Structurally Aware Robust Model Selection for Mixtures

Jiawei Li¹ and Jonathan H. Huggins¹

¹Department of Mathematics & Statistics, Boston University, e-mail: jwli@bu.edu; huggins@bu.edu

Abstract: Mixture models are often used to identify meaningful subpopulations (i.e., clusters) in observed data such that the subpopulations have a real-world interpretation (e.g., as cell types). However, when used for subpopulation discovery, mixture model inference is usually ill-defined a priori because the assumed observation model is only an approximation to the true data-generating process. Thus, as the number of observations increases, rather than obtaining better inferences, the opposite occurs: the data is explained by adding spurious subpopulations that compensate for the shortcomings of the observation model. However, there are two important sources of prior knowledge that we can exploit to obtain well-defined results no matter the dataset size: known causal structure (e.g., knowing that the latent subpopulations cause the observed signal but not vice-versa) and a rough sense of how wrong the observation model is (e.g., based on small amounts of expert-labeled data or some understanding of the data-generating process). We propose a new model selection criteria that, while modelbased, uses this available knowledge to obtain mixture model inferences that are robust to misspecification of the observation model. We provide theoretical support for our approach by proving a first-of-its-kind consistency result under intuitive assumptions. Simulation studies and an application to flow cytometry data demonstrate our model selection criteria consistently finds the correct number of subpopulations.

Keywords and phrases: Cluster analysis; Model selection; Misspecified model; Mixture modeling.

1. Introduction

In scientific applications, mixture models are often used to discover unobserved subpopulations or distinct types that generated the observed data. Examples include cell type identification (e.g., using single-cell assays) (Gorsky, Chan and Ma, 2020; Prabhakaran et al., 2016), behavioral genotype discovery (e.g., using gene expression data) (Stevens et al., 2019), and psychology (e.g., patterns of IQ development) (Bauer, 2007). Further examples include disease recognition (Ghorbani Afkhami, Azarnia and Tinati, 2016; Ferreira da Silva, 2007; Greenspan, Ruf and Goldberger, 2006), anomaly detection (Zong et al., 2018), and types of abnormal heart rhythms from ECG (Ghorbani Afkhami, Azarnia and Tinati, 2016)). Since the true number of types or subpopulations K_{\circ} is usually unknown *a priori*, a key challenge in these applications is to determine K_{\circ} (Cai, Campbell and Broderick, 2021; Frühwirth-Schnatter, 2006; Guha, Ho and Nguyen, 2021; Miller and Dunson, 2019). While numerous inference methods provide consistent estimation when the mixture components are well-specified, if the components are misspecified, then standard methods do not work as intended. As the number of observations increases, rather than obtaining better inferences, the opposite occurs: the data is explained by adding spurious latent structures that compensate for the shortcomings of the observation model, which is known as *overfitting* (Cai, Campbell and Broderick, 2021; Frühwirth-Schnatter, 2006; Miller and Dunson, 2019).

To address the overfitting problem in the misspecified setting, various robust clustering methods have been developed. Heavy-tailed mixtures (Archambeau and Verleysen, 2007;

Bishop and Svensén, 2004; Wang and Blei, 2018) and sample re-weighting (Forero, Kekatos and Giannakis, 2011) both aim to account for slight model mismatches and outlier effects. However, these methods require choosing the number of clusters for the mixture model beforehand, and their performance heavily relies knowing the number of subpopulations. Most closely related to our approach, Miller and Dunson (2019) provides a novel perspective on establishing robustness without prior knowledge of number of clusters. They employ a technique they call *coarsening*: instead of assuming the data was generated from the assumed model, the *coarsened posterior* allows a certain degree of divergence between the model and data distribution. This flexibility permits the overall mixture model to deviate from the true underlying data by a set threshold. While this approach shows good robustness properties in practice, imposing the robustness threshold on the *overall* mixture density does not guarantee the convergence to a meaningful number of components. Moreover, their approach to determining K_{ρ} involves post-processing, specifically eliminating the minimal clusters. An additional challenge when using the coarsened posterior approach is its high computational cost: it requires running Markov chain Monte Carlo dozens of times to heuristically determine a suitable robustness threshold.

In this paper, we propose a model selection criterion to address the statistical and computational shortcomings of existing approaches. In contrast to the coarsened posterior approach, which is based on the overall degree of model-data mismatch, our approach operates at the *component level*. Moreover, our criterion is more flexible than previous approaches and can intuitively incorporate expert and prior knowledge about the nature of the model misspecification. One source of flexibility is the ability to combine it with any parameter estimation technique for mixture models. Another is that it supports a wide range of discrepancy measures between distributions, which can be chosen in an application-specific manner. Given a fitted model for each candidate number of components, the computational cost required to compute our criterion is determined by the cost of estimating the discrepancy measure, which is typically quite small. Because we employ component-wise robustness, we are able to show that, under natural conditions and for a wide variety of discrepancies, including the Kullback–Leibler divergence and the maximum mean discrepancy, our method identifies the number of components correctly in large datasets. We validate the effectiveness and computational efficiency of our model selection criterion when using the Kullback-Leibler divergence as the discrepancy measure through a combination of simulation studies and an application to cell type discovery using flow cytometry data.

2. Setting and Motivation

Consider data $x_{1:N} = (x_1, \ldots, x_N) \in \mathcal{X}^{\otimes N}$ independently and identically distributed from some unknown distribution P_o defined on the measurable space $(\mathcal{X}, \mathcal{B}_x)$. When discovering latent types, we assume that $P_o = \sum_{k=1}^{K_o} \pi_{ok} P_{ok}$, where K_o is the number of types, P_{ok} is the distribution of observations from the *k*th type, and π_{ok} is the probability that an observation belongs to the *k*th type. Thus, $\pi_o = (\pi_{o1}, \ldots, \pi_{oK_o}) \in \Delta_{K_o} = \{\pi \in \mathbb{R}_+^{K_o} \mid \sum_{k=1}^{K_o} \pi_k = 1\}$, the $(K_o - 1)$ -dimensional probability simplex, and we assume $\pi_{ok} > 0$ so all components contribute observations. We posit a mixture model parameterized by $\theta \in \Theta = \bigcup_{K=1}^{\infty} \Theta^{(K)}$, where $\Theta^{(K)} = \Delta_K \times \Phi^{\otimes K}$ for measurable space $(\Phi, \mathcal{B}_{\Phi})$ and $\phi \in \Phi$ parameterizes the family of mixture component distributions $\mathcal{F} = \{F_{\phi} \mid \phi \in \Phi\}$. For $\theta = (\pi, \phi_1, \ldots, \phi_K) \in \Theta$, the mixture model distribution is $G_{\theta} = \sum_{k=1}^{K} \pi_k F_{\phi_k}$. Given $x_{1:N}$, our goals are to (1) find K_o and (2) find a parameter estimate $\hat{\theta} = (\hat{\pi}, \hat{\phi}_1, \ldots, \hat{\phi}_{K_o}) \in \Theta^{(K_o)}$ such that (possibly after a reordering of the components) $\hat{\pi} \approx \pi_o$ and $F_{\hat{\phi}_k} \approx P_{ok}$.

Finding K_o can be challenging for standard model selection approaches given the presence of model misspecification (Cai, Campbell and Broderick, 2021; Frühwirth-Schnatter, 2006; Guha, Ho and Nguyen, 2021; Miller and Dunson, 2019). Specifically, as the number of observations increases, model selection criteria tend to create additional clusters to compensate for the model-data mismatch and thus overestimates K_o . The following toy example illustrates this phenomenon. Suppose data is generated from a mixture of $K_o = 2$ skew normal distributions and we use a Gaussian mixture to model the data. Here the level of model-data mismatch is controlled by the skewness parameter of each skew normal component in the true generative distribution P_o . We consider the following scenarios: two equal-sized clusters with the same level of misspecification (denoted same) and two equal-sized clusters with different levels of misspecification (denoted different). We compare three methods on their ability to find K_o : standard expectation-maximization with the Bayesian information criterion (Chen and Gopalakrishnan, 1998), the coarsened posterior (Miller and Dunson, 2019), and expectation-maximization with our proposed model selection criterion. See Section 6.1 for further details about the experimental set-up.

As shown in Fig. 1, in both scenarios the Bayesian information criterion selects $K > K_o$ to capture the skew-normal distributions. While the coarsened posterior performs well in the same case, its limitations become evident when the degree of misspecification differs significantly between components. In the different scenario, the coarsened posterior overfits the cluster with a larger degree of misspecification.

