Egalitarian Pooling and Sharing of Longevity Risk a.k.a.

The Many Ways to Skin a Tontine Cat

February 2, 2024

Abstract

There is little disagreement among insurance actuaries and financial economists about the societal benefits of longevity-risk pooling in the form of life annuities, defined benefit pensions, self-annuitization funds, and even tontine schemes. Indeed, the discounted value or cost of providing an income for life is lower – in other words, the amount of upfront capital required to generate a similar income stream with the same level of statistical safety is lower – when participants pool their financial resources versus going it alone. Moreover, when participants' financial circumstances and lifespans are homogenous, there is consensus on how to share the "winnings" among survivors, namely by distributing them equally among survivors, a.k.a. a uniform rule. Alas, what is lesser-known and much more problematic is allocating the winnings in such a pool when participants differ in wealth (contributions) and health (longevity), especially when the pools are relatively small in size. The same problems arise when viewed from the dual perspective of decentralized risk sharing (DRS). The positive correlation between health and income and the fact that wealthier participants are likely to live longer is a growing concern among pension and retirement policymakers. With that motivation in mind, this paper offers a modelling framework for distributing longevity-risk pools' income and benefits (or tontine winnings) when participants are heterogeneous. Similar to the nascent literature on decentralized risk sharing, there are several equally plausible arrangements for sharing benefits (a.k.a. "skinning the cat") among survivors. Moreover, the selected rule depends on the extent of social cohesion within the longevity risk pool, ranging from solidarity and altruism to pure individualism. In sum, actuarial science cannot really offer or guarantee uniqueness, only a methodology.

1 Introduction

1.1 Motivation

One of the hallmarks of a developed country is the existance of a national pension scheme which forces all working citizens to contribute savings to a retirement collective, which is then used to pay retirement annuities. National pension schemes are distinct from corporate retirement plans, which (arguably) involve more homogenous groups and whose financial generosity is (arguably) at the discretion of employers.

For example, in a stylized national pension scheme, all workers might contribute 10,000 (real, inflation-adjusted) euros per year in mandatory premiums in exchange for a benefit of 27,000 (real, inflation-adjusted) euros per year beginning at retirement age 65. Therefore, a citizen who makes these contributions during 40 working years, for example, from age 25 until age 65, and then lives to (and then dies exactly at) age 85, will earn an internal rate of return of 1% per year, in real terms.¹

This compares favourably with other real risk-free investments around the world and is effectively guaranteed by the national government. The paternalistic calculus is to force all citizens to participate since many would be unlikely to do so on their own or be able to generate these investment returns themselves.

Alas, the challenge – and impetus for this investigation – is what happens to those unhealthy retirees who don't spend 20 years in retirement and do not live to age 85 in the above example. Those who are unfortunate to live 10 years to age 75, for example, will actually earn a negative internal rate of return of -1.6% per year in real (inflationadjusted) terms. Indeed, contributing a (non-PV adjusted) total of 400,000 euros over the entire life in exchange for only 270,000 euros is not a good investment, especially considering they were forced to participate.

Now, in defence of this stylized national pension scheme, the conventional and centuriesold response by pension economists and insurance actuaries is that for every unlucky person who only lives to age 75 there is another lucky one who lives to a ripe old age 95. They would receive $810,000 = 30 \times 27,000$ euro worth of payments during retirement and thus earn an even better 2% inflation-adjusted return.² Moreover, these defenders argue, that is the nature of longevity risk pooling. Winners and losers are only known at the end, *ex post*, but everyone benefits from longevity pooling, *ex ante*.

Unfortunately, there is a well-known and alarming body of evidence that survival in a group of equally aged persons is not analogous to a series of i.i.d. coin tosses. Whether due to genetics, environment or even lifestyle choices, longevity prospects are heterogenous for individuals at the same chronological age. The most widely cited work documenting

¹Explanation: The 40-year FV of the 10,000 euro is 487,766 euro, which is equal to the 20-year PV of the 27,000 euro, when the rate is equal to 1%. And, since both cash flows are inflation-adjusted, the implied rate is real. These numbers (2.7 multiple between benefit and contribution) do not correspond to any particular country and are meant as an indicative example.

²The FV for the 40 years (of 10,000) is equal to the PV for the 30 years (of 27,000) when the rate is set to 2%.

this effect is Chetty et al. (2016). For these less fortunate groups, there is little chance they will live to an advanced age and benefit from the insurance aspects of longevity risk pooling. Within society these groups have a legitimate claim that national pension schemes aren't fair or equitable. The most widely cited article linking income (or wealth) to life expectancy (in the US) is the study by Chetty et al. (2016). Other researchers have looked at non-financial factors for the so-called *stochastic longevity gap* (a.k.a. the non-homogeneity) vis a vis the implications for pension plans, both from a theoretical and empirical perspective. More on this later.

This problem is more than an academic exercise in probability or a theoretical dilemma. In early 2023, a group representing Aboriginal Australians filed suit claiming the state pension discriminates against them because their life expectancy is much lower than non-aboriginals. Most live to their mid 70s, while the rest of Australia live into their 80s and 90s. Although stochastic, their internal rate of return will fall far short of the safest risk-free alternative. The case has garnered much international attention and is pending before their Federal Court, and various groups are expressing similar concerns worldwide. This is the impetus for our paper; namely, it goes back to the very first principles and asks *how should longevity risk be shared?* Another case in which this arises – and perhaps slightly more controversial position – is that unhealthy males with much lower longevity prospects should (also) be considered for similar treatment; namely, receive higher payments for the same level of contributions.

The literature – on the heterogeneity of longevity and the impact on pension fairness – is vast and growing.³

And, while a footnote list is not a proper review of the unique contribution of every paper in the literature, their underlying messages are identical. Namely, the most crucial empirical takeaway is the existence of an identifiable group within society that will not live as long as the fortunate ones. Yet, most national and corporate pension schemes are all pooled together in one sizeable longevity-risk-sharing fund or pool.

With the motivation and background out of the way, this paper offers a modelling framework for distributing longevity-risk pools' income and benefits when participants are heterogeneous. Our central insight is that – similar to the nascent literature on decentralized risk sharing – there are several equally plausible rules for sharing benefits (a.k.a. "skinning the cat") among survivors. Moreover, the selected rule depends on the extent of social cohesion within the longevity risk pool, ranging from solidarity and altruism to pure individualism. The vehicle we choose to use for analyzing longevity risk pooling and sharing is the one-period tontine. Our aim is to demonstrate that there are a multiplicity of feasible arrangements for sharing gains in a one-period model and as we progress through these models, we will draw highlights and comparisons to the dilemma of pension equity.

1.2 Setting the Stage

In this subsection, we "set the stage" for our paper's main theoretical contributions by illustrating the multitude of ways that in theory could allocate gains and losses from longevity. A more formal and very general model – especially as it relates to the notation – will be presented in subsequent sections. For now, imagine the following situation. A group of n investors (a.k.a. retirees) pool together into the following one-period longevity risk-sharing scheme. They each invest or allocate $\pi_j > 0$ dollars at time zero into an account earning a one-plus risk-free rate: $(1 + R) \ge 1$, but they face a $p_j > 0$ probability of surviving to the end of the period. They decide to share the total fund among survivors, which is also known as a one-period tontine. For the sake of a simple numerical example, we will assume n = 3, $R \ge 0$. The first retiree invests $\pi_1 = \$80$, the second $\pi_2 = \$50$ and third $\pi_3 = \$20$. The one-period survival probabilities are: $p_1 = 20\%$, $p_2 = 50\%$, $p_3 = 80\%$, which reflect mortality rates over a decade at old, middle and early retirement ages. The two tables in subsections 1.2 and 1.3 summarize the in- and outputs for the case in which R = 0, but the example itself would apply for any deterministic $R \ge 0$.

$\pi_1 =$	\$80	$p_1 =$	20%
$\pi_2 =$	\$50	$p_2 =$	50%
$\pi_3 =$	\$20	$p_3 =$	80%
$\sum \pi_k$	\$150.00	and	R = 0%

Clearly, investor j = 1 has placed the most at risk because he/she faces an 80% probability of dying and losing it all and has invested \$80. Think of the function $q(\pi, p) =$ π/p as a theoretical measure of "money at risk", although $g(\pi, p)$ could be defined as any function that is increasing in its first argument and decreasing in its second. Regardless of how exactly "money at risk" is measured, investor i = 3 risks a mere \$20, and faces an 80% probability of surviving, so their $q(\pi, p) = \pi/p = 25$. Note that the third investor expects to survive since $p_3 > 0.5$, while the first investor doesn't. Ergo, and perhaps even for ethical reasons, investor j = 1, with a $q(\pi, p) = 400$, should be entitled to a larger share of the gains if he/she happens to (get lucky) and survive. That should be obvious, the question is how much more. There are: $2^n = 2^3 = 8$ different scenarios, the most vexing is the ω in which everyone dies. Now, one can set the rules of this game in many ways – perhaps even by offering refunds to beneficiaries – but we will assume that in the scenario in which everyone dies, which has a $(1 - p_1)(1 - p_2)(1 - p_3) = 8\%$ probability (assuming independence), the \$150 is taxed, taken by the Government and lost to participants. Why should the Government be entitled to a joint life insurance policy on n heads? Perhaps it's compensation for enforcing the contract in the other $2^n - 1 = 7$ scenarios. Or, it's how things work in the real world for unclaimed money in bank accounts. Either way, that's our assumption for $\omega_{(2^n)}$. There are other n=3 scenarios that are trivial, namely when there is only one survivor who takes the entire: $\sum \pi_k = \$150$, when R = 0, otherwise the sum is larger. This leaves $2^n - n - 1 = 4$ scenarios in which the fund must be distributed in a non-discriminatory manner. An informal discussion with colleagues indicates the lack of any clear consensus on exactly how the funds should be distributed in each of those 4 non-trivial scenarios in a manner that is perceived as *non-discriminatory*.

Now, we should note that due to the (8%) probability (assuming independence) that everyone dies, the expected investment return to the entire group is strictly less than Rwhen $n < \infty$. In further sections, we will return to the implications of this fact, as it relates to matters of fairness. Here we simply explain why. In 7 scenarios, the entire pool shares $150 \times (1+R)$, but in the 8th (all dead) one, the pool gets nothing. Ergo, the pool's expected payout is 92% times $150 \times (1+R)$ plus 8% times zero, which is $138 \times (1+R)$, and the pool's expected investment return is: $(138/150) \times (1+R) - 1$, which is strictly less than R. Again, we will return to this matter – and how one can fix the expected return so that it isn't less than R – later on in the paper.

1.3 One Possible Allocation

As noted earlier, we sent the above query to a number of specialists (who are noted and thanked at the end of this paper) and received a variety of replies. Here we offer one possible way or "rule" that can be used to distribute the \$150, or more generally the 150(1 + R), when $R \ge 0$, in the four *non-trivial* scenarios. This solution or allocation should help set the stage for a more general discussion later on.

ω_1	W_1	ω_2	W_2	ω_3	W_3	ω_4	W_4	ω_5	W_5	ω_6	W_6	ω_7	W_7	ω_8	W_8
1	114.29	0	0	0	0	1	141.18	1	120	1	150	0	0	0	0
1	28.57	1	120	0	0	0	0	1	30	0	0	1	150	0	0
1	7.14	1	30	1	150	1	8.82	0	0	0	0	0	0	0	0
8%		32%		32%		8%		2%		2%		8%		8%	

We note here that although our discussion and methodology is applicable to the case when $R \geq 0$, the numbers displayed in the table are for R = 0. The logic for our allocation is as follows. Start with scenario ω_1 , where all three investors are alive, an event with 8% probability. The first $(\pi_1 = \$80, p_1 = 0.20)$ investor thinks to him or herself: Had I used π_1 to purchase a pure endowment from an insurance company – my payout would have been: $\pi_1/p_1 \times (1+R) = \$400 \times (1+R)$, assuming a technical interest or valuation rate equal to R. This is an insurance claim, but one in which a limited pool of money is available. The insurance claim is $g(\pi, p) \times (1+R)$, where $g(\pi, p)$ is the (above noted) "money at risk" function. Likewise, the second ($\pi_2 = \$50, p_2 = 0.50$) investor is entitled to an insurance claim of: $\pi_2/p_2 \times (1+R) = \$100 \times (1+R)$, and the third investor claims: $\pi_3/p_3 \times (1+R) = \$25 \times (1+R)$, using the same actuarial logic. In total, for the three survivors in scenario ω_1 , the aggregate insurance claim is $\mathbf{C}(\omega_1) := \sum_{k=1}^n (\pi_k/p_k) \times (1+R) = \sum_{k=1}^n g(\pi_k, p_k) \times (1+R) = \$525 \times (1+R)$, but alas there is only $(1+R) \sum_{k=1}^n \pi_k = (1+R) \times \150 available to distribute to the pool.

