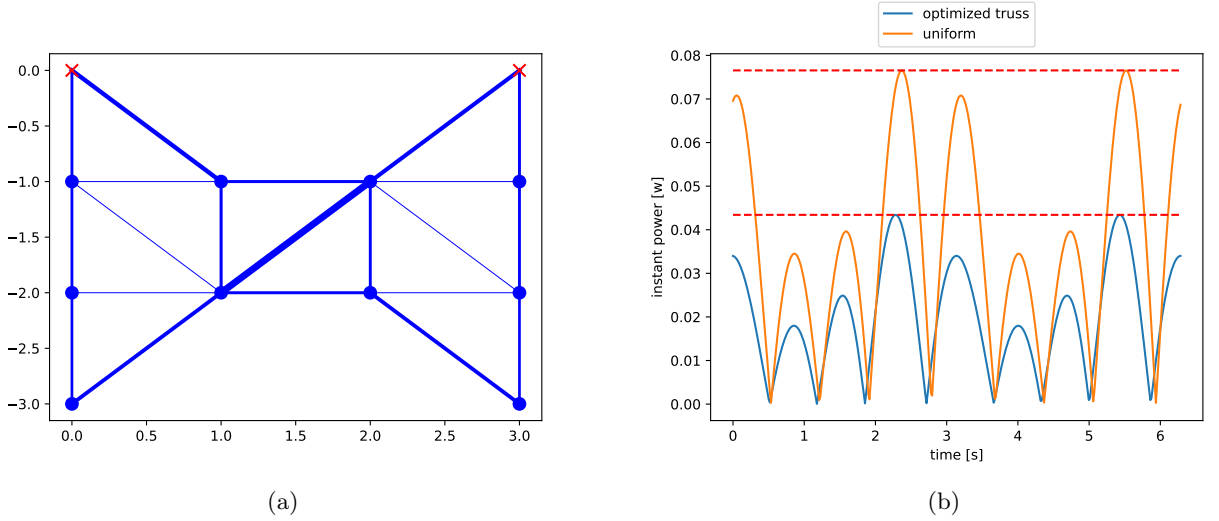

Figure 12: Optimized design of the Heidari *et al.* truss obtained by solving a convex relaxation with penalty $\eta = 10$ and $N = 3$: (a) The optimized design, and (b) Comparison of the instant power function of the uniform truss and of the optimized truss under harmonic loads with 3 Fourier components.

Similar results can be obtained by including a larger number of Fourier components of f . For $N = 5$, the matrix $L_{5, \omega}(a)$ increases in size compared to $L_{3, \omega}(a)$ due to the larger matrix variables X , Q_1 and Q_2 of the respective sizes 15×15 , 10×10 , and 10×10 . Following the former setup, we also adopt the penalty factor $\eta = 10$.

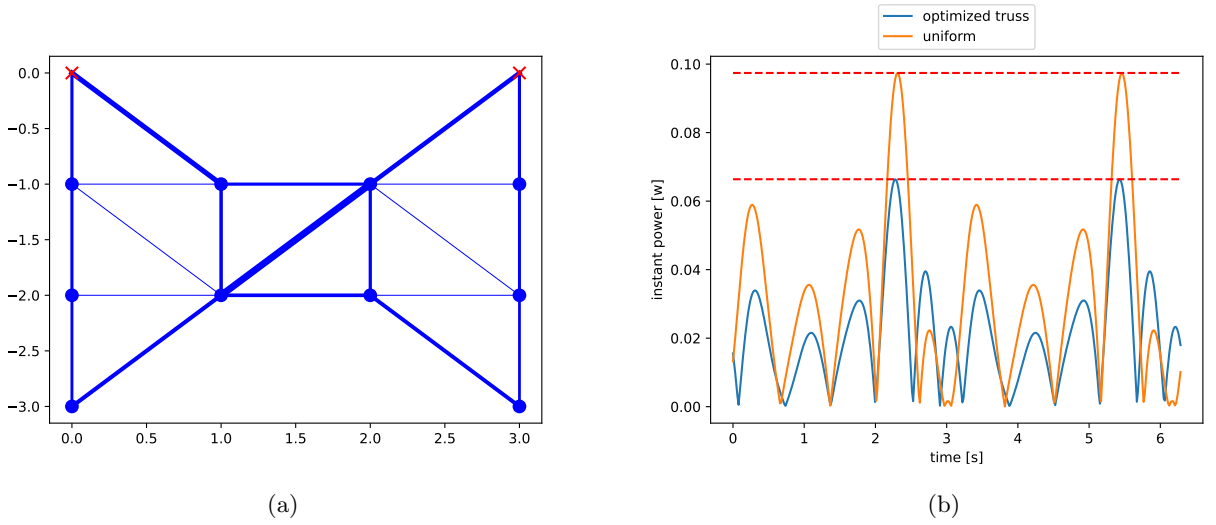

Figure 13: Optimized design of the Heidari *et al.* truss obtained by solving a convex relaxation with penalty $\eta = 10$ and $N = 5$: (a) The optimized design, and (b) Comparison of the instant power function of the uniform truss and of the optimized truss under harmonic loads with 5 Fourier components.