Another disadvantage of the coarsening approach comes from computational considerations. Letting π_0 denote the prior density and $\alpha > 0$, the coarsened posterior is given by

$$\pi_{\alpha}(\theta \mid x_{1:N}) \propto \pi_{0}(\theta) \prod_{n=1}^{N} f_{\phi}(x_{n})^{\frac{\alpha}{N+\alpha}},$$

where α controls the expected degree of misspecification (roughly speaking, that the Kullback– Leibler divergence between the population and estimated distributions is of order $1/\alpha$). Selecting α requires a grid search over dozens or more plausible values. Since a separate power posterior must be estimated for each α value, which typically requires using a slow Markov chain Monte Carlo algorithm, the coarsened posterior has a high computational cost.

To address the limitations of standard model selection methods and the coarsened posterior, we introduce a computationally efficient and statistically sound model selection criterion. As shown in Fig. 1, our method – which we describe in detail in the next section – identifies the correct value for K_o in both scenarios.

3. Structurally Aware Model Selection

3.1. Method

Our starting point for developing our robust model selection approach is to rewrite the model in a form which captures the known causal structure and makes the component distributions – which are the source of misspecification – explicit. The posterior, the coarsened posterior, and standard model selection methods based on point estimates are all based (at least asymptotically) on formulating the mixture model as

$$x_n \sim G_\theta = \sum_{k=1}^K \pi_k F_{\phi_k} \quad (n = 1, \dots, N).$$
 (1)

Fig 1: For the mixture of skew-normals example from Section 2, each panel shows the density of P_o (dashed lines) and the densities of the fitted Gaussian mixture model and each component distribution (solid lines) using $N = 10\,000$ observations. Results are given for three approaches: expectation-maximization with the Bayesian information criterion (first row), the coarsened posterior (second row), and our robust model selection method (third row).

However, Eq. (1) implicitly posits that the structural causal model for each observation is $x_n \leftarrow h(\phi, \pi; \varepsilon_n)$, where $\phi = (\phi_1, \ldots, \phi_K)$, $\pi = (\pi_1, \ldots, \pi_K)$, h is a deterministic function, and ε_n is an independent "noise" random variable. Since h is treated as a black box, it is impossible for inference methods based on Eq. (1) to always correctly account for component-level misspecification. This can lead to deceptive identification regarding the actual model fit from the perspective of individual components, as illustrated in Section 2.

An alternative way to formulate the mixture model is in the "uncollapsed" (latent variable) form

$$z_n \sim \mathsf{Categorical}(\pi), \qquad x_n \mid z_n = k \sim F_{\phi_k} \quad (n = 1, \dots, N).$$
 (2)

Equation (2) can also be written as the structural causal model

$$z_n \leftarrow h_z(\pi; \varepsilon_{z,n}), \qquad x_n \leftarrow h_x(\phi, z_n; \varepsilon_{x,n}) \quad (n = 1, \dots, N),$$
(3)

where h_z and h_x are deterministic functions and $\varepsilon_{z,n}$ and $\varepsilon_{x,n}$ are independent "noise" random variables. For a model selection criterion to reliably select the true number of components, it must make use of the causal structure given in Eq. (3). In particular, we want a method that exploits the fact that we know the relationship $x_n \leftarrow h_x(\phi, z_n; \varepsilon_{x,n})$ is misspecified. Hence, we describe our approach as being "structurally aware." We also rely on the assumption that $z_n \leftarrow h_z(\pi; \varepsilon_{z,n})$ is well-specified, although it is possible that assumption could be relaxed as well.

To construct a structurally aware model selection method that is robust to misspecification, we must have a way of measuring how different the estimated parametric component distribution F_{ϕ_k} is from the true component distribution P_{ok} . Therefore, we introduce a divergence $\mathcal{D}(P_{ok} | F_{\phi_k})$, which can be chosen by the user based on application-specific considerations. We assume that for some $\rho > 0$ representing the degree of misspecification, we can estimate component parameters $\phi_{\star k} \in \Phi$ such that $\mathcal{D}(P_{ok} | F_{\phi_{\star k}}) < \rho$ $(k = 1, \ldots, K_o)$. Let $z = (z_1, \ldots, z_N)$ denote the cluster assignments for the observations defined in Eq. (2). The set of observations assigned to component k, which we denote $X_k(z) = \{x_n | z_n = k, n = 1, \ldots, N\}$, provides samples that are approximately distributed according to P_{ok} . So, we require an estimator $\hat{\mathcal{D}}(X_k(z) | F_{\phi_k})$ which, when the empirical distribution of $X_k(z)$ converges to some limiting distribution \tilde{P}_k as $N \to \infty$, provides a consistent estimate of $\mathcal{D}(\tilde{P}_k | F_{\phi_k})$.

For clarity, we will often write $\theta^{(K)}$, $X_k^{(K)}(z^{(K)})$, etc. to denote that these quantities are associated with the mixture model with K components. Given $\mathcal{D}(\cdot | \cdot)$, $\hat{\mathcal{D}}(\cdot | \cdot)$, and ρ , we would like to design a loss function that will be minimized when $K = K_o$. Hence, the loss function should not decrease if all estimated discrepancies are less than ρ . Based on this requirement, define the *structurally aware loss*

$$\mathcal{R}^{\rho}(\theta^{(K)}; z^{(K)}, x_{1:N}) = \sum_{k=1}^{K} |X_k^{(K)}(z^{(K)})| \max(0, \hat{\mathcal{D}}(X_k^{(K)}(z^{(K)}) \mid F_{\phi_k^{(K)}}) - \rho).$$
(4)

By construction, the structurally aware loss is nonnegative and equal to zero (and therefore minimized) if $\hat{\mathcal{D}}(X_k^{(K)}(z^{(K)}) | F_{\phi_k^{(K)}}) < \rho$ for all k. On the one hand, if $\lim_{N \to \infty} \hat{\mathcal{D}}(X_k^{(K)}(z^{(K)}) | F_{\phi_k^{(K)}}) > \rho$ for some k, then the scaling by $|X_k^{(K)}(z^{(K)})|$ ensures the loss tends to ∞ as $N \to \infty$. Therefore, by minimizing Eq. (4) with respect to K, we can exclude $K < K_o$.

On the other hand, to asymptotically rule out $K > K_o$, we introduce an Akaike information criterion-like penalty term, leading to the *penalized structurally aware loss*

$$\mathcal{R}^{\rho,\lambda}(\theta^{(K)}; z^{(K)}, x_{1:N}) = \mathcal{R}^{\rho}(\theta^{(K)}; z^{(K)}, x_{1:N}) + \lambda K,$$
(5)

where $\lambda > 0$ controls the strength of the penalty. Given choices for λ , $\mathcal{D}(\cdot | \cdot)$, $\hat{\mathcal{D}}(\cdot | \cdot)$, and the maximum number of components to consider, K_{\max} , our robust, structurally aware model selection procedure is as follows:

Algorithm 1: Robust, structurally aware model selection	
1 for $K = 1,, K_{\max}$ do	
2 Obtain parameter estimate $\hat{\theta}^{(K)} \in \Theta^{(K)}$	
3 Sample $z^{(K)}$ from $p(z^{(K)} \hat{\theta}^{(K)}; x_{1:N})$	
4 If necessary, determine an appropriate value for ρ	
5 Compute $\hat{K} = \arg\min_K \mathcal{R}^{\rho,\lambda}(\hat{\theta}^{(K)}; z^{(K)}, x_{1:N})$	
6 return $\hat{ heta}^{(\hat{K})}$	

We next turn to rigorously justifying our proposed approach by proving a first-of-its-kind consistency result (Section 4). We then provide detailed guidance on using our approach in practice (Section 5).

4. Model Selection Consistency

4.1. A General Consistency Result

We now show that our model selection procedure consistently estimates K_o under reasonable assumptions. First, we consider the requirements for $\mathcal{D}(\cdot | \cdot)$ and $\hat{\mathcal{D}}(\cdot | \cdot)$. Some discrepancies are finite only under strong conditions. For example, for the Kullback–Leibler divergence, $\mathcal{D}(P | Q) < \infty$ only if P is absolutely continuous with respect to Q. However, we must work with the discrete estimates of each component, so such absolute continuity conditions may not hold. Therefore, we introduce a possibly weaker metric d on probability measures that detects empirical convergence.