So, our proposed rule is to give investors the relative fraction, i.e. their *personal* insurance claim against the *aggregate* insurance claim of the available funds. The first investor claims $400 \times (1+R)$ out of a total $525 \times (1+R)$, which is 76.19%, or $(0.762)(150) \times (1+R) = \$114.3 \times (1+R)$ from the available $\$150 \times (1+R)$. This is *more* than individual i = 1 invested, but *less* than his *personal* insurance claim. Algebraically this investor

takes: $(1 + R) \times (\pi_1/p_1)/\mathbb{C}(\omega_1)$. The same logic gives the second investor $100 \times (1 + R)$ out of $525 \times (1 + R)$, or 19.04% of the $\$150 \times (1 + R)$ available, which is $\$28.57 \times (1 + R)$, and less than the $\pi_2 = \$50$ invested. The third and final investor makes a personal claim of $25 \times (1 + R)$ from an aggregate claim of $525 \times (1 + R)$, a mere 4.76% of the available $\$150 \times (1 + R)$, for a total payout of $\$7.14 \times (1 + R)$. The third investor, like the second, walks away with less than originally invested, while the (relative) winner is investor number one, who gets more than his original $\pi_1 = \$80$.

The same logic can be applied to the other three scenarios $\omega_2, \omega_4, \omega_5$. While the *personal* insurance claim for $(\pi/p) \times (1+R)$ remains the same for each individual survivor, the *aggregate* insurance claim paid to the survivors is lower due to the smaller number of survivors. For example, the value of $\mathbf{C}(\omega_2) = 125 \times (1+R)$, $\mathbf{C}(\omega_4) = 425 \times (1+R)$ and $\mathbf{C}(\omega_5) = 500 \times (1+R)$. Again, these are the denominators for the fractional allocation of end-of-period available funds, where the numerator is the *personal* claim $(\pi_k/p_k) \times (1+R)$.

In sum, while there are many ways to skin the tontine cat our suggested (general) rule for $W_{(i,j)}$, which represents the payout in scenario ω_i (column) and individual j (row) in the above table, can be written as:

$$W_{(i,j)} = (1+R)\sum_{k=1}^{n} \pi_k \times \left(\frac{(\pi_j/p_j) \times I_{(i,j)}}{\sum_{k=1}^{n} (\pi_k/p_k) \times I_{(i,k)}}\right), \quad j = 1, \dots, n \text{ and } i = 1, \dots, 2^n.$$
(1)

where $I_{(i,j)}$ is the (scalar) life status of the j'th investor in the i'th scenario. Note (once again) that our numerical example assumed R = 0, but nothing stops us from using the same rule or allocation for the case of R > 0. Moreover, in the formula above, the variable (1+R) in the nominator and the denominator cancel each other out. For example, under ω_4 , the indicator variables are: $I_{(4,1)} = 1$, $I_{(4,2)} = 0$, $I_{(4,3)} = 1$, and the denominator is $(80/0.2) \times (1+R) \times 1 + (50/0.5) \times (1+R) \times 0 + (20/0.8) \times (1+R) \times 1$, which is the above noted $\mathbf{C}(\omega_4) = \$425 \times (1+R)$. Again, the quantity in brackets in equation (1) is the ratio of *personal* to *aggregate* insurance claim, which is then multiplied by the money available in the pool. And, when $i = 2^n$, which is the ω scenario in which everyone is dead, we define $W_{(i,j)} := 0$, despite the zero in the denominator. Equation (1), which will reappear in many guises and incarnations over the paper, is a *proportional* risk-sharing rule, but other rules will be proposed and analyzed in due time.

The above $W_{(i,j)}$ formula or equation will be parsed, analyzed and refined later on in this paper. Still, at this early stage, we should note that the expression is not defined (and does not make any sense) for the scenario in which all participants die. This can be easily seen since the denominator will be zero in this case.

1.4 The Tontine Fund

As explained in the above example, a single period tontine fund is an investment made by a group of people and an administrator. Participants each invest a certain amount. At the end of the observation period, surviving participants share the proceeds of the tontine fund, while non-surviving participants do not receive anything. If no participant survives, the administrator owns all the proceeds. The tontine fund is self-financing, meaning that only the available proceeds are distributed, and insolvency or default is not possible. Therefore, no solvency capital needs to be set up at the beginning of the contract.

Denuit, Hieber & Robert (2022) and Denuit & Robert (2023) studied single period tontine funds, also known as longevity funds or endowment contingency funds. Indeed, the literature of tontines as well as group self-annuitzation schemes more generally is large and continues to grow.⁴

We consider tontine funds where only the surviving participants (or the administrator in their absence) receive the proceeds. However, it is possible to distribute the proceeds among participants who meet objective criteria other than survival, such as a pre-defined health event, hospitalization, etc. The mathematical description is similar, but we focus only on survival as a trigger for participants to be entitled to proceeds.

In this paper, we will discuss the scenario where initial investments (wealth) and survival probabilities (health) vary among participants, which we call a heterogeneous case. As a special case, we will also examine the situation where all participants invest the same amount and have the same survival probabilities, which we refer to as the homogeneous case.

As we noted earlier in this paper, one concern with (re-introducing) tontines is their actuarial fairness. Previous research has also addressed the problem we mentioned in our introduction. Namely, a single-period tontine where the probability that all members die before the end date is positive, is clearly unfair (mathematically) since the expected return for the group, after accounting for any investment gains, is less than R. To resolve this issue, some researchers have suggested adding an insurance benefit for beneficiaries of deceased members. Indeed, most papers on tontines written in the last few years have all added this element to repair expectations.

While this approach resolves the mathematical problem, this isn't why people by tontines. Indeed, it violates the spirit of the (historical) tontine in which all rights and ownership benefits are lost at death. This isn't why people buy tontines. Furthermore, some members may not have any beneficiaries, leading to yet another unintended redistribution of wealth. In extreme cases, when there is only one person surviving, this creates a moral hazard. In other words, and for many reasons, while adding a death benefit refund or payout "solves" the math, it "ruins" the elegance of the tontine ideal. Instead, the approach we will present in this paper is new or at least different from the recent literature. We introduce a *tontine administrator* as both a technical and real-world solution to some of these issues, instead of artificially adding legacy or bequest payouts. The same administrator could be invoked within when this problem is examined thru the prism of decentralized risk sharing (DRS), although in that context this "new player" would serve as a legal enforcer more than a mechanism for creating actuarial fairness. More on this DRS aspect is discussed in the appendix.

⁴Key papers in that literature include, alphabetically listed, Bernhardt & Donelly (2019), Bernhardt and Qu (2023), Blake, Boardman & Cairns (2014), Chen, Chen & Xu (2022), Donnelly (2018), Donnelly, Guillien & Nielsen (2014), Forman and Sabin (2015), McKeever (2009), Piggott, Valdez & Detzel (2005), Stamos (2008), Weinert and Grundel (2021).

Why an administrator?

The (modern) tontine scheme is designed to eliminate the need for guarantees, capital, and solvency requirements. However, to ensure that all participants in the scheme behave appropriately, an "authority" must monitor and enforce the "rules of the game". This is not just a real-world friction but a critical aspect of the tontine scheme, as it creates the necessary legal and administrative confidence that payouts will be shared according to pre-specified rules. The tontine administrator, who could be a government agency or regulator, is thus, in our view, a key participant in the scheme and must be provided with compensation for their services. This compensation is the extra leftovers noted above, allocated or bequeathed to the tontine administrator when everyone dies. As we will show, if the administrator contributes to the initial investments, this approach may make the scheme actuarially fair and more realistic for implementation.

Indeed, one of the co-authors of this paper was involved in the introduction of a tontine scheme in Canada and can attest to the fact that participants were extremely concerned about who would monitor and oversee the tontine, since the traditional insurance regulators, who demand capital, were absent. Thus, while a utopian version of longevity risk sharing assumes everyone behaves appropriately and discloses their true survival probabilities, we argue that an administrator is required to keep everyone honest.

In sum, this paper introduces a new player into the (modern) tontine literature, an administrator, and shows how they interact and engage with the group, as well as whether or not they might be asked to pay (which means they also contribute to the fund) for the right to administer if indeed they are going to benefit from the tontine leftovers.

1.5 A simple example

Consider two individuals, denoted as person 1 and person 2, who want to participate in a peculiar game of chance. To enter the game, person 1 pays an amount of money denoted by π_1 , while person 2 pays an amount of money denoted by π_2 . Person 1 tosses a two-sided coin, and person 2 rolls a six-sided die. In this game, person 1 is successful if they toss heads, while person 2 is successful if they roll a 1. Person 1 and person 2 are referred to as "participants" in the game.

In addition to the two participants, a third person is involved, known as the "administrator". The administrator is also allowed to contribute to the prize pool by paying an amount of money denoted by π_3 . According to predetermined rules, the administrator is responsible for collecting the money and distributing it after the coin and die are thrown.

If the coin lands on heads and the die does not land on 1, the total amount of $\pi_1 + \pi_2 + \pi_3$ is awarded to person 1. Similarly, if the coin does not land on heads but the die lands on 1, the total amount of $\pi_1 + \pi_2 + \pi_3$ is awarded to person 2. If both participants are successful (i.e., heads and 1 appear after the respective throws), the total proceeds of $\pi_1 + \pi_2 + \pi_3$ are shared by person 1 and person 2 in a well-defined manner. Finally, if both participants are not successful (i.e., neither heads nor 1 appear after their respective throws), the total proceeds of $\pi_1 + \pi_2 + \pi_3$ go to the administrator. At first glance, it may seem unusual that the administrator also contributes an amount of money π_3 to the prize pool. However, in our example, the probability that the administrator will receive the entire prize pool is $\frac{5}{12}$ assuming independence, and thus it seems reasonable that the administrator should also contribute to the prize pool for this chance of winning.

If at most one of the two participants is successful, the rules for paying out the total proceeds are clear. However, in this paper, we seek to answer the following question: What is a reasonable, acceptable, and possible way to allocate the total proceeds $(\pi_1 + \pi_2 + \pi_3)$ in case both participants have a successful throw? A uniform allocation where each participant receives $\frac{\pi_1 + \pi_2 + \pi_3}{2}$ is often seen as 'unfair' because it does not consider that the chances for success are much larger for participant 1 than for participant 2. To address this, we will denote the payouts to participants 1 and 2 in case of a successful throw by β_1 and β_2 , respectively, with

$$\beta_1 + \beta_2 = \pi_1 + \pi_2 + \pi_3.$$

Introducing the indicator variables I_1 and I_2 where I_i is 1 for a successful participant i and 0 otherwise, the payouts W_1 and W_2 can be expressed as follows:

$$(W_1, W_2) = \begin{cases} (\pi_1 + \pi_2 + \pi_3, 0) & : \text{ if } I_1 = 1 \text{ and } I_2 = 0\\ (0, \pi_1 + \pi_2 + \pi_3) & : \text{ if } I_1 = 0 \text{ and } I_2 = 1\\ (0, 0) & : \text{ if } I_1 = 0 \text{ and } I_2 = 0\\ (\beta_1, \beta_2) & : \text{ if } I_1 = 1 \text{ and } I_2 = 1 \end{cases}$$

In order to write down the payout W_3 to the administrator, we introduce the indicator variable I_3 which is defined by

$$I_3 = (1 - I_1) \times (1 - I_2).$$

This indicator variable equals 1 when neither participant is successful (i.e., $I_1 = I_2 = 0$) and 0 otherwise (i.e., $I_1 = 1$ or $I_2 = 1$). The administrator's payoff can be expressed as:

$$W_3 = \begin{cases} 0 & : \text{ if } I_3 = 0 \\ \pi_1 + \pi_2 + \pi_3 & : \text{ if } I_3 = 1 \end{cases}$$

Before playing a gamble, the two participants and the administrator must agree on a series of payments represented by π_1 , π_2 , and π_3 , as well as appropriate values for β_1 and β_2 . In this paper, we will explore such "exotic" gambles or investments and examine the properties that such investments should have. We will not limit ourselves to the case of only two participants and one administrator, but instead consider the general problem of multiple participants and one administrator.