Using the proposed relaxation with penalization, we reached the optimized design shown in Figure 13(a). This design exhibits the instant power shown in Figure 13(b), with a peak power that is better than that of the uniform truss by approximately 40%; an improvement similar to that achieved for the three harmonics. However, we reached a considerably increased lowest free-vibration eigenfrequency of the value 23.950 rad/s, which is in fact strictly higher than the maximum frequency of the load, $5\pi \approx 15.7$ rad/s.

Clearly, we have observed a certain similarity between the optimal design for $N = 3$ and $N = 5$. To compare them, we calculate the peak power of the different designs when loaded with f truncated up to 3, 5 and 31 Fourier components, which is sufficiently large to approximate the peak power of the original periodic load; see Table 3.

N	$p_{\text{uni}}[c(v)]$	$p_3[c(v)]$	$p_5[c(v)]$
3	0.0765	0.0434	0.0451
5	0.0974	0.0674	0.0664
31	1.631	14.887	0.8694

Table 3: Influence of the number of harmonics on the optimized design for the peak power minimization under multiple frequency loads. N denotes the number of harmonics that we used in the time-varying loads to evaluate the optimized design response, $p_{\text{uni}}[c(v)]$ stands for the peak power of the uniform truss, and $p_{\bullet}[c(v)]$ denotes the peak power obtained when considering \bullet components in the loads f .

In Table 3, design $N = 3$ and $N = 5$ provide the best performance for loads with 3 and 5 Fourier components. This is not surprising since they are optimized with the number of Fourier components retained in f . When loaded with f where we retain a different number of Fourier components, they still outperform the uniform truss in terms of peak power. However, the

effect of optimization is not clear when they are loaded by f with 31 Fourier components. The performance of the design $N = 3$ is worse and the design $N = 5$ is nearly 50% better than the uniform truss.

To explain this observation, we first computed the lowest eigenfrequencies of the two optimal designs. Furthermore, we also evaluated the smallest distance of each eigenfrequency to the multiples of ω and repeated this computation for the uniform truss; see Table 4.

	$(\tilde{\omega}_1, \tilde{\omega}_1 - \ell\omega_0)$	$(\tilde{\omega}_2, \tilde{\omega}_2 - \ell\omega_0)$	$(\tilde{\omega}_3, \tilde{\omega}_3 - \ell\omega_0)$
Design for $N = 3$	(13.063, 0.496)	(17.873, 0.976)	(21.455, 0.537)
Design for $N = 5$	(23.950, 1.183)	(26.272, 1.140)	(33.805, 0.753)
Uniform truss	(20.244, 1.395)	(41.838, 0.998)	(47.643, 0.519)

Table 4: Spectral properties of various designs for the peak power minimization under multiple frequency loads. N denotes the number of harmonics we used to approximate the time-varying load, $\tilde{\omega}_\bullet$ denotes the \bullet -th angular eigenfrequency of the design, ω_0 is the basic frequency, and $\ell \in \mathbb{N}$ is such that $|\tilde{\omega}_\bullet - \ell\omega_0|$ is minimal.

The optimal design with $N = 3$ has the lowest first eigenfrequency; furthermore, the first three eigenfrequencies of $N = 3$ tend to be closer to the frequencies present in the periodic load f . As a result, there is stronger effect of resonance, which results in a worsened performance of peak power when the design is under the time varying load with many frequencies components. This numerical experiments suggests once again that the method we developed in this study is more adapted for optimizing a structure when it is under time-varying load with a small number of harmonic frequencies.

6 Summary

In this study, we have investigated the minimization of the peak power of truss structures under multiple harmonic loads whose driving frequencies are below the lowest resonance frequency of the structure itself. Starting from a general problem formulation, we have exploited the semidefinite representability of the peak power function under the equilibrium condition by exploiting the SOS positivity certificate of trigonometric polynomials. This allows us to extend the results of [Hei+09] to multiple harmonic out-of-phase loads that are decomposed into Fourier series. With this, we have developed an equivalent but generally nonconvex formulation that reduces to a convex setting for in-phase single-frequency loads.

For the general settings, convex reformulation is no longer possible. To address the non-convex problem, we have first introduced a Lagrange-type relaxation by moving the non-convex constraint $\text{Tr}\{X - F^T L(a)^\dagger F\} \leq 0$ —which is a difference of convex functions—into the objective and penalized its violation by a positive penalization factor η . Finally, we neglected the concave term $-\eta \text{Tr}\{F^T L(a)^\dagger F\}$ and derived a convex relaxation. With η large enough, the solution of the convex relaxation is a feasible point for the original non-convex program and hence is its suboptimal solution.