Assumption 1. For $y_{N,n} \in \mathcal{X}$ (N = 1, 2, ...; n = 1, ..., N), define the empirical distribution $\hat{P}_N = N^{-1} \sum_{n=1}^N \delta_{y_{N,n}}$ and assume $\hat{P}_N \to P$ in distribution. The metric d, discrepancy \mathcal{D} , and estimator $\hat{\mathcal{D}}$ satisfy the following conditions:

- (a) The metric detects empirical convergence: $d(\hat{P}_N, P) \to 0$ as $N \to \infty$.
- (b) The metric is jointly convex in its arguments: for all $w \in (0,1)$ and distributions P, P', Q, Q',

$$d(wP + (1 - w)P', wQ + (1 - w)Q') \le w \, d(P, Q) + (1 - w) \, d(P', Q').$$

- (c) The discrepancy estimator is consistent: For any distributions P, Q, if $\mathcal{D}(P \mid Q) < \infty$ and $\hat{P}_N \to P$ in distribution, then $\hat{\mathcal{D}}(\hat{P}_N \mid Q) \to \mathcal{D}(P \mid Q)$ as $N \to \infty$.
- (d) Smoothness of the discrepancy estimator: The map $\phi \mapsto \hat{\mathcal{D}}(\hat{P}_N \mid F_{\phi})$ is continuous.
- (e) The discrepancy bounds the metric: there exists a continuous, non-decreasing function $\phi : \mathbb{R} \to \mathbb{R}$ such that $d(P,Q) \leq \phi(\mathcal{D}(P \mid Q))$ for all distributions P,Q.
- (f) The metric between components is finite: For all $\phi, \phi' \in \Theta$, we have $d(F_{\phi}, F_{\phi'}) < \infty$.

A wide variety of metrics satisfy Assumption 1(a), including the bounded Lipschitz metric, the Kolmogorov metric, maximum mean discrepancies with sufficiently regular bounded kernels, and the Wasserstein metric with a bounded cost function (Simon-Gabriel and

Schölkopf, 2018; Sriperumbudur et al., 2010; van der Vaart and Wellner, 1996; Villani, 2009). Assumption 1(b) also holds for a range of metrics. For example, it is easy to show that all integral probability metrics – which includes the bounded Lipschitz metric, maximum mean discrepancy, and 1-Wasserstein distance – are jointly convex (see Lemma S1 in the Supplementary Materials). Assumption 1(c) is a natural requirement that the divergence estimator is consistent. Such estimators are well studied for many common discrepancies. We discuss consistent estimation of the Kullback–Leibler divergence in Section 5.4. Assumption 1(d) will typically hold as long as the map $\phi \mapsto F_{\phi}$ is well-behaved. For example, for the Kullback–Leibler divergence estimators described in Section 5.4 and standard maximum mean discrepancy estimators (Bharti et al., 2023; Gretton et al., 2012), when F_{ϕ} admits a density f_{ϕ} , it suffices for the map $\phi \mapsto f_{\phi}(x)$ to be continuous for P_{ϕ} -almost every x. Assumption 1(e) is not overly restrictive. See Gibbs and Su (2002) for a extensive overview of the relationships between common metrics and divergences. Assumption 1(f) trivially holds for bounded metrics such as bounded Lipschitz metric and integral probability measures with uniformly bounded test functions.

Our second assumption requires the inference algorithm to be sufficiently regular, in the sense that, for each fixed number of components K, the parameter estimate should consistently estimate an asymptotic parameter $\theta_{\star}^{(K)}$.

Assumption 2. For each K > 0, there exists $\theta_{\star}^{(K)} \in \Theta^{(K)}$ such that the inference algorithm estimate $\hat{\theta}^{(K)} \to \theta^{(K)}_{\star}$ in probability as $N \to \infty$, after possibly reordering of components.

To simplify notation, we will write $F_{\star k}^{(K)} = F_{\phi_{\star k}^{(K)}}$ and $G_{\star k}^{(K)} = G_{\theta_{\star k}^{(K)}}$, and similarly for their densities. Assumption 2 holds for most reasonable algorithms, including expectationmaximization, point estimates based on the posterior distribution, and variational inference (Balakrishnan, Wainwright and Yu, 2017; Walker and Hjort, 2001; Wang and Blei, 2019). Note that we assume that consistency holds for parameters in the equivalence class induced by component reordering, although we keep this equivalence implicit in the discussion that follows. Assumption 2 implies that the empirical data distribution of the kth component, $\hat{P}_k^{(K)} = |X_k(z^{(K)})|^{-1} \sum_{x \in X_k(z^{(K)})} \delta_x$, converges to a limiting distribution

$$\tilde{P}_{k}^{(K)}(\mathrm{d}x) = \frac{p_{\star}^{(K)}(k \mid x)P_{o}(\mathrm{d}x)}{\int p_{\star}^{(K)}(k \mid y)P_{o}(\mathrm{d}y)},\tag{6}$$

where $p_{\star}^{(K)}(k \mid x) = \pi_{\star k}^{(K)} f_{\star k}^{(K)}(x) / g_{\star}^{(K)}(x)$ is the conditional component probability under the limiting model distribution.

Our third assumption concerns the regularity of the data distribution and model.

Assumption 3 (ρ). The data-generating distribution P_{ρ} and component model family \mathcal{F} satisfy the following conditions:

- (a) Meaningful decomposition of the data-generating distribution: for positive integer K_o ,
- $\pi_{o} \in \Delta_{K_{o}}, \text{ and distributions } P_{o1}, \dots, P_{oK_{o}} \text{ on } \mathcal{X}, \text{ it holds that } P_{o} = \sum_{k=1}^{K_{o}} \pi_{ok} P_{ok}.$ (b) Accuracy of the parameter estimates for $K = K_{o}$: for each $k = 1, \dots, K_{o}$, it holds that $\mathcal{D}(\tilde{P}_{k}^{(K_{o})} \mid F_{\star k}^{(K_{o})}) < \rho.$
- (c) Poor model fit when K is too small: for any $K < K_o$, it holds that $d(P_o, G_{\star}^{(K)}) > \phi(\rho)$.

Assumption 3(a) formalizes the decomposition of the data-generating distribution into the subpopulations/types/groups that we aim to recover. Assumption 3(b) requires that, when

the number of components is correctly specified, the divergence between the asymptotic empirical component distribution $\tilde{P}_k^{(K_o)}$ and the asymptotic component $F_{\star k}^{(K_o)}$ is small for each component $k = 1, \ldots, K_o$. In Section 4.3, we give conditions under which $\mathcal{D}(P_{ok}^{(K_o)} | F_{\star k}^{(K_o)}) < \rho_o$ implies the assumption holds for the Kullback–Leibler divergence and integral probability metrics with bounded test functions. Assumption 3(c) formalizes the intuition that model selection will only be successful if, when the number of components is smaller than the true generating process, the mixture model is a poor fit to the data. The necessary degree of mismatch depends on the match between the true and estimated component distributions, which depends on the choice of \mathcal{D} and is measured by ρ , and the relationship between \mathcal{D} and d, which is described by ϕ .

The following result provides a general framework to establish when our method consistently estimates K_o . For notational clarity, let $\hat{K}_N(\rho) = \hat{K} = \arg \min_K \mathcal{R}^{\rho,\lambda}(\hat{\theta}^{(K)}; z^{(K)}, x_{1:N})$ denote the structurally aware robust model choice.

Theorem 1. If Assumptions 1 to $3(\rho)$ hold, then $pr\{\hat{K}_N(\rho) = K_o\} \to 1$ as $N \to \infty$.

To prove Theorem 1 we establish two facts. First, the (unregularized) structurally aware loss satisfies $\operatorname{pr}\{\mathcal{R}^{\rho}(\theta^{(K_o)}; z^{(K_o)}, x_{1:N}) = 0\} \to 1$ as $N \to \infty$. Second, for $K < K_o$, $\mathcal{R}^{\rho}(\theta^{(K)}; z^{(K)}, x_{1:N}) \to \infty$ in probability as $N \to \infty$ Therefore, for $K > K_o$, asymptotically $\mathcal{R}^{\rho,\lambda}(\theta^{(K)}; z^{(K)}, x_{1:N}) \geq \mathcal{R}^{\rho,\lambda}(\theta^{(K_o)}; z^{(K_o)}, x_{1:N}) + \lambda(K - K_o)$, so the minimum is asymptotically attained at $\hat{K} = K_o$.