With some of the introductory concepts and notation behind us, the structure of what follows in this paper is organized as follows. Section 2 models and discusses the process of allocating tontine share. The subsequent Section 3 examines a multitute of expressions for the payout of a tontine fund. Then, Section 4 moves on to matters of actuarial fairness, while Section 5 links the tontine fund to (classical) pure endowment insurance. Section 6 looks at internal share allocation schemes and Section 7 concludes the paper. Finally, an appendix numbered Section 8, flushes out the connection between tontine funds more generally and decentralized risk sharing rules.

2 Tontine funds and tontine shares

Let's consider a scenario where a group of n individuals decide to set up a one-period tontine fund. These individuals are referred to as 'participants'. At the beginning of the investment period, each participant i makes an initial (strictly positive) investment π_i in the fund. Our objective is to establish a fair and practical method for the surviving participants to divide the total investment among themselves if one or more of them survives. There is also a possibility that all participants may pass away, in which case, we need to determine what happens to the fund's proceeds. We have an administrator (party n + 1) to manage the fund. The administrator's role is to collect investments at the beginning of the investment period, invest them, and distribute the proceeds (initial investments and returns) to the surviving participants. If all participants pass away, the administrator receives the full proceeds of the fund. The administrator also contributes an initial (non-negative) investment π_{n+1} to the fund to receive these funds in case of no survivals. To make things simpler, we introduce a vector:

$$\boldsymbol{\pi} = \left(\pi_1, \pi_2, \ldots, \pi_n, \pi_{n+1}\right),$$

which we will call the *investment vector*.

The sum of all the investments made by the participants and the administrator, i.e. $\sum_{j=1}^{n+1} \pi_j$, equals the total value of the fund at the time 0. Each participant invests π_i to buy shares or units in the fund. Each participant *i* who survives until time 1 will cash in exchange for his shares. This paper aims to determine a reasonable and acceptable number of units each participant should receive at time 0 for their initial investment of π_i . We will consider both the chance of inheriting part of the tontine fund and the initial investment amount while answering this question.

Let us denote the (strictly positive) number of shares of the tontine fund received by participant i by f_i . The vector **f** defined by

$$\mathbf{f} = (f_1, f_2, \dots, f_n)$$

will be called the *(tontine)* share allocation vector.

At time 0, the total number of shares issued is calculated by adding up all the shares held by participants, represented by $\sum_{j=1}^{n} f_j$. Similarly, the total investment in the fund at that time is calculated by adding up the contributions of all participants and the administrator, represented by $\sum_{j=1}^{n+1} \pi_j$. It's important to note that the administrator does not receive any shares, but in case no participant survives, all proceeds from the fund will belong to the administrator. We define the time-0 value S(0) of a tontine share as follows:

$$S(0) = \frac{\sum_{j=1}^{n+1} \pi_j}{\sum_{j=1}^n f_j}.$$
(2)

Notice that in the denominator of (2), we divide by the number of allocated shares, that is $\sum_{j=1}^{n} f_j$.

At an individual level, the participant's initial investment is not necessarily equal to the time-0 value of his allocated tontine shares. Indeed,

$$\pi_i \neq S(0) \times f_i, \quad \text{for } i = 1, 2, \dots, n.$$

It's important to understand that the symbol \neq means "not necessarily equal" here. This is because, in certain situations, two participants with the same investment π_i might require different rewards. For example, suppose the first person has a lower survival probability due to a higher risk profile (older age). In that case, they might need to be compensated for the extra risk they're taking by receiving more shares than the second person. In other situations, giving more to those with higher survival probabilities could be more appropriate, as they are expected to live longer and will need more financial support. We'll explore this issue further in this text.

It is also important to note that the shares or units are personalized, meaning that they are not anonymous. Each unit sold at time 0 is linked to a particular individual participant in the fund. Moreover, the allocated shares of each participant can only be exchanged by him for cash at the end of the observation period and only if he survives it. If the participant dies during the observation period, then his units become worthless, and we will say that his tontine shares 'die' in that case.

The number of 'surviving' shares (i.e. shares of which the owner is still alive at time 1) is given by

$$\sum_{j=1}^{n} f_j \times I_j,\tag{3}$$

where I_j stands for the indicator variable (Bernouilli r.v.) which equals 1 in case participant j survives and equals 0 otherwise. On the other hand, the number of shares of which the owner has passed away is given by

$$\sum_{j=1}^{n} f_j \times (1 - I_j) \,. \tag{4}$$

Notice that (3) and (4) may be equal to 0 and $\sum_{j=1}^{n} f_j$, respectively, which will happen in case all participants die.

Apart from the survival indicator variables related to the *n* participants, we also introduce an indicator variable I_{n+1} , that is related to the payoff that the administrator will receive. Specifically, $I_{n+1} = 1$ if all participants die and the administrator receives

all the fund's proceeds. Conversely, $I_{n+1} = 0$ if at least one participant survives and the administrator does not receive any proceeds from the fund. Hence,

$$I_{n+1} = \prod_{j=1}^{n} (1 - I_j).$$
(5)

We have that

$$I_{n+1} = 1 \Leftrightarrow I_1 = I_2 = \ldots = I_n = 0. \tag{6}$$

Hereafter, we will always assume that $0 < \Pr[I_{n+1} = 0] < 1$ or, equivalently,

$$0 < \Pr[I_{n+1} = 1] < 1. \tag{7}$$

This assumption means that the probability that all participant die is strictly positive and also strictly smaller than 1.

To differentiate the shares owned by participants of the tontine fund from regular, anonymous shares, we refer to them as 'tontine shares'. These are individualized shares belonging to a specific person that become worthless in the event of their death.

At time 1, the total investment in the tontine fund has grown to

$$(1+R) \times \left(\sum_{j=1}^{n+1} \pi_j\right),$$

where R is the return over the observation period. We assume that R is deterministic. Notice that we can generalize all coming results to the case where R is random, by replacing R by E[R] in all formulas, provided we assume that R and the I_i are mutually independent.⁵

As previously discussed, we calculate share allocations in a manner such that if no participants survive, the administrator receives the entire time - 1 value of the fund. However, if at least one participant survives, the time-1 value of the fund is distributed among the surviving participants, with each surviving share having a value of S(1) which is defined by the following expression:

$$S(1) = (1+R) \times \frac{\left(\sum_{j=1}^{n+1} \pi_j\right)}{\sum_{j=1}^n f_j \times I_j}, \quad \text{if } I_{n+1} = 0.$$
(8)

In case no participants survive, there are no surviving shares left and hence, we don't have to define S(1) in that case.

Let us denote the time - 1 payouts to the participants and the administrator by W_i , for i = 1, 2, ..., n+1. To define these payouts, we have to consider the cases $I_{n+1} = 0$ (i.e. at least one participant survives) and $I_{n+1} = 1$ (i.e. not any participant survives). We will introduce the notations $(W_i | I_{n+1} = 0)$ and $(W_i | I_{n+1} = 1)$ to distinguish between these two cases.

⁵A separate proof of this can be made available by the authors.

The payouts W_i to the participants and the administrator are defined hereafter. Conditional on $I_{n+1} = 0$, i.e. at least one participant survives, we have that the payouts to the participant and the administrator are given by

$$(W_i \mid I_{n+1} = 0) = \begin{cases} S(1) \times f_i \times I_i, & \text{for } i = 1, 2, \dots, n, \\ 0, & \text{for } i = n+1. \end{cases}$$
(9)

Taking into account the expression (8) of S(1), the conditional payouts for the participants can be expressed as follows:

$$(W_i \mid I_{n+1} = 0) = (1+R) \times \left(\sum_{j=1}^{n+1} \pi_j\right) \times \frac{f_i}{\sum_{j=1}^n f_j \times I_j} \times I_i, \quad \text{for } i = 1, 2, \dots, n.$$
(10)

Hence, in case at least one participant survives, the total proceeds of the fund, that is $(1+R) \times \left(\sum_{j=1}^{n+1} \pi_j\right)$, are shared among all surviving participants, where any survivor receives a part of the total funds, which is proportional to the number of tontine shares f_i which were allocated to him at the set-up time of the fund. In this case, the administrator does not receive any payment.

On the other hand, in case $I_{n+1} = 1$, i.e. not any participant survives, the payouts to all parties involved are defined by

$$(W_i \mid I_{n+1} = 1) = \begin{cases} 0, & \text{for } i = 1, 2, \dots, n, \\ (1+R) \times \left(\sum_{j=1}^{n+1} \pi_j\right), & \text{for } i = n+1. \end{cases}$$
(11)

Hence, in case at not any participant survives, the total proceeds of the fund are owned by the administrator, while the (heirs of the) participants do not receive anything.

From (9) and (11), we see that only the conditional payouts for the participants i = 1, 2, ..., n, given that $I_{n+1} = 0$, depend on the number of allocated tontine shares. In other words, $(W_{n+1} | I_{n+1} = 0)$ and $(W_i | I_{n+1} = 1)$, i = 1, 2, ..., n + 1, are independent of the choice on the number of allocated tontine shares.

Remark that the r.v.'s $\sum_{j=1}^{n} f_j \times I_j$ and I_{n+1} are 'mutually exclusive', which is a special kind of countermonotonicity, introduced in the actuarial literature in Dhaene & Denuit (1999). This means that $\sum_{j=1}^{n} f_j \times I_j$ and I_{n+1} are both non-negative, while the one being strictly positive implies the other being equal to zero. Hence, the realization of $\sum_{j=1}^{n+1} f_j \times I_j$, where f_{n+1} is an arbitrarily chosen strictly positive number can never be equal to 0. In addition to the above-noted reference, two other relevant actuarial papers considering 'mutual exclusivity' are Cheung and Lo (2014) and Lauzier, Lin and Wang (2024).

Taking into account this observation and the expressions (10) and (11), we can express the payouts W_i to the participants and the administrator in the following way:

$$W_i = (1+R) \times \left(\sum_{j=1}^{n+1} \pi_j\right) \times \frac{f_i}{\sum_{j=1}^{n+1} f_j \times I_j} \times I_i, \quad \text{for } i = 1, 2, \dots, n+1, \quad (12)$$

In other words, our proposed rule is to give each surviving investor a fraction of the available funds, where each survivor's fraction is defined as the number of his personally appointed tontine shares against the number of tontine shares that were appointed to all surviving participants. In case no participants survive, then the administrator receives all available funds. Notice that any positive value of f_{n+1} is allowed, as the particular choice does not influence the payouts W_i of the participants and the administrator.

It is a straightforward exercise to verify that the payouts to the participants can also be written as follows:

$$W_i = (1+R) \times \left(\sum_{j=1}^{n+1} \pi_j\right) \times \frac{f_i}{f_i + \sum_{j \neq i}^n f_j \times I_j} \times I_i, \quad \text{for } i = 1, 2, \dots, n,$$

where in $\sum_{j\neq i}^{n} f_j \times I_j$, the sum is taken over all values j from 1 to n, except for j = i. This expression is used in Denuit & Robert (2023) in the special case that $\pi_{n+1} = 0$ and all f_i are equal to 1.

From (12), we find that

$$\sum_{j=1}^{n+1} W_j = (1+R) \sum_{j=1}^{n+1} \pi_j,$$
(13)

which means that the sum of all payments to the participants and the administrator is equal to the total proceeds of the fund. Hence, there is no default risk. For obvious reasons, we call this property (13) the 'self-financing property' of the tontine fund.