These theoretical results have been numerically illustrated with four examples. These illustrations revealed that the method indeed reduces to the case of [Hei+09] for single-frequency in-phase loads, and for more general cases the method converges to suboptimal points with small KKT residuals, thus providing almost locally optimal solutions.

Furthermore, the numerical examples also uncovered directions for potential future improvements. First, the frequency components of the load must be integer multiples of a basic frequency. Thus, if the basic frequency is small and the driving frequencies of the loads are high, the number of considered frequency components must be large. This also suggests that exploiting the sparsity [Kim+11; Koč21] in the constraint

$$\begin{pmatrix} X & F^T \\ F & L(a) \end{pmatrix} \succeq 0$$

would substantially help with solution of large-scale instances. Finally, the last example has revealed that the presented method applies to loads with frequencies below the first resonance, and not all periodic loads satisfy such assumption. When some of the frequencies components of the load are higher than the first resonance frequency, the peak power minimization remains an open question.

A Semidefinite representability of peak power under harmonic loads

A.1 Nonnegativity certificate of trigonometric polynomial

Readers can find the main results of this subsection in the book [Dum17], which covers applications in signal processing such as filter design. We are interested in the so-called trigonometric polynomials in what follows.

Definition A.1 (Trigonometric polynomial) *A trigonometric polynomial f is a real-valued function with a variable in \mathbb{T} . It takes the form:*

$$f(z) = \sum_k c_k z^{-k} \quad (\text{A.1})$$

with finitely many non-zero coefficients c_k with $k \in \mathbb{Z}$. Being real valued for all $z \in \mathbb{T}$, the sequence of coefficients must satisfy the symmetry condition $\forall k \in \mathbb{Z}, c_{-k} = c_k^*$. The degree of f is the largest index k of the non-zero coefficient c_k .

A *nonnegative* trigonometric polynomial is one that satisfies $f(z) \geq 0, \forall z \in \mathbb{T}$. We want to obtain a tractable characterization of the nonnegativity of a trigonometric polynomial. For univariate trigonometric polynomials, a powerful characterization is available using sum-of-squares (SOS).

Definition A.2 (SOS trigonometric polynomial) *A SOS trigonometric polynomial f is such that there exists a finite family of complex polynomials $\{h_j(z) = \sum_{k=0}^N h_{jk} z^k\}_{j=1, \dots, r}$ satisfying*

$$\forall z, f(z) = \sum_{j=1}^r h_j(z) h_j(z)^*. \quad (\text{A.2})$$

Being SOS, such a polynomial is trivially nonnegative. However, the converse is true for univariate trigonometric polynomials only; we refer the reader to [Dum17, Theorem 1.1]. The converse is false for trigonometric polynomials with more than 2 variables. The proof relies on a careful study of the position of roots of a univariate polynomial.

Theorem A.1 (SOS certificate of nonnegativity) *A univariate trigonometric polynomial is nonnegative iff it is SOS.*

The next theorem provides a link between the SOS characterization and PSD matrices. Testing if a trigonometric polynomial is SOS has been shown to be equivalent to the existence of a PSD matrix representation of the polynomial. Consider the following vector ψ

$$\psi(z) = (1, z, \dots, z^N)^T \quad (\text{A.3})$$

containing all the canonical basis polynomials up to degree N . A trigonometric polynomial has a so-called Gram matrix representation.

Definition A.3 *Consider a degree N trigonometric polynomial f . A Hermitian matrix $Q \in \mathbb{S}^{N+1}$ is a Gram matrix of f if*

$$\forall z, f(z) = \psi(z)^* Q \psi(z). \quad (\text{A.4})$$

There exists a family of constant matrices that establishes a link between Q and the coefficients of f . To see this, we note that

$$\psi(z)^* Q \psi(z) = \text{Tr} \{ \psi(z) \psi(z)^* Q \}, \quad (\text{A.5})$$

where

$$\psi(z) \psi(z)^* = \begin{pmatrix} 1 & z^{-1} & z^{-2} & \dots & z^{-N} \\ z & 1 & z^{-1} & \ddots & \\ z^2 & z & 1 & \ddots & \\ \vdots & \ddots & \ddots & \ddots & z^{-1} \\ z^N & & & z & 1 \end{pmatrix}. \quad (\text{A.6})$$

By defining matrices Λ_k with Toeplitz structure,

$$(\Lambda_k)_{i,j} = 1 \iff j - i = k \quad (\text{A.7})$$

and $(\Lambda_k)_{i,j} = 0$ otherwise, we see that $\psi(z) \psi(z)^* = \sum_{k=-N}^N \Lambda_k z^{-k}$. Thus, by identifying the coefficients, we also observe that

$$\forall z, f(z) = \sum_k c_k z^{-k} = \sum_k \text{Tr} \Lambda_k Q z^{-k} \iff \forall k, c_k = \text{Tr} \Lambda_k Q. \quad (\text{A.8})$$

The Gram matrix Q of a trigonometric polynomial is not unique.