Theorem 1 leaves two important questions open. First, what choices of \mathcal{D} and d can satisfy Assumption 1 (and for what choice of ϕ)? While Assumption 3 requires that $\mathcal{D}(\tilde{P}_{k}^{(K_{o})} | F_{\star k}^{(K_{o})}) < \rho$, it is more natural to require a bound on $\mathcal{D}(P_{ok} | F_{\star k}^{(K_{o})})$. So, the second question is, Does a bound on the latter imply the former? We address each of these questions in turn.

4.2. Choice of Divergence

There are many possible choices for the divergence, including the Kullback–Leibler divergence (Joyce, 2011), maximum mean discrepancy (Sriperumbudur et al., 2010), Hellinger distance (Gibbs and Su, 2002), or Wasserstein metric (Villani, 2009). We next show that both the Kullback–Leibler divergence and mean maximum discrepancy can satisfy Assumption 1(a,b,e) with an appropriate choice of d. Specifically, we will make use of integral probability metrics. Given a collection \mathcal{H} of real-valued functions on \mathcal{X} , the corresponding integral probability metric is

$$d_{\mathcal{H}}(P,Q) = \sup_{h \in \mathcal{H}} \left| \int h(x)P(\mathrm{d}x) - \int h(y)Q(\mathrm{d}y) \right|.$$

If \mathcal{D} is the Kullback–Leibler divergences, we choose d to be the bounded Lipschitz metric. Assume that \mathcal{X} is equipped with a metric m and define the bounded Lipschitz norm $\|h\|_{\mathrm{BL}} = \|h\|_{\infty} + \|h\|_{L}$, where $\|h\|_{L} = \sup_{x \neq y} |h(x) - h(y)|/m(x, y)$ and $\|h\|_{\infty} = \sup_{x} |h(x)|$. Letting $\mathcal{H} = \mathcal{H}_{\mathrm{BL}} = \{h : \|h\|_{\mathrm{BL}} \le 1\}$ gives the bounded Lipschitz metric $d_{\mathrm{BL}} = d_{\mathcal{H}_{\mathrm{BL}}}$.

Proposition 1. If $d(P,Q) = d_{BL}(P,Q)$ and $\mathcal{D}(P \mid Q) = KL(P \mid Q)$, then Assumption 1(a,b,e) holds with $\phi(\rho) = (\rho/2)^{1/2}$.

If we choose the divergence to be a mean maximum discrepancy, d can be the same. Let $\mathcal{K} : \mathcal{X} \times \mathcal{X} \to \mathbb{R}$ denote a positive definite kernel. Denote the reproducing kernel Hilbert space with kernel \mathcal{K} as $\mathcal{H}_{\mathcal{K}}$. Denote its inner product by $\langle \cdot, \cdot \rangle_{\mathcal{K}}$ and norm by $\|\cdot\|_{\mathcal{K}}$. Letting

 $\mathcal{H} = \mathcal{B}_{\mathcal{K}} = \{h \in \mathcal{H}_{\mathcal{K}} : \|h\|_{\mathcal{K}} \leq 1\}, \text{ the unit ball, gives the mean maximum discrepancy} d_{MMD} = d_{\mathcal{B}_{\mathcal{K}}}.$

Proposition 2. If \mathcal{K} is chosen such that d_{MMD} metrizes weak convergence, and $d(P,Q) = \mathcal{D}(P \mid Q) = d_{\text{MMD}}(P,Q)$, then Assumption 1(a,b,e) holds with $\phi(\rho) = \rho$.

For conditions under which d_{MMD} metrizes weak convergence, see Simon-Gabriel et al. (2023); Sriperumbudur et al. (2010).

4.3. Bounding the Component-level Discrepancy

Assumption $3(\rho)(b)$, requires the discrepancy between the limiting empirical component distribution and the model component be less than ρ . However, such a requirement is not completely satisfactory since \tilde{P}_k depends on both P_o and the mixture model family. A more intuitive and natural assumption would bound the divergence between true component distribution and model component – that is, be of the form $\mathcal{D}(P_{ok} \mid F_{\star k}^{(K_o)}) < \rho_o$ for some $\rho_o > 0$. In this section, we show how to relate ρ_o to ρ for the Kullback–Leibler divergence and integral probability metrics, including the maximum mean discrepancy.

Define the conditional component probabilities for the true generating distribution as

$$p_o(k \mid x) = \frac{\pi_{ok} p_{ok}(x)}{p_o(x)}.$$
(7)

We rely on the following assumption.

Assumption 4. There exist constants $\epsilon_{\pi}, \epsilon_{z} > 0$ such that for all $k = 1, \ldots, K_{o}$,

$$\frac{\pi_{\star k}}{\pi_{ok}} < 1 + \epsilon_{\pi}, \qquad \frac{p_{\star}^{(K_o)}(k \mid x)}{p_o(k \mid x)} < 1 + \epsilon_z. \tag{8}$$

We first consider the Kullback–Leibler divergence case.

Proposition 3. If $\mathcal{D}(P \mid Q) = \mathrm{KL}(P \mid Q)$, Assumption 4 holds, and $\mathrm{KL}(P_{ok} \mid F_{\star k}^{(K_o)}) < \rho_o$ for $k = 1, \ldots, K_o$, then Assumption $3(\rho)(b)$ holds for $\rho = (1 + \epsilon_{\pi})(1 + \epsilon_z)[\rho_o + \log(1 + \epsilon_{\pi})(1 + \epsilon_z)]$.

For integral probability measures, we will focus on the common case where the test functions are uniformly bounded.

Proposition 4. If $\mathcal{D}(P \mid Q) = d_{\mathcal{H}}(P,Q)$, Assumption 4 holds, there exists M > 0 such that $\|h\|_{\infty} < M$ for all $h \in \mathcal{H}$, and $d_{\mathcal{H}}(P_{ok}, F_{\star k}^{(K_o)}) < \rho_o$ for $k = 1, \ldots, K_o$, then Assumption $\mathfrak{Z}(\rho)(b)$ holds for $\rho = M(\epsilon_{\pi} + \epsilon_z + \epsilon_{\pi}\epsilon_z) + \rho_o$.

Proposition 4 provides justification for a broad class of metrics including the bounded Lipschitz metric, the total variation distance, and the Wasserstein distance when \mathcal{X} is a compact metric space. In addition, it applies to maximum mean discrepancies as long as $\mathcal{K}(x, x)$ is uniformly bounded since, for $h \in \mathcal{B}_{\mathcal{K}}$,

$$h(x) = \langle h, \mathcal{K}(x, \cdot) \rangle_{\mathcal{K}} \le \|h\|_{\mathcal{K}} \|\mathcal{K}(x, \cdot)\|_{\mathcal{K}} = \mathcal{K}(x, x)^{1/2}, \tag{9}$$

so we may take $M = \sup_x \mathcal{K}(x, x)^{1/2}$.

5. Practical Considerations

5.1. Computation

Our model selection framework can be used with any parameter estimation algorithm (e.g., expectation-maximization, Markov chain Monte Carlo, or variational inference). Thus, the choice of algorithm can be based the statistical and computational considerations relevant to specific problem at hand. In our experiments we use an expectation-maximization algorithm to approximate the maximum likelihood parameter estimates for each possible choice of K.

Once parameter estimates have been obtained, the other major cost is computing the penalized structurally aware loss $\mathcal{R}^{\rho,\lambda}(\hat{\theta}^{(K)}; z^{(K)}, x_{1:N})$, which is generally dominated by the computation of the divergence estimator. We discuss the particular case of Kullback–Leibler divergence estimation in Section 5.4. Numerous approaches exists for estimating other metrics such as the maximum mean discrepancy (Bharti et al., 2023; Gretton et al., 2012).

5.2. Choosing ρ

While the results from Section 4 show that, with an appropriate choice of ρ , our method consistently estimates the number of mixture model components, those results do not suggest a way to select ρ in practice. Hence, we propose two complementary approaches to selecting ρ that take advantage of the fact that the structurally aware loss is a piecewise linear function of ρ . Therefore, given a fitted model for each candidate K, we can easily compute the structurally aware loss for all values of ρ .

Our first approach aims to leverage domain knowledge. Specifically, it is frequently the case that some related datasets are available with "ground-truth" labels either through manual labeling or via *in silico* mixing of data where group labels are directly observed (see, e.g., de Souto et al., 2008). In such cases an appropriate ρ value or range of candidate values for one or more such datasets with ground-truth labels can be determined by maximizing a clustering accuracy metric such as *F*-measure. Because ρ quantifies the divergence between the true component distributions and the model estimates, we expect the values found using this approach will generalize to new datasets that are reasonably similar. This approach is employed in our real-data experiments with flow cytometry data, discussed in Section 6.