Let us now introduce the notation I for the random vector consisting of all the survival indicator variables of the participants:

$$\mathbf{I} = (I_1, I_2, \ldots, I_n).$$

A tontine fund may be set up if the *n* participants with survival indicator vector $\mathbf{I} = (I_1, I_2, \ldots, I_n)$ and the administrator agree on the vector of investments $\boldsymbol{\pi}$ and the share allocation vector \mathbf{f} . Setting up a tontine fund only requires a group of participants and an administrator, as well as agreement between them on the vectors $\boldsymbol{\pi}$ and \mathbf{f} . Stated differently, the payout vector $\boldsymbol{W} = (W_1, W_2, \ldots, W_{n+1})$, of the single period tontine fund is fully characterized by $\mathbf{I}, \boldsymbol{\pi}$ and \mathbf{f} . Therefore, we will often identify the tontine fund with the triplet $(\mathbf{I}, \boldsymbol{\pi}, \mathbf{f})$. Notice that no probabilities have to be assumed to make the tontine fund operational. There must only be an agreement on the vectors $\boldsymbol{\pi}$ and \mathbf{f} . Of course, typically \mathbf{f} may depend on $\boldsymbol{\pi}$ and eventually also on the different participants' agreed set of survival probabilities. Specific choices of the share allocation vector \mathbf{f} will be considered hereafter.

3 Other expressions for the payouts of a tontine fund.

Taking into account (2) we can rewrite the payouts W_i of the tontine fund $(\mathbf{I}, \boldsymbol{\pi}, \mathbf{f})$ defined in (12) as follows:

$$W_i = (1+R) \times \left(S(0) \times \sum_{j=1}^n f_j\right) \times \frac{f_i}{\sum_{j=1}^{n+1} f_j \times I_j} \times I_i, \quad \text{for } i = 1, 2, \dots, n+1.$$

These expressions for the payouts of the participants and the administrator can easily be transformed into

$$W_{i} = S(0) \times (1+R) \times f_{i} \times \left(1 + \frac{\sum_{j=1}^{n+1} f_{j} \times (1-I_{j}) - f_{n+1}}{\sum_{j=1}^{n+1} f_{j} \times I_{j}}\right) \times I_{i}, \quad \text{for } i = 1, 2, \dots, n+1.$$
(14)

The expression (14) of the payout W_i to participant *i* has a straightforward interpretation: In case participant *i* survives, then $I_{n+1} = 0$, and he will receive two payments at time 1. The first one is the time-1 value $S(0) \times (1+R) \times f_i$ of the tontine shares he was allocated at time 0, where at time 1 each share is valuated by $S(0) \times (1+R)$. This means that the first payment is the time-1 value of his allocated shares, in case they were part of a financial fund with a return R. In addition, the shares of the persons who did not survive, that is $\sum_{j=1}^{n} f_j \times (1-I_j)$, are distributed among the survivors, where each survivor gets a part of it proportional to the shares he was allocated at time 0. Hence, person *i* receives in addition $\sum_{j=1}^{n} f_j \times (1-I_j) \times \frac{f_i}{\sum_{j=1}^{n} f_j \times I_j}$ shares, where each additional share is also evaluated by $S(0) \times (1+R)$. The value of these extra shares corresponds to the second payment at time 1.

Notice that (14) implies that

$$W_i \ge S(0) \times (1+R) \times f_i \times I_i, \qquad \text{for } i = 1, 2, \dots, n, \tag{15}$$

which means that in case participant *i* survives, he will always receive at least the time-1 value of the tontine shares that were allocated to him at time 0, where accumulation is performed with the tontine fund return R. Notice that (15) does not mean that upon survival, the participant receives at least the accumulated value of his initial investment π_i . Hence, upon survival,

$$W_i \geqq \pi_i \times (1+R) \times I_i, \qquad \text{for } i = 1, 2, \dots, n, \tag{16}$$

where \geqq has to be interpreted as 'not necessarily larger than or equal to'. Remark that $W_i \ge \pi_i \times (1+R) \times I_i$ will hold for each participant in case $f_i = \pi_i$ for all participants *i*. We will come back to this tontine share allocation in a further section.

For any i, we can rewrite formula (14) as follows:

$$W_i = \pi_i \times (1+R) \times (1+R'_i) \times (1+R'') \times I_i, \quad \text{for } i = 1, 2, \dots, n+1, \quad (17)$$

with

$$(1+R_i') = \frac{S\left(0\right) \times f_i}{\pi_i}$$

and

$$(1+R'') = \left(1 + \frac{\sum_{j=1}^{n+1} f_j \times (1-I_j) - f_{n+1}}{\sum_{j=1}^{n+1} f_j \times I_j}\right).$$

This means that the return that participant *i* receives on his initial investment π_i upon survival is composed of 3 parts: the investment return *R* of the fund, a risk adjustment return R'_i (because at time 0, the investment π_i is used to buy shares, where the number of allocated shares to each participant in one way or another reflect his risk profile), and finally the return R'' which is caused by the mortality credits, as the investments of the participants who died are shared among the surviving participants. Notice that R and R'' are non-negative and independent of *i*, whereas the risk adjustment return R'_i is participant-specific and may be negative. We should point out that R and R''_i are deterministic, whereas R'' is stochastic.

Remark 1 Suppose that $\pi_1 = \pi_2 = \ldots = \pi_n = \pi$, and also that the participants are ordered in such a way that

$$f_1 \le f_2 \le \ldots \le f_n.$$

Intuitively, participant 1 is the one who gets the least amount of shares (e.g. because he is the youngest, implying that his investment is least at risk), while participant n is the one who gets the most shares (e.g. because he is the oldest participant). Then we find that

$$S(0) \times f_1 = \frac{n \times \pi + \pi_{n+1}}{\sum_{j=1}^n f_j} \times f_1 \le \frac{n \times \pi + \pi_{n+1}}{n \times f_1} \times f_1 = \pi + \frac{\pi_{n+1}}{n}$$

This observation leads to

$$(1+R'_1) = \frac{S(0) \times f_1}{\pi} \le 1 + \frac{1}{n} \frac{\pi_{n+1}}{\pi}.$$

In case $\pi_{n+1} = 0$, the person who is allocated the least amount of tontine shares person receives a negative adjustment return $R'_1 \leq 0$. On the other hand, one has that

$$S(0) \times f_n = \frac{n \times \pi + \pi_{n+1}}{\sum_{j=1}^n f_j} \times f_n \ge \frac{n \times \pi + \pi_{n+1}}{n \times f_n} \times f_n = \pi + \frac{\pi_{n+1}}{n}$$

and hence,

$$(1+R'_n) = \frac{S(0) \times f_n}{\pi} \ge 1 + \frac{1}{n} \frac{\pi_{n+1}}{\pi} \ge 1.$$

This means that the 'person who gets the most shares' receives a positive risk adjustment return $R'_n \geq 0$.

4 Actuarial fairness of a tontine fund

Following, Bernard, Feliciangeli & Vanduffel (2022) and others in the next definition, we say that a tontine fund is 'actuarially fair' for the participants in case it is an actuarial fair deal for each participant. This means that the time 1 value of each participant's initial investment π_i is equal to his expected payoff $E[W_i]$ at time 1.

Definition 1 The tontine fund (I, π, f) is actuarial fair for each of its participants in case

$$\pi_i \times (1+R) = E[W_i], \quad for \ i = 1, 2, \dots, n.$$
 (18)

We are loath to introduce yet additional notations or generalizations for the precise magnitude of R, in a real-world scenario. But, in terms of structure, one could differentiate between a technical (valuation) interest rate, which is used to *discount* expected cash flows, and the deterministic return of the fund itself, that is, the rate by which the fund grows. Carrying those two Rs wouldn't add much to the underlying longevity risk-sharing insights and would (only) add clutter to the equations.

As the payouts for the participants are 0 in case not any person survives, we have the tontine fund $(\mathbf{I}, \boldsymbol{\pi}, \mathbf{f})$ is actuarially fair in the case

$$\pi_i \times (1+R) = E\left[W_i \mid I_{n+1} = 0\right] \times \Pr\left[I_{n+1} = 0\right], \quad \text{for } i = 1, 2, \dots, n.$$
(19)

Taking into account (10), the *n* fairness conditions (19) can be written as follows:

$$\pi_{i} = \left(\sum_{j=1}^{n+1} \pi_{j}\right) \times E\left[\frac{f_{i} \times I_{i}}{\sum_{j=1}^{n} f_{j} \times I_{j}} \mid I_{n+1} = 0\right] \times \Pr\left[I_{n+1} = 0\right], \quad \text{for } i = 1, 2, \dots, n.$$
(20)

We leave for future work, or perhaps to an enterprising student, a formal proof that – under some appropriate and suitable conditions – *at least* one solution π exists to the above set of equations. Also, on the topic of future work, in the event the survival probabilities are themselves stochastic (or entirely unknown) one could devise an *ex ante* agreement for sharing the proceeds of the fund, notwithstanding the fact it might not be "actuarially fair".

Theorem 1 If the tontine fund $(\mathbf{I}, \boldsymbol{\pi}, \mathbf{f})$ is actuarial fair for each of its participants, then for any $\alpha > 0$ and $\beta > 0$ also the tontine fund $(\mathbf{I}, \alpha \times \boldsymbol{\pi}, \beta \times \mathbf{f})$ is actuarially fair for all participants.

Proof: The proof follows immediately from the fairness conditions (20).

The theorem above implies that if a tontine fund $(\mathbf{I}, \boldsymbol{\pi}, \mathbf{f})$ is actuarially fair for its participants, then the tontine fund $(\mathbf{I}, \alpha \times \boldsymbol{\pi}, \mathbf{f})$, where we multiply all the investments of all participants and the administrator by a uniform factor α , is also actuarially fair for these same participants. In other words, for a given group of participants with given survival index vector \mathbf{I} and given tontine share allocation vector \mathbf{f} not depending on $\boldsymbol{\pi}$, the set of *n* equations (20) with unknown $\boldsymbol{\pi}$ can never have a single solution: if $\boldsymbol{\pi}$ is a solution of (20), then for any $\alpha > 0$ also $\alpha \times \boldsymbol{\pi}$ is a solution. **Definition 2** The tontine fund (I, π, f) is actuarial fair for the administrator in case

$$\pi_{n+1} \times (1+R) = E[W_{n+1}]. \tag{21}$$

Taking into account that the payout to the administrator is 0 in case at least one participant survives, we find that the tontine fund is actuarially fair for the administrator in case

$$\pi_{n+1} \times (1+R) = E[W_{n+1} \mid I_{n+1} = 1] \times \Pr[I_{n+1} = 1],$$

or equivalently, taking into account (11), the tontine fund is actuarial fair for the administrator if and only if

$$\pi_{n+1} = \left(\sum_{j=1}^{n} \pi_j\right) \times \frac{\Pr\left[I_{n+1} = 1\right]}{\Pr\left[I_{n+1} = 0\right]}.$$
(22)

Notice that in case the number of participants n is large, we will typically have that the probability that at least one participant survives, i.e. $\Pr[I_{n+1} = 0]$, will be close to 1. That means that in this case, we will have that

$$\pi_{n+1} \approx 0.$$

In the special case that all I_i are i.i.d. with $\Pr[I_i = 0] = q$, we have that $\Pr[I_{n+1} = 1] = q^n$ and $\Pr[I_{n+1} = 0] = 1 - q^n$, and (22) transforms into

$$\pi_{n+1} = \left(\sum_{j=1}^n \pi_j\right) \times \frac{q^n}{1-q^n}$$

A question that we will consider in the following theorem is whether a tontine fund which is fair for all participants is also fair for the administrator.

Theorem 2 A tontine fund $(\mathbf{I}, \boldsymbol{\pi}, \mathbf{f})$ that is actuarial fair for each of its participants is also actuarial fair for the administrator, i.e. the conditions (18) imply that π_{n+1} is given by (22).

Proof: Suppose that the tontine fund is actuarial fair for each participant. This means that the conditions (20) hold for all participants. Summing these n actuarial fairness conditions,

$$\sum_{j=1}^{n} \pi_j = \left(\sum_{j=1}^{n+1} \pi_j\right) \times \Pr\left[I_{n+1} = 0\right],$$

implies that π_{n+1} is given by (22), and hence, the tontine fund is actuarial fair for the administrator.