Example A.1 *Let us now consider the degree-2 trigonometric polynomial*

$$f(z) = c_{-2} z^2 + c_{-1} z + c_0 + c_1 z^{-1} + c_2 z^{-2}$$

and we search a Gram matrix representation $Q = \begin{pmatrix} q_{00} & q_{01} & q_{02} \\ \bar{q}_{01} & q_{11} & q_{12} \\ \bar{q}_{02} & \bar{q}_{12} & q_{22} \end{pmatrix}$. Q must satisfy:

$$\begin{aligned} k = -2 : \text{Tr} \{ \Lambda_{-2} Q \} &= q_{02} = c_{-2}, \\ k = -1 : \text{Tr} \{ \Lambda_{-1} Q \} &= q_{01} + q_{12} = c_{-1}, \\ k = 0 : \text{Tr} \{ \Lambda_0 Q \} &= q_{00} + q_{11} + q_{22} = c_0, \end{aligned} \quad (\text{A.9})$$

and so forth. The constant matrices Λ_k for degree-2 trigonometric polynomials are

$$\Lambda_{-2} = \begin{pmatrix} 0 & 0 & 0 \\ 0 & 0 & 0 \\ 1 & 0 & 0 \end{pmatrix} \quad \Lambda_{-1} = \begin{pmatrix} 0 & 0 & 0 \\ 1 & 0 & 0 \\ 0 & 1 & 0 \end{pmatrix} \quad \Lambda_0 = \begin{pmatrix} 1 & 0 & 0 \\ 0 & 1 & 0 \\ 0 & 0 & 1 \end{pmatrix} \quad (\text{A.10})$$

and so on.

Finally, we state the main theorem of this section.

Theorem A.2 (Semidefinite certificate of nonnegativity, [Dum17, Theorem 2.5]) *A trigonometric polynomial is SOS iff there exists a Gram matrix Q that is positive semidefinite.*

For reader's information, we notice that the smallest number r of complex polynomials h_j such that $f(z) = \sum_j h_j(z)h_j(z)^*$ is upper bounded by the rank of PSD matrices Q satisfying linear constraints (A.8). Since Q has size $(N+1) \times (N+1)$, r is at most $N+1$. To find an SOS representation with minimal number of h_j is equivalent to a rank minimization problem.

Suppose that f is SOS and that we have found $Q \succeq 0$ being a Gram matrix of f . By the spectral decomposition of $Q = \sum_j \sigma_j v_j v_j^*$ where σ_j are the positive eigenvalues of Q and v_j the corresponding unitary family of eigenvectors, the following equation allows to find complex polynomials h_j :

$$f(z) = \varphi(z)^* Q \varphi(z) \quad (\text{A.11})$$

$$= \sum_j \sigma_j (\varphi(z)^* v_j) (\varphi(z)^* v_j)^* \quad (\text{A.12})$$

Thus $h_j(z) = \sqrt{\sigma_j} \varphi(z)^* v_j$.

A.2 Semidefinite representability of peak power functional

In this subsection, we show that the peak power is SDr, using the second type of semidefinite representation in Definition 4.2, with respect to the Fourier coefficients of the nodal velocities v . We recall that the peak power is a function defined as

$$p[c(v)] = \max_{t \in [0, \frac{2\pi}{\omega}]} \left\{ \left| \sum_{n,m} c_n(f)^T c_m(v) e^{i(n+m)\omega t} \right| \right\}. \quad (\text{A.13})$$

By collecting the coefficients of the complex exponential, we observe that

$$\sum_{n,m} c_n(f)^T c_m(v) e^{i(n+m)\omega t} = \sum_{k=-2N}^{2N} \sum_{n=-N}^N c_{k-n}(f)^T c_n(v) e^{ik\omega t}, \quad (\text{A.14})$$

with the inner summation conveniently written over $-N$ to N . We have extended the sequence $\{c_n(f)\}$ for $|n|$ strictly larger than N by 0. In addition, set $z = e^{-i\omega t}$ and define $q_k = \sum_{n=-N}^N c_{k-n}(f)^T c_n(v)$. Then, it follows that

$$p[c(v)] = \max_{z \in \mathbb{T}} |q(z)|, \quad (\text{A.15})$$

where $q(z) = \sum_{k=-2N}^{2N} q_k z^{-k}$. We have $q_0 = 0$, since the average power over one period delivered by the harmonic load is equal to 0.