For applications where there are no related datasets with ground-truth labels available, we propose a second, more heuristic approach. After estimating the model parameters for each fixed $K = 1, \ldots, K_{\text{max}}$ and computing all component-wise divergences, we plot the penalized loss as a function of ρ for each $K \in \{1, \ldots, K_{\text{max}}\}$. The optimal model is determined by identifying the number of components which is best over a wide range of ρ values, with ρ as small as possible. The idea behind this selection rule is to identify the first instance of stability, indicating that increasing ρ further doesn't notably improve the loss. However, subsequent stable regions that appear afterward might introduce too much tolerance, potentially resulting in model underfitting. This approach is similar in spirit to the one introduced for heuristically selecting the α parameter for the coarsened posterior (Miller and Dunson, 2019).

We illustrate our second approach using a Poisson mixture model simulation study. Suppose data x_1, \ldots, x_N is generated from a negative binomial mixture $P_o = \sum_{k=1}^{K_o} \pi_{ok} \text{NegBin}(m_k, p_k)$. The assumed model is $G_{\theta} = \sum_{k=1}^{K} \pi_k \text{Poiss}(\phi_k)$. We set $N = 20\,000, K_o = 3, m = (55, 75, 100), p = (0.5, 0.3, 0.5)$, and $\pi_o = (0.3, 0.3, 0.4)$. We use the plug-in Kullback–Leibler estimator (see

11

Fig 2: Fitting a Poisson mixture model to data from a mixture of negative binomial distributions (Section 5.2). Left: Penalized loss plot for K = 1 (blue), K = 2 (orange), K = 3 (green) and K = 4 (gray). The cross mark indicates the first wide stable region and is labeled with the number of clusters our method selects. **Right:** Estimated model distribution (orange) compared to the observed data (blue).

Eq. (10) in Section 5.4 below). Based on Fig. 2(left), the first wide and stable region corresponds to the true number of components K = 3. The observed data and fitted model distribution for K = 3 are shown in Fig. 2(right).

5.3. Choosing λ

The penalized structurally aware loss function requires selecting the penalty parameter λ . In practice the primary purpose of the penalty is to select the smallest value of K that results in $\mathcal{R}^{\rho}(\theta^{(K)}; z_{1:N}, x_{1:N}) = 0$. So, we recommend setting λ to a value that is small relative to the estimates of the divergence. For example, we set $\lambda = 0.01$ in our simulation studies and set $\lambda = 10$ in the real-data experiments so as to ensure the ρ versus loss plots were easy to read. In particular, choosing smaller values would not have changed the results.

5.4. Estimation of Kullback-Leibler divergence

Our theoretical results naturally require a consistent estimator of the divergence. Thus, we briefly cover the question of how best to estimate the Kullback-Leibler divergence in practice. For further details, refer to the Supplementary Materials. We consider a general setup with observations $y_{1:N} = (y_1, \ldots, y_N) \in \mathcal{X}^{\otimes N}$ independent, identically distributed from a distribution P. First consider the case where \mathcal{X} is countable, and let $N(x) = #\{n \in \{1, \ldots, N\} \mid y_n = x\}$ denote the number of observations taking the value $x \in \mathcal{X}$. Letting Q be a distribution with probability mass function q, we can use the plug-in estimator for $\mathrm{KL}(P \mid Q)$,

$$\widehat{\mathrm{KL}}(y_{1:N} \mid F) = \sum_{x \in \mathcal{X}} \frac{N(x)}{N} \log\left\{\frac{N(x)}{Nq(x)}\right\},\tag{10}$$

which is consistent under modest regularity conditions (Paninski, 2003).

Next we consider the case of general distributions on $\mathcal{X} = \mathbb{R}^D$, when estimation of Kullback–Leibler divergence is less straightforward. One common approach is to utilize

k-nearest-neighbor density estimation. For r > 0, let $V_D(r) = \frac{\pi^{D/2}}{\Gamma(D/2+1)} r^D$ denote the volume of an D-dimensional ball of radius r and let $r_{k,n}$ denote the distance to the kth nearest neighbor of y_n . Following the same approach as Zhao and Lai (2020) and assuming the distribution Q has Lebesgue density q, we obtain a one-sample estimator for KL($P \mid Q$):

$$\widehat{\mathrm{KL}}_{k}^{\mathrm{b}}(y_{1:N} \mid Q) = \frac{1}{N} \sum_{n=1}^{N} \log \left\{ \frac{k/(N-1)}{V_{D}(r_{k,n})q(y_{n})} \right\}.$$
(11)

As we discuss in the Supplementary Materials, for fixed k, the estimator in Eq. (11) is asymptotically biased. However, it is easy to correct this bias, leading to the unbiased, consistent estimator

$$\widehat{\mathrm{KL}}_{k}^{\mathrm{u}}(y_{1:N} \mid Q) = \widehat{\mathrm{KL}}_{k}^{\mathrm{b}}(y_{1:N} \mid Q) - \log k + \psi(k), \qquad (12)$$

where $\psi(k)$ denotes the digamma function. Another way to construct a consistent estimator is to let $k = k_N$ depend on the data size N, with $k_N \to \infty$ as $N \to \infty$. A canonical choice is $\widehat{\mathrm{KL}}_{k_N}^{\mathrm{b}}(y_{1:N} \mid Q)$ with $k_N = N^{1/2}$.

We compare the three estimators for various dimensions in Supplementary Materials. Our results show that the bias-corrected estimator slightly improves the biased version when $N \geq 5000$, while the adaptive estimator with $k_N = N^{1/2}$ has the most reliable performance when D = 4. Since the data dimensions are relatively low in all our experiments, we use the adaptive estimator with $k_N = N^{1/2}$.

It is important to highlight that Kullback–Leibler divergence estimators require density estimation, which in general requires the sample size to grow exponentially with the dimension (Donoho, 2000). This limits the use of such estimators with generic high dimensional data. However, a general strategy to address this would be to take advantage of some known or inferable structure in the distribution to reduce the effective dimension of the problem. We provide a more detailed illustration of this strategy in Section 6.2 with simulated data that exhibits weak correlations across coordinates.

6. Numerical Experiments

6.1. Simulation Study: Skew-normal mixture

We now provide further details about the motivating example in Section 2, and illustrate that our method selects the correct number of components under a variety of conditions on the level of misspecification and the relative sizes of the mixture components. We generate data $x_1, \ldots, x_n \in \mathbb{R}$ from skew-normal mixtures of the form $P_o = \sum_{k=1}^{K_o} \pi_{ok} SN(\mu_{ok}, \sigma_{ok}, \gamma_{ok})$, where $SN(\cdot)$ denotes the skew-normal distribution and γ_{ok} denotes the skewness parameter. The density of the skew-normal distribution $SN(\mu, \sigma, \gamma)$ is $f(x) = 2\phi(x; \mu, \sigma)\Phi(\gamma x; \mu, \sigma)$, where $\phi(x; \mu, \sigma)$ and $\Phi(x; \mu, \sigma)$ denote the probability density function and the cumulative distribution function of $N(\mu, \sigma)$ respectively. We model the data using Gaussian mixture model $G_{\theta} = \sum_{k=1}^{K} \pi_k N(\mu_k, \sigma_k)$. The bigger $|\gamma_{ok}|$, the larger the deviation from the Gaussian distribution, hence introducing a higher degree of misspecification.

In Section 2, we considered the case of two clusters of similar sizes. We set $\pi_o = (0.5, 0.5)$, $\mu_o = (-3, 3)$, and $\sigma_o = (1, 1)$ for the two scenarios in Fig. 1: $\gamma_o = (-10, -1)$ (denoted different) and $\gamma_o = (-10, -10)$ (denoted same). We now compare our approach to the

Fig 3: Comparison between the coarsened posterior and our method when using a Gaussian mixture model to fit data generated from a mixture of skew-normal distributions. First row: Densities of the model and components selected using the coarsened posterior (solid lines) and the density of the data distribution (dashed line). The title specifies the data-generating distribution and the number of components selected. In the middle plot of the first row, the minor cluster contains two components. Second row: Densities of the model and components selected using our structurally aware robust method. Third row: Penalized loss plots, where the cross mark indicates the first wide stable region and is labeled with the number of clusters our method selects. Line colors correspond to different K values. See caption in Fig. 2 for details.

coarsened posterior with data from two-component mixtures of different cluster sizes. We set $\pi_o = (0.95, 0.05)$, $\mu_o = (-3, 3)$, and $\sigma_o = (1, 1)$ for the following three scenarios: $\gamma_o = (-10, -1)$ (denoted large-small), $\gamma_o = (-1, -10)$ (denoted small-large), and $\gamma_o = (-10, -10)$ (denoted large-large).