From the theorem above, we conclude that a necessary condition for a tontine fund to be actuarially fair for each of its participants is that it is actuarial fair for the administrator. In other words, in case a tontine fund is not actuarial fair for its administrator, it cannot be actuarial fair for all its participants. In the literature, usually the investment π_{n+1} of the administrator is set equal to 0, which means that the tontine fund is not actuarial fair for the administrator, which in turn implies that it can also not be actuarial fair for all its participants. This observation can also be seen as follows. In case $\pi_{n+1} = 0$, we find from (12) that

$$\sum_{j=1}^{n} E[W_j] = \sum_{j=1}^{n} E[W_j \mid I_{n+1} = 0] \times \Pr[I_{n+1} = 0]$$
$$= (1+R) \left(\sum_{j=1}^{n} \pi_j\right) \times \Pr[I_{n+1} = 0]$$
$$< (1+R) \left(\sum_{j=1}^{n} \pi_j\right)$$

This inequality implies that it is impossible that the tontine fund is actuarial fair for each participant, i.e. $E[W_i] = (1+R) \times \pi_i$ for all *i*, and for at least one participant *i*, one must have that $E[W_i] < \pi_i \times (1+R)$. Milevsky and Salisbury (2016) call such rules 'equitable' in the sense that no specific or identifiable member is disadvantaged in time-zero (a.k.a. initial) expectations.

More specifically, in that paper they investigate how to construct a multi-age tontine scheme and "determine the proper share prices to charge participants so that it is equitable and doesn't discriminate against any age or any group." The tontine they propose is a closed pool that does not allow anyone to enter or exit after the initial set-up. To quote from Milevsky & Salisbury (2016):

"...By the word fair, we mean that the expected present value of income will always be less than the amount contributed or invested into the tontine. However, a heterogeneous tontine scheme can often (though not always) be made equitable by ensuring that the present value of income (although less than the amount contributed) is the same for all participants in the scheme regardless of age. This scheme will not discriminate against any one cohort although it won't be fair..."

We should note that they (too) discuss the challenges in designing longevity-risk sharing rules that work for small groups, and they conclude:

"...We have proved that it is possible to mix cohorts without discriminating provided the diversity of the pool satisfies certain dispersion conditions and we propose a specific design that appears to work well in practice..."

Once again, this is consistent with the main tenor of this paper, that there are an assortment or multitude of methods in which longevity risk can be shared – the many ways to $skin \ a \ cat$ – and that $a \ priori$ one isn't necessarily better or worse than the other.

Theorem 3 The tontine fund $(\mathbf{I}, \boldsymbol{\pi}, \mathbf{f})$ is actuarial fair for each participant if and only if the following conditions are satisfied:

$$\frac{\pi_i}{\pi_{n+1}} = E\left[\frac{f_i \times I_i}{\sum_{j=1}^n f_j \times I_j} \mid I_{n+1} = 0\right] \times \frac{\Pr\left[I_{n+1} = 0\right]}{\Pr\left[I_{n+1} = 1\right]}, \quad \text{for } i = 1, 2, \dots, n.$$
(23)

Proof: (a) Let us first assume that the tontine fund $(\mathbf{I}, \boldsymbol{\pi}, \mathbf{f})$ is actuarial fair for each participant. Then we have from Theorem 2 that the tontine fund is also actuarial fair for the administrator and his investment π_{n+1} follows from (22). The actuarial fairness for the participants means that (20) holds for any $i = 1, 2, \ldots, n$. These *n* expressions lead to the stated expressions (23) for the participant's investments. (b) Next, we assume the conditions (23) are satisfied. Summing these *n* equations leads to (22), which is the actuarial fairness condition for the administrator. The conditions (23) can be rewritten as

$$\frac{\pi_i}{\pi_{n+1}} = \left(\frac{\Pr\left[I_{n+1}=0\right]}{\Pr\left[I_{n+1}=1\right]} + 1\right) \times E\left[\frac{f_i \times I_i}{\sum_{j=1}^n f_j \times I_j} \mid I_{n+1}=0\right] \times \Pr\left[I_{n+1}=0\right].$$

Taking into account the expression (22) for π_{n+1} leads to the actuarial fairness conditions (20) for the participants.

Those looking for an application to the above theorem might consider the following. If a group wanted to construct a tontine fund or scheme that was actuarially fair, the order of operations would start by choosing the administrator's investment π_{n+1} and then the share allocation vector \mathbf{f} . The individual investments – again, so that the scheme is actuarially fair, would follow from (23). Of course, in practice, this order is often reversed when the investment vector $\boldsymbol{\pi}$ is chosen first, and the share allocation vector \mathbf{f} is an afterthought, depending on the choice of π .

From Theorem 2, we know that if a tontine fund is actuarially fair for each of its participants, then it is also fair for the administrator. However, the opposite implication does not hold: Actuarial fairness for the administrator is not sufficient to have actuarial fairness for each of its participants. Let us now introduce a weaker form of actuarial fairness, which we baptize "collective actuarial fairness", equally described as "socially just" to avoid the overused and rather loaded term, fair.

Definition 3 The tontine fund $(\mathbf{I}, \pi, \mathbf{f})$ is collective actuarial fair for its participants in case

$$\left(\sum_{j=1}^{n} \pi_j\right) \times (1+R) = E\left[\sum_{j=1}^{n} W_j\right].$$
(24)

Collective actuarial fairness (a.k.a. socially just) means that the time 1 value of the sum of all participant's initial investments $\sum_{j=1}^{n} \pi_j$ is equal to the expected value of the sum of all their payoffs $\sum_{j=1}^{n} W_j$ at time 1.

Theorem 4 A tontine fund $(\mathbf{I}, \boldsymbol{\pi}, \mathbf{f})$ is collective actuarial fair for its participants if and only if it is actuarial fair for the administrator, i.e. the conditions (24) and (22) are equivalent.

Proof: In the general case, where $\pi_{n+1} \ge 0$, the expected value of the total payouts to all participants is given by

$$E\left[\sum_{j=1}^{n} W_{j}\right] = E\left[\sum_{j=1}^{n} W_{j} \mid I_{n+1} = 0\right] \times \Pr\left[I_{n+1} = 0\right]$$
$$= (1+R) \times \left(\sum_{j=1}^{n+1} \pi_{j}\right) \times \Pr\left[I_{n+1} = 0\right].$$
(25)

This means that the condition (24) for collective actuarial fairness can be rewritten as follows:

$$\left(\sum_{j=1}^{n} \pi_{j}\right) = \left(\sum_{j=1}^{n+1} \pi_{j}\right) \times \Pr\left[I_{n+1} = 0\right],$$

which is equivalent with the condition (22) of actuarial fairness for the administrator.

Remark that the proof of the previous Theorem also follows directly from the selffinancing property (13). Indeed, this property implies that

$$E\left[\sum_{j=1}^{n+1} W_j\right] = (1+R)\sum_{j=1}^{n+1} \pi_j,$$

which immediately leads to the proof of the Theorem.

In the following theorem, we consider the situation where the participants are indistinguishable in the sense that the random vector (I_1, I_2, \ldots, I_n) is exchangeable. A special case of the exchangeability assumption is that all I_i are i.i.d.

Theorem 5 Consider the tontine fund denoted by $(\mathbf{I}, \boldsymbol{\pi}, \mathbf{f})$. Suppose that the indicator vector $\mathbf{I} = (I_1, I_2, \ldots, I_n)$ is exchangeable and assume that the fund applies a uniform tontine share allocation vector $\mathbf{f} = (f, f, \ldots, f)$. Then we have that the tontine fund is actuarial fair for any of its participants if and only if the following condition is satisfied: All participants pay the same initial investment, that is $\pi_i = \pi$, for $i = 1, 2, \ldots, n$, with:

$$\pi = \frac{\pi_{n+1}}{n} \times \frac{\Pr\left[I_{n+1} = 0\right]}{\Pr\left[I_{n+1} = 1\right]}$$
(26)

Proof: Consider the tontine fund $(\mathbf{I}, \boldsymbol{\pi}, \mathbf{f})$, where $\mathbf{I} = (I_1, I_2, \ldots, I_n)$ is exchangeable and $\mathbf{f} = (f, f, \ldots, f)$. From (23), we know that the tontine fund is actuarial fair for any of its participants if and only if

$$\pi_i = \pi_{n+1} \times E\left[\frac{I_i}{\sum_{j=1}^n I_j} \mid I_{n+1} = 0\right] \times \frac{\Pr\left[I_{n+1} = 0\right]}{\Pr\left[I_{n+1} = 1\right]}, \quad \text{for } i = 1, 2, \dots, n.$$
(27)

Taking into account the exchangeability of (I_1, I_2, \ldots, I_n) , a symmetry argument leads to the conclusion that $E\left[\frac{I_i}{\sum_{j=1}^n I_j} \mid I_{n+1} = 0\right]$ is equal for all *i*. Further, as

$$\sum_{i=1}^{n} E\left[\frac{I_i}{\sum_{j=1}^{n} I_j} \mid I_{n+1} = 0\right] = 1,$$

we find that

$$E\left[\frac{I_i}{\sum_{j=1}^n I_j} \mid I_{n+1} = 0\right] = \frac{1}{n}, \quad \text{for } i = 1, 2, \dots, n.$$

We can conclude that the *n* actuarial fairness conditions for the participants are equivalent with $\pi_i = \pi$, for i = 1, 2, ..., n, where π satisfies (26).

5 Single period tontine vs. classical pure endowment

Consider *n* persons with survival indicator vector **I**, who want to set up a one-period tontine fund and start negotiations about how much everyone should invest and how the tontine shares should be allocated. To come up with a reasonable tontine fund structure characterized by $(\mathbf{I}, \boldsymbol{\pi}, \mathbf{f})$, they start by deciding on the vector $\boldsymbol{\pi}$. Once this vector is specified, the participants observe the insurance market to find out what kind of pure endowment insurance each could buy for a premium equal to his tontine fund investment. Suppose that person *i* can buy a pure endowment with survival benefit L_i for a premium equal to π_i . We do not require any particular premium principle to determine the π_i . In other words, we assume the π_i to be chosen and the corresponding L_i to be observed in the market.

In case the n persons buy the insurance from a particular insurer, this insurer faces a possibility of insolvency, that is a possibility that the event

$$\sum_{j=1}^{n} L_j \times I_j - (1+R) \times \sum_{j=1}^{n} \pi_j > 0$$

might occur.

In traditional life insurance, the insurer "solves" the insolvency issue by charging sufficiently high premiums and setting up a solvency capital.

To solve this issue for the tontine fund under construction, the *n* persons appoint an external administrator, who is assumed to contribute $\pi_{n+1} \ge 0$. As before, we introduce the Bernoulli r.v., defined as follows:

$$I_{n+1} = \prod_{j=1}^{n} (1 - I_j).$$
(28)

Furthermore, let L_{n+1} be an arbitrarily chosen strictly positive number. Then, for each participant, the 'insurance payout' $L_i \times I_i$ is replaced by the 'tontine payout'

$$W_i = \alpha \left(\mathbf{I} \right) \times L_i \times I_i, \qquad \text{for } i = 1, 2, \dots, n+1, \tag{29}$$

where α (**I**) follows from

$$\alpha\left(\mathbf{I}\right) \times \left(\sum_{j=1}^{n+1} L_j \times I_j\right) - (1+R) \times \left(\sum_{j=1}^{n+1} \pi_j\right) = 0,$$

or, equivalently,

$$\alpha \left(\mathbf{I} \right) = (1+R) \times \frac{\sum_{j=1}^{n+1} \pi_j}{\sum_{j=1}^{n+1} L_j \times I_j}.$$
(30)

Hence, the random coefficient $\alpha(\mathbf{I})$ is chosen such that the benefits $\alpha(\mathbf{I}) \times L_i \times I_i$ satisfy the full allocation condition.

Notice that α (I) is identical for any particular participant and the administrator, but it is only observable at time 1. It is straightforward to verify that the particular choice of L_{n+1} does not influence the payouts W_i .

Furthermore, from (30) and (29), we find that

$$W_{i} = (1+R) \times \left(\sum_{j=1}^{n+1} \pi_{j}\right) \times \frac{L_{i}}{\sum_{j=1}^{n+1} L_{j} \times I_{j}} \times I_{i}, \quad \text{for } i = 1, 2, \dots, n+1.$$
(31)

We find that these payouts are exactly equal to the payouts of the tontine fund $(\mathbf{I}, \boldsymbol{\pi}, \mathbf{f})$ with payouts W_i defined in (12), provided the allocated shares are given by

$$\mathbf{f} = \mathbf{L},$$

where

$$\mathbf{L} = (L_1, L_2, \ldots, L_n).$$

This rule pays the survivors the relative fraction, i.e. their personal insurance claim against the aggregate insurance claim of the surviviors, of the available funds.