Next, we assume $(\theta, c(v))$ in the epigraph of $p[\cdot]$. Then, we have

$$\theta \geq p[c(v)] \iff \theta \pm q \text{ are positive trigonometric polynomials.} \quad (\text{A.16})$$

By Theorem A.2 and using the notation in Example A.1, and since the coefficients of $\theta \pm q$ depend linearly on θ and $c(v)$, $(\theta, c(v))$ is in the epigraph of the peak power function *iff* there exists $Q_1 \in \mathbb{S}_+^{2N+1}$ and $Q_2 \in \mathbb{S}_+^{2N+1}$ that satisfy the equality constraints of (4.5). Therefore, the peak power function is SDr. More precisely, $\theta \pm q$ are positive *iff* the following two sequences of linear equations hold:

$$\exists Q_1 \in \mathbb{S}_+^{2N+1}, \begin{cases} \theta = \text{Tr}\{\Lambda_0 Q_1\}, \\ q_k = \text{Tr}\{\Lambda_k Q_1\}, \forall k \neq 0, \end{cases} \quad (\text{A.17a})$$

$$\exists Q_2 \in \mathbb{S}_+^{2N+1}, \begin{cases} -\theta = \text{Tr}\{\Lambda_0 Q_2\}, \\ -q_k = \text{Tr}\{\Lambda_k Q_2\}, \forall k \neq 0. \end{cases} \quad (\text{A.17b})$$

Finally, we insert the expression $q_k = \sum_{n=-N}^N c_{k-n}(f)^T c_n(v)$.

Example A.2 (Single harmonic $N = 1$) We take the Hermitian matrices $Q_1, Q_2 \in \mathbb{S}^3$ and $f(t) = c_{-1}(f)e^{-i\omega t} + c_1(f)e^{i\omega t}$:

$$\begin{aligned} q_{-2} &= c_{-1}(f)^T c_{-1}(u), \\ q_{-1} &= c_{-1}(f)^T c_0(u) + c_0(f)^T c_{-1}(u) = 0, \\ q_1 &= c_1(f)^T c_0(u) + c_0(f)^T c_1(u) = 0, \\ q_2 &= c_1(f)^T c_1(u). \end{aligned} \quad (\text{A.18})$$

Example A.3 (Double harmonic $N = 2$) We take $Q_1, Q_2 \in \mathbb{S}^5$ and

$$f(t) = c_{-2}(f)e^{-2i\omega t} + c_{-1}(f)e^{-i\omega t} + c_1(f)e^{i\omega t} + c_2(f)e^{2i\omega t}.$$

Therefore, it holds that

$$\begin{aligned} q_{-4} &= c_{-2}(f)^T c_{-2}(u) + c_{-3}(f)^T c_{-1}(u) + c_{-4}(f)^T c_0(u) + c_{-5}(f)^T c_1(u) + c_{-6}(f)^T c_2(u) \\ &= c_{-2}(f)^T c_{-2}(u), \\ q_{-3} &= c_{-1}(f)^T c_{-2}(u) + c_{-2}(f)^T c_{-1}(u) + c_{-3}(f)^T c_0(u) + c_{-4}(f)^T c_1(u) + c_{-5}(f)^T c_2(u) \\ &= c_{-1}(f)^T c_{-2}(u) + c_{-2}(f)^T c_{-1}(u), \\ q_{-2} &= c_0(f)^T c_{-2}(u) + c_{-1}(f)^T c_{-1}(u) + c_{-2}(f)^T c_0(u) + c_{-3}(f)^T c_1(u) + c_{-4}(f)^T c_2(u) \\ &= c_{-1}(f)^T c_{-1}(u), \\ q_{-1} &= c_1(f)^T c_{-2}(u) + c_0(f)^T c_{-1}(u) + c_{-1}(f)^T c_0(u) + c_{-2}(f)^T c_1(u) + c_{-3}(f)^T c_2(u) \\ &= c_1(f)^T c_{-2}(u) + c_{-2}(f)^T c_1(u). \end{aligned} \quad (\text{A.19})$$

Then, by the symmetry condition, we receive

$$\begin{aligned} q_4 &= c_2(f)^T c_2(u), \\ q_3 &= c_1(f)^T c_2(u) + c_2(f)^T c_1(u), \\ q_2 &= c_1(f)^T c_1(u), \\ q_1 &= c_{-1}(f)^T c_2(u) + c_2(f)^T c_{-1}(u). \end{aligned} \quad (\text{A.20})$$

B Independence of peak power of non-physical solution

To state the independence of peak power with non-physical solution, we need to introduce the generalized eigenvalue problem related to $K(a)$ and $M(a)$. The generalized eigenvalue problem consists of finding λ and w such that

$$K(a)w = \lambda M(a)w. \quad (\text{B.1})$$

By the construction of $M(a)$ and $K(a)$, we can show that $\ker M(a) \subseteq \ker K(a)$ (see [AK08]). Any solution w in the null space of $M(a)$ is thus a trivial solution of the eigenproblem. To eliminate this case, we define the so-called well-defined eigenproblem:

Definition B.1 (Well-defined eigenproblem) *The well-defined solution of (B.1) is a pair of (λ, w) such that*

$$K(a)w = \lambda M(a)w \quad (\text{B.2})$$

and $w \notin \ker M(a)$.