For the coarsened posterior, we calibrate the hyperparameter α following the procedure from Miller and Dunson (2019, Section 4). First, we use Markov chain Monte Carlo to approximate the coarsened posterior for α values ranging from 10 to 10^5 . Then, we select the coarsened posterior with the α value at the clear cusp that indicates a good fit and low complexity. See the Supplementary Materials for further details and calibration plots. As shown for large-small and large-large in Fig. 3, when the larger cluster has large misspecification, the coarsened posterior introduces one additional cluster to explain the larger cluster. For the small-large case, when the larger cluster exhibits a small degree of misspecification, the coarsened posterior introduces one additional cluster to explain the smaller cluster.

Fig 4: Application of our method to simulated high dimensional data. Left: The penalized loss plot for determining the number of components. See Fig. 2 for description of line colors. Right: Selected two-dimensional projections of ground truth.

Our method correctly calibrates the model mismatch cutoff ρ using the penalized loss plots shown in Fig. 3, as in all cases K = 2 corresponds to the first wide, stable region. By the density plots in the middle column, we can see that our structurally aware robust model selection method is able to properly trade off a worse density estimate for better model selection. Our approach also enjoys improved computational efficiency compared to coarsened posterior (see discussion in Section 2). This is verified in the runtime comparison that running one scenario using our structurally aware robust model selection method (code in Python) takes about 1 minute while using the coarsened posterior (code in Julia) takes 140 minutes, despite Julia generally being much faster than Python in scientific computing applications (Perkel et al., 2019).

6.2. High Dimensional Study

As discussed in Section 5.4, the Kullback–Leibler k-nearest-neighbor estimator becomes less accurate with increasing data dimension. While a general solution is unlikely to exist, we illustrate one approach to address this challenge. Specifically, if we believe the coordinates are likely to be only weakly correlated, we can employ the k-nearest-neighbor method on each coordinate by assuming the coordinates are independent.

We generalize the simulation example from Section 6.1 to generate data from multivariate skew normal mixtures and fit a multivariate normal mixture model. Suppose $x_1, \ldots, x_N \in \mathbb{R}^D$ is generated from $P_o = \sum_{k=1}^{K_o} \pi_{ok} S \mathcal{N}(m_{ok}, \sum_{ok}, \gamma_{ok})$, where γ_{ok} is a *D*-dimensional vector controlling the skewness of the distribution, m_{ok} and \sum_{ok} are the means and covariance matrix of the *k*th component. The density for multivariate skew normal distribution is $f(x; m, \Sigma, \gamma) =$ $2\phi(x; m, \Sigma)\Phi(\gamma \odot x; m, \Sigma)$, where $\phi(x; m, \Sigma)$ and $\Phi(x; m, \Sigma)$ are the probability density function and cumulative distribution function of multivariate normal $\mathcal{N}(m, \Sigma)$ respectively. For each covariance matrix, we introduce weak correlations by letting $\Sigma_{ok} = \Sigma$, where $\Sigma_{ij} = \exp\{-(i-j)^2/\sigma^2\}$ and σ controls the strength of the correlation. We set $\sigma = 0.6$ and sample $N = 10\,000$ observations of dimension D = 50. As shown in Fig. 4(left), the wide and stable region corresponds to the true number of components K = 3. Fig. 4(right) illustrates the value of model-based clustering, particularly in high dimensions: 2-dimensional projections of the data give the appearance of there being four clusters in total, when in fact there are only three.

Fig 5: ρ versus F-measure for training datasets 1–6 (solid lines). The black dashed line indicates averaged F-measure over the training datasets.

6.3. Application to Flow Cytometry Data

Flow cytometry is a technique used to analyze properties of individual cells in a biological material. Typically, flow cytometry data measures 3–20 properties of tens of thousands cells. Cells from distinct populations tend to fall into clusters and discovering cell populations by identifying clusters is of primary interest in practice. Usually, scientists identify clusters manually which is labor-intensive and subjective. Therefore, automated and reliable clustering inference is invaluable. We follow the approach of Miller and Dunson (2019) and test our method on the same 12 flow cytometry datasets originally from a longitudinal study of graft-versus-host disease in patients undergoing blood or marrow transplantation (Brinkman et al., 2007). For these datasets, we calibrate ρ using the first 6 datasets. We take the manual clustering as the ground truth. The datasets consist of D = 4 dimensions and varying number of observations for each dataset.

As shown in Fig. 5, all training datasets 1-6 have a nearly identical trend of clustering accuracy as a function of ρ . The averaged F-measure achieves the maximum when $\rho \approx 1.16$, which is a point of maximum F-measure for all 6 datasets. The consistency of our method compares favorably to using coarsening, where drastically different α values maximize the F-measure (Miller and Dunson, 2019, Figure 5). These results provide evidence that our approach is taking better advantage of the common structure and degree of misspecification across datasets.

For test datasets 7-12, we propose to pick the value of K that achieves a stable structurally aware loss and uses a value of ρ that is as close as possible to the estimated ρ values of 1.16. As shown in Table 1, our method provides essentially the same average accuracy as the coarsened posterior while being substantially more computationally efficient, despite using a much slower programming language (2 hours using Python versus 30 hours using Julia).

F-measures on flow cytometry test datasets 7-12								
	7	8	9	10	11	12		
Structurally aware	0.63	0.92	0.94	0.99	0.99	0.98		
Coarsened	0.67	0.88	0.93	0.99	0.99	0.99

Appendix A: Technical Lemma

The following lemma states that integral probability metrics (as defined in Eq. (8)) are jointly convex – that is, they satisfy Assumption 1(b).

Lemma 1. Suppose P_i and Q_i , i = 1, ..., n are probability measures defined on \mathcal{X} . Then for $0 \le w_i \le 1$ and $\sum_{i=1}^n w_i = 1$,

$$d_{\mathcal{H}}\left(\sum_{i=1}^{n} w_i P_i, \sum_{i=1}^{n} w_i Q_i\right) \leq \sum_{i=1}^{n} w_i d_{\mathcal{H}}(P_i, Q_i).$$

Proof. By definition of the integral probability metric,

$$d_{\mathcal{H}}\left(\sum_{i=1}^{n} w_{i}P_{i}, \sum_{i=1}^{n} w_{i}Q_{i}\right) = \sup_{h\in\mathcal{H}} \left| \int_{\mathcal{X}} h(x) \left(\sum_{i=1}^{n} w_{i}P_{i}(\mathrm{d}x)\right) - \int_{\mathcal{X}} h(x) \left(\sum_{i=1}^{n} w_{i}Q_{i}(\mathrm{d}x)\right) \right|$$
$$= \sup_{h\in\mathcal{H}} \left| \sum_{i=1}^{n} w_{i} \left(\int_{\mathcal{X}} h(x)P_{i}(\mathrm{d}x) - \int_{\mathcal{X}} h(x)Q_{i}(\mathrm{d}x) \right) \right|$$
$$\leq \sup_{h\in\mathcal{H}} \sum_{i=1}^{n} w_{i} \left| \int_{\mathcal{X}} h(x)P_{i}(\mathrm{d}x) - \int_{\mathcal{X}} h(x)Q_{i}(\mathrm{d}x) \right|$$
$$\leq \sum_{i=1}^{n} w_{i} \sup_{h\in\mathcal{H}} \left| \int_{\mathcal{X}} h(x)P_{i}(\mathrm{d}x) - \int_{\mathcal{X}} h(x)Q_{i}(\mathrm{d}x) \right|$$
$$= \sum_{i=1}^{n} w_{i}d_{\mathcal{H}}(P_{i},Q_{i}).$$
(13)

Appendix B: Proofs

B.1. Notation

We write $o_P(g(N))$ to denote a random function f that satisfies $f(N)/g(N) \to 0$ in probability for $N \to \infty$. Let $\hat{\phi}_k^{(K,N)}$ denote the kth component parameter estimate using $x_{1:N}$ for the mixture model with K components. More generally, we replace superscript (K) with (K, N)to make the dependence on N explicit. Let $\hat{n}_k^{(K,N)} = |X^{(k)}(z^{(K,N)})|$ and $\hat{\pi}_k^{(K,N)} = \hat{n}_k^{(K,N)}/N$. Note that, with probability 1, $\hat{n}_k^{(K,N)} \to \infty$ as $N \to \infty$. For simplicity, we introduce the shorthand notation $F_k^{(K,N)} = F_{\hat{\phi}_k^{(K,N)}}, \mathcal{R}_N^{\rho}(\theta^{(K)}) = \mathcal{R}^{\rho}(\theta^{(K)}; z^{(K,N)}, x_{1:N})$, and $\mathcal{R}_N^{\rho,\lambda}(\theta^{(K)}) = \mathcal{R}^{\rho,\lambda}(\theta^{(K)}; z^{(K,N)}, x_{1:N})$.