In order to be able to apply (31), the participants and the administrator only have to agree on the vectors $\boldsymbol{\pi}$ and \mathbf{L} . This means that they only have to decide and agree on what everyone invests at time 0 and on what the participants would receive as survival benefit in a classical pure endowment insurance environment for their investment used as a premium. The choice of the premium principle or a mortality table is not required.

So far, we did not consider the choice of π_{n+1} . A possible choice for the administrator's contribution is given by (22),

$$\pi_{n+1} = \left(\sum_{j=1}^{n} \pi_j\right) \times \frac{\Pr\left[I_{n+1} = 1\right]}{\Pr\left[I_{n+1} = 0\right]}.$$

This choice of π_{n+1} makes the tontine fund $(\mathbf{I}, \boldsymbol{\pi}, \mathbf{L})$ fair for the administrator, and hence, also collective fair for the group of participants.

A possible way to fix **L** is chosing the L_i such that

$$\pi_i = \frac{1}{(1+R')} \times L_i \times p_i, \quad \text{for } i = 1, 2, \dots, n$$

for a given (agreed) life table and technical interest R'. This means that the participants agree on a lifetable and choose the amounts L_i as the survival benefit corresponding to the net premium in a pure endowment insurance with net premium π_i . Under this choice, we find that (31) reduces to

$$W_{i} = (1+R) \times \left(\sum_{j=1}^{n+1} \pi_{j}\right) \times \frac{\frac{\pi_{i}}{p_{i}}}{\sum_{j=1}^{n+1} \frac{\pi_{j}}{p_{j}} \times I_{j}} \times I_{i}, \quad \text{for } i = 1, 2, \dots, n+1.$$
(32)

In the following section, we will come back to the particular payout scheme defined in (32).

6 Tontine funds with an internal share allocation scheme.

Let us consider a group of n persons with survival indicator vector $\mathbf{I} = (I_1, I_2, \ldots, I_n)$. As mentioned above, a tontine fund for this group is characterized by $(\mathbf{I}, \boldsymbol{\pi}, \mathbf{f})$. Let us now assume that the n participants and the administrator agree on a probability vector

$$\mathbf{p}=\left(p_1,\ p_2,\ldots,\ p_n\right),$$

where $p_i, i = 1, 2, ..., n$ is the survival probability of participant *i*, i.e. $p_i = P[I_i = 1]$. The vector **p** of the survival probabilities has to be interpreted as an 'agreed vector', which may be different from the 'real vector' of the survival probabilities of the participants.

We assume that the share allocation vector \mathbf{f} is a function of the contribution vector $\boldsymbol{\pi}$ and the probability vector \mathbf{p} :

$$\mathbf{f} = \mathbf{f}\left(oldsymbol{\pi}, \mathbf{p}
ight) = \left(f_1\left(oldsymbol{\pi}, \mathbf{p}
ight), f_2\left(oldsymbol{\pi}, \mathbf{p}
ight), \ldots, f_n\left(oldsymbol{\pi}, \mathbf{p}
ight)
ight),$$

where the value of $f_i(\boldsymbol{\pi}, \mathbf{p})$ corresponds to the number of tontine shares received by person i in the tontine fund $(\mathbf{I}, \boldsymbol{\pi}, \mathbf{f})$.

Each $f_i(\boldsymbol{\pi}, \mathbf{p})$, i = 1, 2, ..., n, can be interpreted as a measure of the 'risk exposure' of the corresponding participant, taking into account the information on initial investments and survival probabilities of all participants. We call the function **f** an *internal share allocation scheme* in the sense that the allocated number of shares only depends on internal information of the pool, i.e. on $(\boldsymbol{\pi}, \mathbf{p})$. More generally, one could also consider more complex share allocation schemes, where the number of allocated shares does not only depend on $\boldsymbol{\pi}$ and **p**, but also on other deterministic information and time 1 observable random variables, such as the state of the economy, the occurrence (or not) of a pandemic over the coming year, the precise magnitude of medical inflation over the coming year, etc.

From (12), we find that the payouts W_i can be expressed as follows:

$$W_{i} = (1+R) \times \left(\sum_{j=1}^{n+1} \pi_{j}\right) \times \frac{f_{i}(\boldsymbol{\pi}, \mathbf{p})}{\sum_{j=1}^{n+1} f_{j}(\boldsymbol{\pi}, \mathbf{p}) \times I_{j}} \times I_{i}, \quad \text{for } i = 1, 2, \dots, n+1.$$
(33)

At the set-up of the tontine fund with an internal share allocation rule, an assumption about (or agreement on) the survival probabilities of the participants are required to be able to define the payouts. But once the set-up is ready, i.e. once the tontine fund is launched, it only needs an administrator who collects info about the survival or death of the participants, from which he can then determine each payout W_i via formula (33). Notice that any strictly positive choice for $f_{n+1}(\pi, \mathbf{p})$ can be made as the payouts are not dependent on this choice.

In certain situations, it may be reasonable to impose a linear behaviour between the number of allocated tontine shares f_i and the initial investment π_i , when the survival probability p_i is fixed. That means that it may be appropriate to assume that

$$f_i(\boldsymbol{\pi}, \mathbf{p}) = \pi_i \times g(p_i), \quad \text{for } i = 1, 2, \dots, n.$$
(34)

for all participants i, where g is strictly positive and decreasing (or increasing, or something else) in the survival probability p_i . A decreasing g corresponds to the mathematical translation that 'a participant with a smaller survival probability receives a larger number of tontine shares than a person with the same initial investment but higher survival probability.' Such an approach is inspired by the idea that the person with a smaller survival probability has a higher chance of losing his initial investment. On the other side, in case one imposes an increasing g that means that the allocation rule is such that it favours participants with higher survival probabilities. This might be a desirable property in a closely connected social group, and would be in the hands of the scheme's architects. Finally, notice that we assume here that g is not participant-specific and hence, does not depend on i. More generally, one could introduce a participant-specific function g_i .

In case (34) holds, we have that (33) transforms into

$$W_{i} = (1+R) \times \left(\sum_{j=1}^{n+1} \pi_{j}\right) \times \frac{\pi_{i} \times g(p_{i})}{\sum_{j=1}^{n+1} \pi_{j} \times g(p_{j}) \times I_{j}} \times I_{i}, \quad \text{for } i = 1, 2, \dots, n+1.$$
(35)

Hereafter, we introduce some important special cases of the share allocation scheme defined in (33).

Example 1 The **DM** allocation scheme.

Let us assume the internal share allocation scheme (34), where $g(p_i) = 1/p_i$. In other words, we consider the following tontine share allocation scheme:

$$f_i^{\text{DM}}(\boldsymbol{\pi}, \mathbf{p}) = \frac{\pi_i}{p_i}, \qquad i = 1, 2, \dots, n+1.$$
 (36)

In this case, the payouts (35) of the participants are given by

$$W_i^{\rm DM} = (1+R) \times \left(\sum_{j=1}^{n+1} \pi_j\right) \times \frac{\frac{\pi_i}{p_i}}{\sum_{j=1}^{n+1} \frac{\pi_j}{p_j} \times I_j} \times I_i, \qquad \text{for } i = 1, 2, \dots, n+1, \qquad (37)$$

which corresponds with the tontine fund payouts W_i that we introduced in (32). A special case was considered in (1). Notice that we have chosen $f_{n+1}^{\text{DM}}(\boldsymbol{\pi}, \mathbf{p}) = \frac{\pi_{n+1}}{p_{n+1}}$, with $p_{n+1} = P[I_{n+1} = 1]$, but any other strictly positive value of $f_{n+1}^{\text{DM}}(\boldsymbol{\pi}, \mathbf{p})$ will lead to the same payouts.

A motivation for this allocation (36) in terms of traditional insurance benefits was given in the previous section.

It's interesting to note that a rather special case of the above will arise if all participants are required to have the same risk exposure in the sense that $\frac{\pi_i}{p_i} = c$, where c, is a given constant. In that special case, for a given (or assumed) vector of survival probabilities, the investments are then given by:

$$\pi_i = c \times p_i, \qquad i = 1, 2, \dots, n+1,$$

and (37) reduces to:

$$W_i = (1+R) \times \left(\sum_{j=1}^{n+1} \pi_j\right) \times \frac{I_i}{\sum_{j=1}^{n+1} I_j}, \quad \text{for } i = 1, 2, \dots, n+1$$

Example 2 The T allocation scheme.

Consider the internal share allocation scheme (34) with $g(p) \equiv 1$:

$$f_i^{\rm T}(\boldsymbol{\pi}, \mathbf{p}) = \pi_i, \qquad \text{for } i = 1, 2, \dots, n+1.$$

Then (35) becomes

$$W_i^{\rm T} = (1+R) \times \left(\sum_{j=1}^{n+1} \pi_j\right) \times \frac{\pi_i}{\sum_{j=1}^{n+1} \pi_j \times I_j} \times I_i, \qquad \text{for } i = 1, 2, \dots, n+1.$$
(38)

Notice that from (2), it follows that the time - 0 value of a tontine share, notation $S^{T}(0)$ is now given by

$$S^{\mathrm{T}}(0) = \frac{\sum_{j=1}^{n+1} \pi_j}{\sum_{j=1}^{n} \pi_j} = 1 + \frac{\pi_{n+1}}{\sum_{j=1}^{n} \pi_j}$$

From (14) it follows then that (38) can be rewritten as follows:

$$W_i^{\rm T} = \left(1 + \frac{\pi_{n+1}}{\sum_{j=1}^n \pi_j}\right) \times (1+R) \times \pi_i \times \left(1 + \frac{\sum_{j=1}^{n+1} \pi_j \times (1-I_j) - \pi_{n+1}}{\sum_{j=1}^{n+1} \pi_j \times I_j}\right) \times I_i,$$

for $i = 1, 2, \dots, n+1.$ (39)

When $\pi_{n+1} = 0$, formula (39) remains to hold, provided we replace π_{n+1} in $\frac{\sum_{j=1}^{n+1} \pi_j \times (1-I_j) - \pi_{n+1}}{\sum_{j=1}^{n+1} \pi_j \times I_j}$ by a strictly positive value f_{n+1} . In this case, we find that

$$W_i^{\rm T} = (1+R) \times \pi_i \times \left(1 + \frac{\sum_{j=1}^n \pi_j \times (1-I_j) - f_{n+1} \times I_{n+1}}{\sum_{j=1}^n \pi_j \times I_j + f_{n+1} \times I_{n+1}} \right) \times I_i, \qquad \text{for } i = 1, 2, \dots, n+1$$

In case at least one participant survives, i.e. $I_{n+1} = 0$, we have that

$$\left(W_{i}^{\mathrm{T}} \mid I_{n+1} = 0\right) = (1+R) \times \pi_{i} \times \left(1 + \frac{\sum_{j=1}^{n} \pi_{j} \times (1-I_{j})}{\sum_{j=1}^{n} \pi_{j} \times I_{j}}\right) \times I_{i}, \quad \text{for } i = 1, 2, \dots, n.$$

In the questionnaire survey that we noted in the early part of the paper, one of the replies⁶ that we received was the above-noted formula, and which we denote as Tavin allocation scheme. That scheme favours younger participants, individuals with higher survival probabilities. Indeed, consider two participants, *i* and *j*, who invest the same amount $\pi_i = \pi_j$, but the first one is younger than the second one in the sense that $p_i > p_j$. Then obviously, the younger person is favoured as in the case of survival, both receive the same amount, although the younger one has a higher survival probability. To paraphrase Tavin (2023):

"...In this allocation, the recorded amount upon survival is only driven by the agent's initial stake compared to the others' stakes. This system plays a role in terms of the welfare of the social group. Namely, there is a reallocation of wealth (the total amount in the fund) that is favourable to those who are likely to survive long after the liquidation of the tontine, compared to the risk-return-based allocation, which favours the agents who are likely not to survive long after the liquidation of the tontine. This system increases the group's welfare if we look at the welfare obtained by the surviving agents after time 1. Conditional on survival at time 1, those likely to live long after time 1 need more (because they probably need to take care of an elder parent or children) and are more likely to have projects that benefit the social group (e.g. opening or financing a business). On the other hand, the agent who is not likely to survive long after time 1 will probably not have enough time to enjoy the received amount..."