For any feasible a , we can show that there is a minimal solution $\lambda_{\min}(a) > 0$ of the well-defined eigenproblem. The following proposition is true for $\lambda_{\min}(a)$:

Proposition B.1 (LMI characterization of minimal solution, [AK08, Proposition 2.2(c)])

$$\forall \omega, \omega^2 < \lambda_{\min}(a) \iff -\omega^2 M(a) + K(a) \succeq 0. \quad (\text{B.3})$$

Lemma B.1 (Characterization of the range of dynamic stiffness matrices) *If $(a, c(v))$ is feasible for the peak power minimization, then all the dynamic stiffness matrices $K_{n\omega}(a) = -n^2\omega^2 M(a) + K(a)$ have the same range.*

Proof. $(a, c(v))$ is feasible iff the following constraints are satisfied:

$$a_i \geq 0, a^T q \leq m, -N^2\omega^2 M(a) + K(a) \succeq 0, \quad (\text{B.4})$$

$$(-k^2\omega^2 M(a) + K(a))c_k(v) = ik\omega c_k(f), \forall k. \quad (\text{B.5})$$

By the LMI constraint, each of the $n^2\omega^2$ is strictly less than $\lambda_{\min}(a)$. For a fixed n , let us consider the solution of

$$K_{n\omega}(a)c_n(v) = in\omega c_n(f), \quad (\text{B.6})$$

It must have the form $c_n(v) = inK_{n\omega}(a)^\dagger c_n(f) + c_0$ for any $c_0 \in \ker K_{n\omega}(a)$. If $c_0 \notin \ker M(a)$, then $n^2\omega^2$ would be a well-defined solution of the generalized eigenvalue problem. However, this is not possible since $n^2\omega^2 \leq N^2\omega^2 < \lambda_{\min}(a)$.

What we have shown is, in fact, that $\ker K_{n\omega}(a) = \ker M(a)$ for all n . By orthogonal complementarity, the range of $\ker K_{n\omega}(a)$ is the same for all n . ■

Finally, if all $c_n(f)$ are in the range of $K_{n\omega}(a)$,

$$\forall m, c_m(f)^T c_n(v) = c_m(f)^T K_{n\omega}(a)^\dagger c_n(f). \quad (\text{B.7})$$

The peak power is thus independent of the nonphysical solution, since its semidefinite representation is also independent of the nonphysical solution.

C Convex relaxation of the peak power minimization

We recall the peak power minimization under equilibrium equation constraint

$$\begin{aligned} & \min_{a, c(v), \theta, Q_1, Q_2} \theta \\ & \text{s.t.} \begin{cases} a_i \geq 0, a^T q \leq m, -N^2\omega^2 M(a) + K(a) \succeq 0, \\ (-k^2\omega^2 M(a) + K(a))c_k(v) = ik\omega c_k(f), \forall k = -N, \dots, N, \\ \theta = \text{Tr}\{\Lambda_0 Q_1\} = -\text{Tr}\{\Lambda_0 Q_2\}, \\ q_k = \text{Tr}\{\Lambda_k Q_1\} = -\text{Tr}\{\Lambda_k Q_2\}, \forall k \neq 0, \\ Q_1, Q_2 \succeq 0. \end{cases} \quad (\mathcal{P}_{\text{pp}}) \end{aligned}$$

The coefficients q_k are written as

$$\forall k \in \{-2N, \dots, 2N\}, q_k = \sum_{n=-N}^N c_{k-n}(f)^T c_n(v), \quad (\text{C.1})$$

with the convention that $c_m(f) = 0$ if $|m| > N$. Due to the symmetry condition $c_{-k}(v) = \overline{c_k(v)}$, we only need to consider equilibrium equations $(-k^2\omega^2 M(a) + K(a))c_k(v) = ik\omega c_k(f)$ for $k \in \{1, \dots, N\}$. Thus,

$$\begin{aligned} q_k &= \sum_{n=-N}^N c_{k-n}(f)^T c_n(v) \\ &= \sum_{n=1}^N c_{n-k}(f)^* c_n(v) + c_n(v)^* c_{k+n}(f) \\ &= \sum_{n=1}^N c_{n-k}(f)^* K_{n\omega}(a)^\dagger in\omega c_n(f) + (in\omega c_n(f))^* K_{n\omega}(a)^\dagger c_{k+n}(f). \end{aligned} \quad (\text{C.2})$$

Let us define $Dc(f) = (i\omega c_1(f)^T \ \dots \ in\omega c_N(f)^T)^T$, a column block vector such that each block corresponds to the vector $in\omega c_n(f)$. Similarly, we consider $c(f)$, a column block vector with block $c_n(f)$. Using the shifting operator $T_k c(f)$ such that the n -th block of $T_k c(f)$ is $c_{n+k}(f)$, we can see q_k as

$$q_k = (T_{-k}c(f))^* L_{N,\omega}(a)^\dagger Dc(f) + (Dc(f))^* L_{N,\omega}(a)^\dagger T_k c(f), \quad (\text{C.3})$$

where $L_{N,\omega}(a) = \text{diag}\{K_\omega(a), \dots, K_{N\omega}(a)\}$. By convention, $c_m(f)$ is zero for $m > N$. We see that $T_k c(f) = 0$ for any $k \geq N$. Thus, we define the matrix F such that

$$F = (T_{N-1}c(f) \ \dots \ T_1c(f) \ Dc(f) \ T_{-1}c(f) \ \dots \ T_{-2N}c(f)). \quad (\text{C.4})$$