Define the conditional component probabilities based on optimal model distribution and true generating distribution respectively as

$$p_{\star}^{(K)}(k \mid x) = \frac{\pi_{\star k}^{(K)} f_{\star k}^{(K)}(x)}{g_{\star}^{(K)}(x)}, \qquad p_o(k \mid x) = \frac{\pi_{ok} p_{ok}(x)}{p_o(x)}.$$

For conditional probabilities of model distribution, we denote as $\hat{p}^{(K,N)}(k \mid x) = \hat{\pi}_k^{(K,N)} f_k^{(K,N)}(x) / g^{(K,N)}(x)$. Note that $\hat{p}^{(K,N)}(k \mid x) \to p_\star^{(K)}(k \mid x)$ as $N \to \infty$ with probability 1.

B.2. Proof of Theorem 1

We show that (1) for $K = K_o$, $\mathcal{R}_N^{\rho}(\theta_{\star}^{(K)}) \to 0$ in probability as $N \to \infty$, and (2) for $K < K_o$, $\mathcal{R}^{\rho}_{N}(\theta^{(K)}_{\star}) \to \infty$ in probability as $N \to \infty$. The theorem conclusion follows immediately from these two results since the unpenalized loss is lower bounded by zero, so the penalized loss will be asymptotically minimized at the smallest K which has unpenalized loss of zero.

Proof of part (1). Fix $K = K_o$. It follows from Assumptions 1(c,d) and 2 that $\hat{\mathcal{D}}(\hat{P}_k^{(K_o,N)} | F_k^{(K,N)}) \to \mathcal{D}(\tilde{P}_k | F_{\star k}^{(K_o)})$ in probability. Hence, it follows from Assumption $3(\rho)(\mathbf{b})$ that there exists $\epsilon > 0$ such that

$$\hat{\mathcal{D}}(\hat{P}_k^{(K_o,N)} \mid F_k^{(K,N)}) < \rho - \epsilon + o_P(1).$$

Using this inequality, it follows that

$$\mathcal{R}_{N}^{\rho}(\theta_{\star}^{(K_{o})}) = \sum_{k=1}^{K_{o}} \hat{n}_{k}^{(K_{o},N)} \max\{0, \hat{\mathcal{D}}(\hat{P}_{k}^{(K_{o},N)} \mid F_{k}^{(K_{o},N)}) - \rho\}$$
(14)

$$\leq \sum_{k=1}^{K_o} \hat{n}_k^{(K_o,N)} \max\{0, -\epsilon + o_P(1)\}.$$
(15)

Hence, we can conclude that $\lim_{N\to\infty} \operatorname{pr}[\mathcal{R}^{\rho}_{N}(\theta^{(K_{o})}_{\star}) = 0] = 1$. **Proof of part (2).** Now we consider the case of $K < K_{o}$. Note the empirical distribution can be written as $\hat{P}^{(K,N)} = \sum_{k=1}^{K} \hat{\pi}^{(K,N)}_{k} \hat{P}^{(K,N)}_{k}$. By dominated convergence, we know that for $N \to \infty$,

$$\hat{\pi}_{k}^{(K,N)} = \int \hat{p}^{(K,N)}(k \mid y) P_{o}(\mathrm{d}y) \to \int p_{\star}^{(K)}(k \mid y) P_{o}(\mathrm{d}y) = \pi_{\star k}^{(K)}, \tag{16}$$

where convergence is in probability.

For the purpose of contradiction, assume that for all $k = 1, \ldots, K$, $\mathcal{D}(\tilde{P}_k \mid F_{\star k}^{(K)}) \leq \rho$. Consider

$$d\left(G_{\star}^{(K)}, P_{o}\right) \tag{17}$$

$$\leq d\left(G_{\star}^{(K)}, \hat{P}^{(K,N)}\right) + d\left(\hat{P}^{(K,N)}, P_{o}\right) \tag{18}$$

$$= d\left(\sum_{k=1}^{K} \pi_{\star k}^{(K)} F_{\star k}^{(K)}, \sum_{k=1}^{K} \hat{\pi}_{k}^{(K,N)} \hat{P}_{k}^{(K,N)}\right) + o_{P}(1)$$
(19)

$$\leq d\left(\sum_{k=1}^{K} \pi_{\star k}^{(K)} F_{\star k}^{(K)}, \sum_{k=1}^{K} \hat{\pi}_{k}^{(K,N)} F_{\star k}^{(K)}\right) + d\left(\sum_{k=1}^{K} \hat{\pi}_{k}^{(K,N)} F_{\star k}^{(K)}, \sum_{k=1}^{K} \hat{\pi}_{k}^{(K,N)} \hat{P}_{k}^{(K,N)}\right) + o_{P}(1),$$

$$(20)$$

where Eq. (19) follows by Assumption 1(a). Define $\pi_k^{\min} = \min\{\pi_{\star k}^{(K)}, \hat{\pi}_k^{(K,N)}\}$ and $\bar{\pi} =$

$$1 - \sum_{k=1}^{K} \pi_k^{\min}$$
. Let $\|\cdot\|_1$ denote the ℓ_1 -norm. For the first term in Eq. (20), we can write

$$d\left(\sum_{k=1}^{K} \pi_{\star k}^{(K)} F_{\star k}^{(K)}, \sum_{k=1}^{K} \hat{\pi}_{k}^{(K,N)} F_{\star k}^{(K)}\right)$$
(21)

$$= d\left(\sum_{k=1}^{K} \pi_{k}^{\min} F_{\star k}^{(K)} + \bar{\pi} \sum_{k=1}^{K} \frac{\pi_{\star k}^{(K)} - \pi_{k}^{\min}}{\bar{\pi}} F_{\star k}^{(K)}, \sum_{k=1}^{K} \pi_{k}^{\min} F_{\star k}^{(K)} + \bar{\pi} \sum_{k=1}^{K} \frac{\hat{\pi}_{k}^{(K,N)} - \pi_{k}^{\min}}{\bar{\pi}} F_{\star k}^{(K)}\right)$$
(22)

$$\leq \sum_{k=1}^{K} \pi_{k}^{\min} d\left(F_{\star k}^{(K)}, F_{\star k}^{(K)}\right) + \bar{\pi} d\left(\sum_{k=1}^{K} \frac{\pi_{\star k}^{(K)} - \pi_{k}^{\min}}{\bar{\pi}} F_{\star k}^{(K)}, \sum_{k=1}^{K} \frac{\hat{\pi}_{k}^{(K,N)} - \pi_{k}^{\min}}{\bar{\pi}} F_{\star k}^{(K)}\right)$$
(23)

$$\leq \|\pi_{\star}^{(K)} - \hat{\pi}^{(K,N)}\|_{1} d \left(\sum_{k=1}^{K} \frac{\pi_{\star k}^{(K)} - \pi_{k}^{\min}}{\bar{\pi}} F_{\star k}^{(K)}, \sum_{k=1}^{K} \frac{\hat{\pi}_{k}^{(K,N)} - \pi_{k}^{\min}}{\bar{\pi}} F_{\star k}^{(K)} \right)$$
(24)

$$= \|\pi_{\star}^{(K)} - \hat{\pi}^{(K,N)}\|_{1}$$

$$\times d \left(\sum_{k=1}^{K} \sum_{k=1}^{K} \frac{(\pi_{\star k}^{(K)} - \pi_{k}^{\min})(\hat{\pi}_{l}^{(K,N)} - \pi_{l}^{\min})}{\bar{\pi}^{2}} F_{\star k}^{(K)}, \sum_{k=1}^{K} \sum_{k=1}^{K} \frac{(\pi_{\star k}^{(K)} - \pi_{k}^{\min})(\hat{\pi}_{l}^{(K,N)} - \pi_{l}^{\min})}{\bar{\pi}^{2}} F_{\star l}^{(K)} \right)$$
(25)