Example 3 Consider the share allocation rule with:

$$f_i(\boldsymbol{\pi}, \mathbf{p}) = \frac{1}{p_i}, \qquad i = 1, 2, \dots, n.$$

In this case, we find from (33) that

$$W_i = (1+R) \times \left(\sum_{j=1}^{n+1} \pi_j\right) \times \frac{\frac{1}{p_i}}{\sum_{j=1}^{n+1} \frac{I_j}{p_j}} \times \frac{I_i}{p_i}, \quad \text{for } i = 1, 2, \dots, n+1.$$
(40)

⁶Private communication from Bertrand Tavin.

This rule favors 'poorer' participants (i.e. participants who invest less). Indeed, consider two persons *i* and *j* with initial investments $\pi_i < \pi_j$. Suppose that both have the same survival probability. Then in case of survival both receive the same amount, whereas person *i* invested less.

Example 4 The **DR** allocation scheme, following the work of Denuit & Robert (2023). Consider the uniform rule with

$$f_i^{\rm DR} = 1, \qquad i = 1, 2, \dots, n+1.$$

In this case, we find from (33) that

$$W_i^{\text{DR}} = (1+R) \times \left(\sum_{j=1}^{n+1} \pi_j\right) \times \frac{I_i}{\sum_{j=1}^{n+1} I_j}, \quad \text{for } i = 1, 2, \dots, n+1.$$
 (41)

From (2), we find that $S^{\text{DR}}(0) = \frac{\sum_{j=1}^{n+1} \pi_j}{n}$. Hence, from (14), we find that

$$W_i^{\rm DR} = (1+R) \times \frac{\sum_{j=1}^{n+1} \pi_j}{n} \times \left(1 + \frac{\sum_{j=1}^{n+1} (1-I_j) - 1}{\sum_{j=1}^{n+1} I_j}\right) \times I_i, \quad \text{for } i = 1, 2, \dots, n+1.$$

This scheme is advantageous for individuals who are younger and poorer. Suppose there are two people, i and j. If i is younger and has a higher chance of survival, but is poorer and pays less to the tontine fund than j, but pays less, he will receive the same payout money if they both survive. Therefore, the tontine arrangement benefits the younger and less affluent person i. A similar scheme can be found in Denuit & Robert (2023), with the difference being that they make their rule fair by returning the initial investments if all participants pass away and defining the initial investments so that the allocations are actuarially fair.

While this isn't the main focus of our paper, we should note the following about the (rather loaded term) "actuarial fairness". Namely, taking into account Theorem 4, the above discussed allocation schemes or arrangements – although not generally fair to any given individual – can be made collectively fair (in the sense of Definition 3), or perhaps the proper word is actuarially "just" to add another term of the growing lexicon, by introducing the administrator.

7 Summary and Conclusion

The launching pad for this paper – both conceptually and in practice – revolves around the many justifiable ways in which a group of heterogenous individuals could in theory, share the proceeds of a (longevity) risk-pooling agreement. We motivated the examples using the concept of a one-period tontine, a product that is enjoying a resurgence of interest worldwide, both in academia and industry. If members of this heterogeneous group invested unequal amounts into the tontine pool, our (small pool) numerical example made the multiplicity of possible solutions evident. Therefore, the primary contribution of this paper is to argue that the payout structure for a tontine fund can be quite comprehensive, catering to a broad range of groups wishing to share longevity risks without the interference of an external entity assuming the risk of insolvency.

These insights are particularly beneficial for closely-knit smaller groups aiming to redistribute wealth from their older, wealthier members to their younger, less prosperous counterparts. In such scenarios, the emphasis isn't on actuarial fairness or the magnitude of the administrator's contribution. Instead, the focus is on the collective benefit of the group, as the administrator embodies the group's interests, and their contributions directly benefit the group.

Our methodology can accommodate larger groups, even when participants may not share social connections or interpersonal ties. In these situations surviving members ought to be compensated based on the actuarial risks they've accepted and been exposed to. Individuals with a lower likelihood of survival should be entitled to a more substantial reward. An external entity, like an insurance company or a government regulator, administrator in these contexts. They could also contribute in scenarios with a significant likelihood of none of the participants surviving.

In sum, while the objective of modern tontines, and more generally uninsured decumulation products (UDP),⁷ is to eliminate the costly capital associated with insurance **guarantees**, we are not advocating the elimination of insurance **regulators**. Rather, under these arrangements, the role of the regulator would be to administer the fund – in exchange for "a piece of the action" – which would serve two distinct roles. First, oversight. They would ensure all participants in the scheme were abiding by their obligations and commitments. Second, and just as importantly, administrators in the scheme would make it collectively actuarially fair, that is, socially just.

The next step is to extend this one-period framework to a multiperiod tontine fund, which would be constructed as a sequence of linked one-period funds. Defining the relations between indicator vectors, premium vectors, share allocation vectors, and the all-important payout vectors in consecutive periods is left in an honoured tradition for future research. In the same category of plans for future research, we leave the discussion of allowing π_i and even f_i to equal zero, allowing certain groups to avoid paying (and still benefiting) or not benefiting (and still paying.) Examples would be targetted demographic groups such as the young and old respectively.

We conclude by noting that the single-period tontine fund, which is described within the body of this paper can be treated or viewed as a special case of (what we will call) *compensation-based* decentralized risk-sharing (DRS) arrangements, where at time t = 0one contributes (deterministic) premiums (or investments) and at time t = 1 one receives (random) compensations, which are set such that the risk-sharing scheme is self-financing. Like the literature on tontines, there is a growing literature on this type of DRS. A somewhat less obvious insight is that the single period tontine fund can also be expressed

⁷This is the term recently introduced by Canadian regulators to describe the arrangements of this sort. See: *https://www.fsrao.ca/regulation/guidance/understanding-decumulation-products*.

in the form of (what we will call) a *contribution-based* DRS scheme, which is characterized by time 1 (random) contributions and time 1 (random) benefits or claims, and where the compensations are determined such that the risk-sharing scheme is again self-financing. There is also a growing literature on this type of DRS. For an overview of a unified theory of DRS, we refer to Feng (2023) and the references in that book. The above-mentioned observations are further explored in some detail in the Appendix.

7.1 Acknowledgement & Thanks.

The authors would like to acknowledge many helpful comments and input, as well as the efforts involved in responding to our survey questionnaire, from Robert Bertrand, Servaes van Bilsen, Andrew Carrothers, Doug Chandler, Michel Denuit, Runhuan Feng, Faisal Habib, Peter Hieber, Aleksi Leeuwenkamp, Andrew McDiarmid, Kent McKeever, Branislav Nikolic, Christian Robert and Thomas Salisbury. The early drafts of this paper benefited (immensely) from their insights and individuals have been noted, and thanked in specific places, as deemed appropriate. Finally, Jan Dhaene gratefully acknowledges funding from FWO and F.R.S.-FNRS under the Excellence of Science (EOS) programme, project ASTeRISK (40007517), and Moshe A. Milevsky acknowledges funding from the IFID Centre (Grant # 2023.12).

8 Appendix: Tontines & Decentralized Risk Sharing

Two areas of insurance research whose literature has grown lately are: (i) decentralized risk-sharing systems and (ii) retirement tontine arrangements. The former system is characterized by a risk-sharing rule without solvency capital or a formal third-party guarantor. The latter investment arrangements are designed as alternatives to life annuities, characterized by a group covenant in which longevity risk is pooled and mortality credits aren't guaranteed. This appendix models the concepts of single period decentralized risk-sharing and tontine endowments – which was the focus on the main body of the paper – in one unified framework and "proves" they can be viewed as mathematical duals of each other. While others, and especially the recent work by Feng & Liu (2024), have hinted at these connections, our objective in this appendix is to continue the work of unifying two disparate literatures under one banner.

8.1 A Brief Review

To illustrate and explain the essence of decentralized risk sharing (DRS) in which nothing is guaranteed and therefore, no solvency risk capital is required, we begin by reviewing the basics of classical insurance theory and thus set notation and terminology as well. To that end, consider a pool of n > 1 economic agents or individual policyholder participants. Each one of these n policyholders purchases an insurance contract at time t = 0, which entitles him or her to a random claim amount denoted by X_i , measurable and payable at time T = 1. This claim can be a random loss related to a well-defined peril (e.g. hospitalization-related expenses), or it can be a random benefit contingent on the occurrence of a well-defined event (e.g. a pure endowment, which entitles the survivor to a predefined amount of money) due at time 1.

For simplicity, we assume that the above-noted time interval [0, 1], is a calendar year, but one could obviously adopt and modify what follows to larger time intervals of T = 5, T = 10, or T = 20 years, etc. Rather, the point here is that our setup is a one-period model with no intermediate cash-flows or payouts.

Suppose further that each policyholder *i* pays the insurer (to be explained) a premium amount π_i at time t = 0, to acquire said protection or benefit and the totality of all premiums $\sum_{i=1}^{n} +\pi_i$ is collectively invested in a risk-free (i.e. default-free) asset, subject to a return of *R* per period. In other words \$1 grows to $(1 + R)^r$ at the end of the period.

Now let's focus on the premiums π_i and how they are determined. The job of an actuary – regardless of the particular risk being insured – is to ensure that the probability that the aggregate claims $\sum_{i=1}^{n} X_i$ due at time 1 are not larger than the available assets at time 1 for the insurance portfolio under consideration. Here, the available assets consist of the time-1 value of the premiums $(1+R)\sum_{i=1}^{n} \pi_i$ and the time-1 value (1+R)SC of the solvency capital SC to be set up at time 0. In particular, the insurer will become

insolvent and end the period in bankruptcy if the following undesirable event occurs:

$$(1+R)\left(\sum_{i=1}^{n}\pi_i + SC\right) < \sum_{i=1}^{n}X_i$$

While the above condition is rather obvious and intuitive, namely that premiums and solvency capital haven't accumulated enough to pay all the claims, the opposite condition can be re-written and expressed in the following (equally obvious) manner:

Insurance Solvency Condition:

$$\sum_{j=1}^{n} X_j \le (1+R) \left(\sum_{j=1}^{n} \pi_j + SC \right).$$
 (42)

This intuition is straightforward namely the insurer (i.e. guarantor) can fulfill his/her liabilities *if-and-only-if* the total claims to be paid at time T = 1 are **not** larger than the accumulated value of the premiums and solvency capital, that is, the assets available to pay all claims.

Classical insurance is of the form of "centralized" (versus decentralized) risk sharing. This implies or is associated with a risk-sharing mechanism under which individual losses faced by policyholders of the pool are transferred to a central insurer. Every single one of the *n* policyholders is compensated *ex-post* from the insurer for the experienced loss, which we denoted by X_i . In return for that total and absolute coverage, the insurer charges an insurance premium *ex-ante*, paid by each of the *n* insured policyholders. Now, the premiums π_i themselves will follow from an appropriate *premium principle*, selected in such a manner so that the probability of the event that the sum of all accumulated premiums and solvency capital exceeds the aggregate loss of the insurance portfolio is sufficiently high (e.g. 99.5%). Now, and this is key, the centralized approach with *exante* premiums requires capital to be set up by the insurer to be able to meet his *ex-post* obligations. Premiums should be large enough so that the solvency capital does not have to be extremely high (which the owners of the insurance company will not want), but premiums should not be too large in order to remain competitive in the market.

8.2 DRS via Compensations

Consider a pool of n + 1 individual random future claims X_i , each related to to a welldefined peril or contingent benefit. The vector or pool of all risks (benefits or losses) is denoted by **X**:

$$\mathbf{X} = (X_1, X_2, \dots, X_{n+1})$$

And, we assume that at time 0, each participants pays a premium (or invests an amount) of size π_i , with the vector of all premiums labeled the **premium vector**:

$$\boldsymbol{\pi} = (\pi_1, \pi_2, \ldots, \pi_{n+1}).$$

Important to mention is that participant n + 1 is the *administrator*. He is the person responsible for the management of the fund (collecting investments, paying compensations).

Important is that the administrator can also take part in the DRS scheme, by paying a premium π_{n+1} and receiving an appropriate compensation, see further.