For example, consider $N = 3$ and $c(f) = (c_1(f)^T \ c_2(f)^T \ c_3(f)^T)^T$. The matrix F is then

$$F = \begin{pmatrix} c_3(f) & c_2(f) & i\omega c_1(f) & c_0(f) & \overline{c_1(f)} & \overline{c_2(f)} & \dots & 0 \\ 0 & c_3(f) & 2i\omega c_2(f) & c_1(f) & c_0(f) & \overline{c_1(f)} & \dots & 0 \\ 0 & 0 & 3i\omega c_3(f) & c_2(f) & c_1(f) & c_0(f) & \dots & \overline{c_3(f)} \end{pmatrix}. \quad (\text{C.5})$$

If $X = F^* L_{N,\omega}(a)^\dagger F$, then there are constant matrices C_k such that

$$q_k = \text{Tr}\{C_k X\}. \quad (\text{C.6})$$

By introducing the Hermitian variable X of size $3N \times 3N$, the peak power minimization problem (\mathcal{P}_{pp}) is equivalent to

$$\begin{aligned} &\min_{a, X, \theta, Q_1, Q_2} \theta \\ &\text{s.t.} \begin{cases} a_i \geq 0, a^T q \leq m, -N^2\omega^2 M(a) + K(a) \succeq 0, \\ c_k(f) \in \text{Range}\{-k^2\omega^2 M(a) + K(a)\}, \forall k \in \{1, \dots, N\}, \\ X = F^* L_{N,\omega}(a)^\dagger F, \\ \theta = \text{Tr}\{\Lambda_0 Q_1\} = -\text{Tr}\{\Lambda_0 Q_2\}, \\ \text{Tr}\{C_k X\} = \text{Tr}\{\Lambda_k Q_1\} = -\text{Tr}\{\Lambda_k Q_2\}, \forall k \neq 0, \\ Q_1, Q_2 \succeq 0, \end{cases} \end{aligned} \quad (\text{C.7})$$

where \mathcal{C} is the linear operator $X \mapsto (\text{Tr}\{C_k X\})_{k=-2N, \dots, 2N}$. Finally, using the techniques presented in Sections 4.3 and 4.4, the previous problem is at first equivalent to

$$\begin{aligned} & \min_{a, X, \theta, Q_1, Q_2} \theta \\ & \text{s.t.} \begin{cases} a_i \geq 0, a^T q \leq m, -N^2 \omega^2 M(a) + K(a) \succeq 0, \\ \begin{pmatrix} X & F^* \\ F & L_{N, \omega}(a) \end{pmatrix} \succeq 0, \\ X = F^* L_{N, \omega}(a)^\dagger F, \\ \theta = \text{Tr}\{\Lambda_0 Q_1\} = -\text{Tr}\{\Lambda_0 Q_2\}, \\ \text{Tr}\{C_k X\} = \text{Tr}\{\Lambda_k Q_1\} = -\text{Tr}\{\Lambda_k Q_2\}, \forall k \neq 0, \\ Q_1, Q_2 \succeq 0, \end{cases} \end{aligned} \quad (\text{C.8})$$

and its Lagrange relaxation reads as

$$\begin{aligned} & \min_{a, X, \theta, Q_1, Q_2} \theta + \eta \text{Tr}\{X\} - \eta \text{Tr}\{F^* L_{N, \omega}(a)^\dagger F\} \\ & \text{s.t.} \begin{cases} a_i \geq 0, a^T q \leq m, -N^2 \omega^2 M(a) + K(a) \succeq 0, \\ \begin{pmatrix} X & F^* \\ F & L_{N, \omega}(a) \end{pmatrix} \succeq 0, \\ \theta = \text{Tr}\{\Lambda_0 Q_1\} = -\text{Tr}\{\Lambda_0 Q_2\}, \\ \text{Tr}\{C_k X\} = \text{Tr}\{\Lambda_k Q_1\} = -\text{Tr}\{\Lambda_k Q_2\}, \forall k \neq 0, \\ Q_1, Q_2 \succeq 0. \end{cases} \end{aligned} \quad (\text{C.9})$$