Decentralized Risk-Sharing (henceforth, DRS) refers to risk-sharing mechanisms under which the participants in the pool share or allot the risks among each other in such a way that the administrator of the payments incurs no insolvency risk. In fact, to avoid any confusion with centralized risk-sharing, which is only missing a *de*, we introduce the concept of a *community*, which administers the scheme but doesn't guarantee anything. One can think of this *community* as a collection of individuals. And, even if they are properly regulated, have formal administrators, and might even be incorporated, they differ from insurance *companies*.

To achieve that objective and figure out the allotment, premium payments are made at time T = 0, but these aren't premiums in the classical insurance sense. Rather, each participant *i* from the pool of size n + 1 is eventually and only partially compensated *ex-post* for their loss X_i . In other words, they do not receive of get reimbursed for the total amount X_i . The pool – or perhaps better labeled the community – will pay or compensate in the amount $W_i(\mathbf{X})$, for a claim X_i . Now, the vector of all compensations is called the **Compensation Vector**:

$$\mathbf{W}(\mathbf{X}) = (W_1(\mathbf{X}), W_2(\mathbf{X}), \dots, W_{n+1}(\mathbf{X}))$$

The function which transforms any **X** into the compensation vector $\mathbf{W}(\mathbf{X})$ is called a compensation-based risk-sharing rule. We do not necessarily assume that **W** is a function from \mathbb{R}^{n+1} to \mathbb{R}^{n+1} . Rather, we only assume that **W** is a function from a given set of (n + 1)-dimensional random vectors defined on a given probability space to this same set of random vectors. Hereafter, we will denote the compensation-based DRS described above by $(\boldsymbol{\pi}, \mathbf{W}(\mathbf{X}))$.

In order to avoid insolvency risk, the risk-sharing rule is such that the following compensation-based condition is fulfilled:

Compensation-Based Solvency Condition:
$$\sum_{j=1}^{n+1} W_j(\mathbf{X}) = (1+R) \sum_{j=1}^{n+1} \pi_j, \quad (43)$$

which means that the sum of all compensations is exactly equal to the time t = 1 value of the sum of all premiums paid by the participants and the administrator. It should be clear that in the compensation-based risk-sharing scheme $(\pi, \mathbf{W}(\mathbf{X}))$, the time 1 value of the total cash-inflow for participant *i* is given by:

$$W_i(\mathbf{X}) - (1+R) \times \pi_i. \tag{44}$$

As an example, consider the case where for each participant i with claim X_i , the compensation function $W_i(\mathbf{X})$ follows from

$$W_i^{\text{prop}}(\mathbf{X}) = (1+R) \times \left(\sum_{j=1}^{n+1} \pi_j\right) \times \frac{X_i}{\sum_{j=1}^{n+1} X_j} \quad \text{for } i = 1, 2, \dots, n+1.$$
 (45)

This compensation-based risk-sharing rule is called the **proportional risk-sharing rule**: Given the aggregate claims $\sum_{j=1}^{n+1} X_j$, each participant *i* receives a compensation proportional to his observed claim X_i , where the proportional factors are determined such that the full compensation condition (43) is satisfied. The key insight in the tontine literature is that similar to the Markowitz trade-off between investment risk and return, policyholders should be able to choose between insurance with (costly) guarantees versus pooling arrangements, or perhaps even a mixture.

Now, just as we encountered for the one-period tontine fund described within the body of the paper, in general there is non-zero probability that $\sum_{j=1}^{n} X_j$ is equal to 0 in (45). That is, using our tontine fund language, that nobody survives to the end of the period. This is the rationale for introducing the tontine administrator – although in the context of this appendix, this entity would be better described as the DRS administrator. As far as the notation is concerned, the administrator would be captured by X_{n+1} , being mutually exclusive, with $\sum_{j=1}^{n} X_j$. In this case, $W_i^{\text{prop}}(\mathbf{X})$ is always well-defined, as the denominator in (45) is always strictly positive.

The tontine fund described in this paper arises as a special case of the compensationbased DRS scheme (45) by choosing

$$\mathbf{X} = (f_1 \times I_1, f_2 \times I_2, \dots, f_{n+1} \times I_{n+1}),$$

with the survival indicator and share allocation vectors \mathbf{I} and \mathbf{f} as defined before in this paper. In this case, (45) transforms in (12).

8.3 DRS via Contributions

In contrast to a system with premiums replaced by compensations, this section considers a *contribution*-based system for DRS. Consider again a pool of n + 1 individuals with random end-of-period claims X_i , properly contracted and related to a well-defined peril or contingent benefit. The total or combined vector of all dollar value claims is simply called the <u>claims vector</u> and is again denoted by the bold **X**:

$$\mathbf{X} = (X_1, X_2, \dots, X_{n+1})$$

As alluded earlier, DRS refers to risk-sharing mechanisms under which the participants in the pool share their risks without generating or creating any insolvency risk. To achieve that objective, in this particular section, we assume that each of the n + 1 participants in the risk-sharing pool is fully compensated *ex-post* for his claim X_i . But, in return each participant pays an *ex-post* contribution $C_i(\mathbf{X})$ to the pool, which is managed by the insurance *community* versus a conventional insurance *company*. The vector of all contributions or allotments is called the <u>Contribution Vector</u>:

$$\mathbf{C}(\mathbf{X}) = (C_1(\mathbf{X}), C_2(\mathbf{X}), \dots, C_{n+1}(\mathbf{X}))$$

Now, the function which transforms or maps any \mathbf{X} into the contribution vector $\mathbf{C}(\mathbf{X})$ is called the contribution-based risk-sharing rule. Note that in this formulation, we do

not necessarily assume that \mathbf{C} is a function from \mathbb{R}^n to \mathbb{R}^n . Rather, the only assumption made here is that \mathbf{C} is a function from an appropriate set of *n*-dimensional random vectors defined on a given probability space, mapped to this same (or another) set of random vectors. We denote the above-described contribution-based DRS scheme by $(\mathbf{X}, \mathbf{C}(\mathbf{X}))$

Moving on, to avoid insolvency risk – since there is no guarantor company – which is present in centralized risk-sharing, we assume that the the risk-sharing rule is such that the following condition, which we will call the contribution-based solvency condition is fulfilled:

Contribution-Based Solvency Condition:
$$\sum_{j=1}^{n+1} X_j = \sum_{j=1}^{n+1} C_j(\mathbf{X}), \quad (46)$$

This condition is interpreted to mean that the sum of all contributions paid by the participants (including the administrator) matches the sum of all losses the pool covers. It should be clear that the cash-inflow for participant i at time T = 1 in the above-described decentralized risk-sharing scheme $(\mathbf{X}, \mathbf{C} (\mathbf{X}))$ is given by:

$$X_i - C_i\left(\mathbf{X}\right),\tag{47}$$

which obviously may be positive or negative depending on the magnitude of their loss relative to their share of the entire pool's losses.

For example, consider the **uniform risk-sharing rule** C^{uni} , which is defined by

$$\mathbf{C}^{\text{uni}}\left(\mathbf{X}\right) = \left(\frac{\sum_{j=1}^{n+1} X_j}{n+1}, \frac{\sum_{j=1}^{n+1} X_j}{n+1}, \dots, \frac{\sum_{j=1}^{n+1} X_j}{n+1}\right)$$
(48)

Another example is the **conditional mean risk-sharing rule** \mathbf{C}^{cm} , introduced in the actuarial literature in Denuit & Dhaene (2012):

$$\mathbf{C}^{\mathrm{cm}}\left(\mathbf{X}\right) = \left(\mathbb{E}\left[X_1 \mid \sum_{j=1}^{n+1} X_j\right], \mathbb{E}\left[X_2 \mid \sum_{j=1}^{n+1} X_j\right], \dots, \mathbb{E}\left[X_{n+1} \mid \sum_{j=1}^{n+1} X_j\right]\right)$$

The properties of these and other risk-sharing rules have been investigated in detail by Denuit, Dhaene & Robert (2022) and Denuit, Dhaene, Ghossoub & Robert (2023) among others. An axiomatic characterization of the conditional mean risk-sharing rule is given in Jiao, Kou, Liu & Wang (2023).

8.4 Some dualities

In the subsections above, we have described two types of decentralized risk-sharing; compensation-based and contribution-based systems, denoted by $(\boldsymbol{\pi}, \mathbf{W}(\mathbf{X}))$ and $(\mathbf{X}, \mathbf{C}(\mathbf{X}))$, respectively. Full solvency could be satisfied via appropriate time-1 compensations $\mathbf{W}(\mathbf{X})$

satisfying the compensation-based solvency condition (43), or via appropriate time-1 contributions $\mathbf{C}(\mathbf{X})$ satisfying the contribution-based solvency condition in equation (46).

Now, it is easy to see that in fact the two systems are 'equivalent'. Indeed, the at time 1 evaluated cash inflows for participant i are equal under the compensation-based system $(\pi, \mathbf{W}(\mathbf{X}))$ and the contribution-based system $(\mathbf{X}, \mathbf{C}(\mathbf{X}))$ in case the following conditions hold:

$$W_i(\mathbf{X}) - (1+R) \times \pi_i = X_i - C_i(\mathbf{X}), \qquad i = 1, 2, \dots, n+1.$$
 (49)

This means that a contribution-based system $(\mathbf{X}, \mathbf{C}(\mathbf{X}))$ can be transformed into a compensation-based system $(\boldsymbol{\pi}, \mathbf{W}(\mathbf{X}))$ where any person *i* pays an arbitrary chosen premiums π_i at time 0 and receives the following contribution at time 1:

$$W_i(\mathbf{X}) = (1+R) \times \pi_i + X_i - C_i(\mathbf{X}), \qquad i = 1, 2, \dots, n+1.$$
 (50)

Remark that transforming a contribution-based system into a compensation-based system requires the choice of a premium vector. But the net payoff to the participant is indifferent to the choice of this premium vector.

Also remark that 'equivalence' has to be interpreted not in terms of equal cashflows, but in terms of equal time-1 values of the total cashflows, which is exactly expressed in the equations (49).

In a similar way, a compensation-based risk-sharing system $(\boldsymbol{\pi}, \mathbf{W}(\mathbf{X}))$ can be transformed into a contribution-based risk-sharing system $(\mathbf{X}, \mathbf{C}(\mathbf{X}))$ where person *i* receives X_i at time 1 and pays the following contribution at that time:

$$C_i(\mathbf{X}) = (1+R) \times \pi_i + X_i - W_i(\mathbf{X}), \qquad i = 1, 2, \dots, n.$$
 (51)

As a first example, consider the contribution-based uniform risk-sharing rule $(\mathbf{X}, \mathbf{C}^{\text{uni}}(\mathbf{X}))$ defined in (22). In this case, we have that

$$C_i^{\mathrm{uni}}\left(\mathbf{X}\right) = \frac{\sum_{j=1}^{n+1} X_j}{n+1},$$

meaning that participant *i* receives X_i at time 1, and at that same time pays the contribution $\frac{\sum_{j=1}^{n+1} X_j}{n+1}$. Chosing a premium vector $\boldsymbol{\pi}$ and taking into account (50), we transform $(\mathbf{X}, \mathbf{C}^{\text{uni}}(\mathbf{X}))$ into the compensation-based system $(\boldsymbol{\pi}, \mathbf{W}(\mathbf{X}))$, with

$$W_i^{\text{uni}}(\mathbf{X}) = (1+R) \times \pi_i + X_i - \frac{\sum_{j=1}^{n+1} X_j}{n+1}.$$

In this system, participant *i* pays the premium π_i at time 0, while he receives the compensation $(1+R) \times \pi_i + X_i - \frac{\sum_{j=1}^{n+1} X_j}{n+1}$ at time 1.

As a second example, consider the compensation-based risk-sharing scheme $(\pi, \mathbf{W}^{\text{prop}}(\mathbf{X}))$ defined in (45). We can transform this scheme in the contribution-based scheme $(\mathbf{X}, \mathbf{C}^{\text{prop}}(\mathbf{X}))$, with

$$C_i^{\text{prop}}(\mathbf{X}) = (1+R) \times \pi_i + X_i - (1+R) \times \left(\sum_{j=1}^{n+1} \pi_j\right) \times \frac{X_i}{\sum_{j=1}^{n+1} X_j}, \quad \text{for } i = 1, 2, \dots, n+1$$

In this system, at time 1 participant *i* receives X_i and contributes $C_i^{\text{prop}}(\mathbf{X})$ to the insurance community.