By discarding the non convex term $\text{Tr}\{F^* L_{N, \omega}(a)^\dagger F\}$ we find the convex relaxation with penalty which evaluates as

$$\begin{aligned} & \min_{a, X, \theta, Q_1, Q_2} \theta + \eta \text{Tr}\{X\} \\ & \text{s.t.} \begin{cases} a_i \geq 0, a^T q \leq m, -N^2 \omega^2 M(a) + K(a) \succeq 0, \\ \begin{pmatrix} X & F^* \\ F & L_{N, \omega}(a) \end{pmatrix} \succeq 0, \\ \theta = \text{Tr}\{\Lambda_0 Q_1\} = -\text{Tr}\{\Lambda_0 Q_2\}, \\ \text{Tr}\{C_k X\} = \text{Tr}\{\Lambda_k Q_1\} = -\text{Tr}\{\Lambda_k Q_2\}, \forall k \neq 0, \\ Q_1, Q_2 \succeq 0. \end{cases} \end{aligned} \quad (\text{C.10})$$

D Sensitivity analysis of the peak power

We propose here a way to compute the sensitivity of the peak power function with respect to the design variables a using the adjoint model. It will thus be possible to use a general non-linear programming method to find local minima of the peak power, but this is not considered in this study.

To compute the sensitivity of a function $\phi[c(v)]$ with respect to a such that $K_{n\omega} c_n(v) = in\omega c_n(f)$ for $n \in \{-N, \dots, N\}$, we need to write the augmented function $\tilde{\phi}[c(v)]$ with $\lambda_n = \overline{\lambda_{-n}}$:

$$\tilde{\phi}[c(v)] = \phi[c(v)] + \sum_{n=-N}^N \lambda_n^T (K_{n\omega}(a) c_n(v) - in\omega c_n(f)). \quad (\text{D.1})$$

For the sensitivity with respect to a_j , we differentiate and obtain

$$\frac{\partial \tilde{\phi}}{\partial a_j} = \sum_{n=-N}^N \nabla_{c_n(v)} \phi[c(v)]^T \frac{\partial c_n(v)}{\partial a_j} + \sum_{n=-N}^N \lambda_n^T \frac{\partial K_{n\omega}(a)}{\partial a_j} c_n(v) + \lambda_n^T K_{n\omega}(a) \frac{\partial c_n(v)}{\partial a_j}. \quad (\text{D.2})$$

If λ_n are the solutions of the adjoint models $K_{n\omega}(a)\lambda_n = -\nabla_{c_n(v)} \phi[c(v)]$ for $n \in \{-N, \dots, N\}$, then

$$\forall j, \frac{\partial \phi}{\partial a_j} = \frac{\partial \tilde{\phi}}{\partial a_j} = \sum_{n=-N}^N \lambda_n^T \frac{\partial K_{n\omega}(a)}{\partial a_j} c_n(v).$$

For the peak power function $p[c(v)]$ in particular, it is the optimal value of the linear SDP problem

$$\begin{aligned} & \min_{\theta, Q_0, Q_1} && \theta \\ & \text{s.t.} && \begin{cases} \theta = \text{Tr}\{\Lambda_0 Q_1\} = -\text{Tr}\{\Lambda_0 Q_2\}, \\ q_k = \text{Tr}\{\Lambda_k Q_1\} = -\text{Tr}\{\Lambda_k Q_2\}, \forall k \neq 0, \\ Q_1, Q_2 \succeq 0, \end{cases} \end{aligned} \quad (\text{D.3})$$

where we insert the expression $q_k = \sum_{n=-N}^N c_{k-n}(f)^T c_n(v)$, which is linear in $c(v)$. To compute the sensitivity of the peak power, we need to compute the sensitivity of a linear conic program with respect to its data defining the linear constraints. This problem has recently been investigated in [Agr+20], which resulted in implementation of the technique in the Python package **CVXPY** [DB16].

Let $\mathcal{P}(q)$ denotes the optimal value of (D.3) as a function of q . by the chain rule we obtain that

$$\nabla_{c_n(v)} p[c(v)] = \sum_{k=-2N}^{2N} \frac{\partial \mathcal{P}}{\partial q_k} c_{k-n}(f). \quad (\text{D.4})$$

Thus, we can compute the sensitivity $\frac{\partial p[c(v)]}{\partial a_j}$ using the adjoint model method. At each fixed design vector a , we first solve for direct models $K_{n\omega}(a)c_n(v) = in\omega c_n(f)$ and follow with the solution of adjoint models $\forall n \in \{-N, \dots, N\}$:

$$K_{n\omega}(a)\lambda_n = \sum_{k=-2N}^{2N} \frac{\partial \mathcal{P}}{\partial q_k} c_{k-n}(f). \quad (\text{D.5})$$

Then, the sensitivities are evaluated as $\frac{\partial p[c(v)]}{\partial a_j} = \sum_{n=-N}^N \lambda_n^T \frac{\partial K_{n\omega}(a)}{\partial a_j} c_n(v)$.

If a satisfies the LMI $\begin{pmatrix} X & F \\ F^* & L_{N,\omega}(a) \end{pmatrix} \succeq 0$, it is guaranteed that the right hand side of the adjoint model (D.5) is in the range of $K_{n\omega}(a)$.