$$a \left(\sum_{k=1}^{\infty} \sum_{l=1}^{\overline{\pi^2}} \overline{\pi^2} \right)^{-1} \chi_k, \sum_{k=1}^{\infty} \sum_{l=1}^{\overline{\pi^2}} \overline{\pi^2} \right)^{-1} \chi_k$$

$$(26)$$

$$\leq \|\pi_{\star}^{(K)} - \hat{\pi}^{(K,N)}\|_{1} \sum_{k=1}^{K} \sum_{l=1}^{K} \frac{(\pi_{\star k}^{(K)} - \pi_{k}^{\min})(\hat{\pi}_{l}^{(K,N)} - \pi_{l}^{\min})}{\bar{\pi}^{2}} d\left(F_{\star k}^{(K)}, F_{\star l}^{(K)}\right)$$
(27)

$$\leq \|\pi_{\star}^{(K)} - \hat{\pi}^{(K,N)}\|_{1} \max_{\substack{k,l \in \{1,\dots,K\}\\k \neq l}} d\left(F_{\star k}^{(K)}, F_{\star l}^{(K)}\right)$$
(28)

$$=o_P(1), (29)$$

where Eq. (23) uses Assumption 1(b), Eq. (24) follows by the fact that $\bar{\pi} = 1 - \sum_{k=1}^{K} \pi_k^{\min} \leq \sum_{k=1}^{K} \pi_k^{\max} - \sum_{k=1}^{K} \pi_k^{\min} = \|\pi_{\star}^{(K)} - \hat{\pi}^{(K,N)}\|_1$, and Eq. (29) follows by Assumption 1(f) and Eq. (16).

For the second term in Eq. (20), we can upper bounded as

$$d\left(\sum_{k=1}^{K} \hat{\pi}_{k}^{(K,N)} F_{\star k}^{(K)}, \sum_{k=1}^{K} \hat{\pi}_{k}^{(K,N)} \hat{P}_{k}^{(K,N)}\right) \leq \sum_{k=1}^{K} \hat{\pi}_{k}^{(K,N)} d\left(F_{\star k}^{(K)}, \hat{P}_{k}^{(K,N)}\right)$$
(30)

$$\leq \sum_{k=1}^{K} \hat{\pi}_{k}^{(K,N)} \phi\left(\mathcal{D}(\hat{P}_{k}^{(K,N)} \mid F_{\star k}^{(K)})\right)$$
(31)

$$\leq \sum_{k=1}^{K} \hat{\pi}_{k}^{(K,N)} \phi\left(\rho\right) \tag{32}$$

$$=\phi(\rho),\tag{33}$$

where Eq. (30) follows by Assumption 1(b), Eq. (31) follows by Assumption 1(e), and Eq. (32)

follows by our assumption for purposes of contradiction. Plugging Eqs. (29) and (33) into Eq. (20) yields the final inequality $d\left(G_{\star}^{(K)}, P_{o}\right) \leq$ $\phi(\rho) + o_P(1)$, which contradicts Assumption $3(\rho)(c)$. Therefore, there must exist \tilde{k} such that $\mathcal{D}(\tilde{P}_{\tilde{k}} \mid F_{\star \tilde{k}}^{(K)}) > \rho. \text{ Hence, for some } \epsilon > 0, \ \mathcal{D}(\hat{P}_{\tilde{k}}^{(K,N)} \mid F_{\tilde{k}}^{(K,N)}) = \rho + \epsilon + o_P(1). \text{ Hence, we have}$

$$\mathcal{R}_{N}^{\rho}(\theta_{\star}^{(K)}) \ge \hat{n}_{\tilde{k}}^{(K,N)} \max\{0, \hat{\mathcal{D}}(\hat{P}_{\tilde{k}}^{(K,N)} \mid F_{\tilde{k}}^{(K,N)}) - \rho\}$$
(34)

$$= \hat{n}_{\tilde{k}}^{(K,N)} \max\{0, \mathcal{D}(\dot{P}_{\tilde{k}}^{(K,N)} \mid F_{\tilde{k}}^{(K,N)}) - \rho + o_P(1)\}$$
(35)

$$= \hat{n}_{\tilde{k}}^{(K,N)} \max\{0, \epsilon + o_P(1)\}$$
(36)

$$\rightarrow \infty,$$
 (37)

where Eq. (35) follows from Assumption 1(c) and Eq. (37) follows since $\hat{n}_{\tilde{k}}^{(K,N)} \to \infty$ in probability for $N \to \infty$.

B.3. Proof of Proposition 1

Assumption 1(a) follows by Wellner (1981, Theorem 1). Assumption 1(b) holds by Lemma 1. Assumption 1(e) holds with $\phi(\rho) = (\rho/2)^{1/2}$ by the fact that, letting $d_{\rm TV}$ denote total variation distance, $d_{\rm BL} \leq d_{\rm TV}$ and $(2d_{\rm TV})^2 \leq {\rm KL}$ (Gibbs and Su, 2002, Section 3). Assumption 1(f) holds since $d_{\rm BL} \leq 1 < \infty$.

B.4. Proof of Proposition 2

Assumption 1(a) follows by the assumption that d_{MMD} metrizes weak convergence. Assumption 1(b) holds by Lemma 1. Assumption 1(e) holds by choosing $\phi(\rho) = \rho$ for maximum mean discrepancy. Assumption 1(f) holds for maximum mean discrepancy with bounded kernels since $d_{\text{MMD}} \leq \sup_{x} \mathcal{K}(x, x)^{1/2} < \infty$.

B.5. Proof of Proposition 3

Let p_{ok} be the density for the true kth component distribution. Let $g_{\star}^{(K)}(x) = \sum_{\ell=1}^{K} \pi_{\star\ell}^{(K)} f_{\star\ell}^{(K)}(x)$. It follows by the definition of $\operatorname{pr}_{\star}(z=k \mid x)$ and Assumption $3(\rho)(a)$ that

$$\tilde{P}_{k}(\mathrm{d}x) = \frac{p_{\star}^{(K_{o})}(k \mid x)P_{o}(\mathrm{d}x)}{\int p_{\star}^{(K_{o})}(k \mid y)P_{o}(\mathrm{d}y)} = f_{\star k}^{(K_{o})}(x)\frac{\sum_{\ell=1}^{K_{o}}\pi_{ok}P_{o\ell}(\mathrm{d}x)}{\sum_{\ell=1}^{K_{o}}\pi_{\star \ell}^{(K_{o})}f_{\star \ell}^{(K_{o})}(x)}.$$
(38)

We can rewrite $\tilde{P}_k(dx)$ in terms of the rations $p_{\star}^{(K_o)}(k \mid x)/p_o(k \mid x)$ and $\pi_{ok}/\pi_{\star k}^{(K_o)}$:

$$\tilde{P}_{k}(\mathrm{d}x) = \frac{\pi_{ok}}{\pi_{\star k}^{(K_{o})}} \cdot \frac{\pi_{\star k}^{(K_{o})} f_{\star k}^{(K_{o})}(x)}{\pi_{ok} p_{ok}(x)} \cdot \frac{\sum_{\ell=1}^{K_{o}} \pi_{ok} p_{o\ell}(x)}{\sum_{\ell=1}^{K_{o}} \pi_{\star \ell}^{(K_{o})} f_{\star \ell}^{(K_{o})}(x)} \cdot P_{ok}(\mathrm{d}x).$$
(39)

$$= \frac{\pi_{ok}}{\pi_{\star k}^{(K_o)}} \cdot \frac{\pi_{\star k}^{(K_o)} f_{\star k}^{(K_o)}(x)}{\sum_{\ell=1}^{K_o} \pi_{\star \ell}^{(K_o)} f_{\star \ell}^{(K_o)}(x)} \cdot \frac{\sum_{\ell=1}^{K_o} \pi_{ok} p_{o\ell}(x)}{\pi_{ok} p_{ok}(x)} \cdot P_{ok}(\mathrm{d}x)$$
(40)

$$= \frac{\pi_{ok}}{\pi_{\star k}^{(K_o)}} \cdot \frac{p_{\star}^{(K_o)}(k \mid x)}{p_o(k \mid x)} \cdot P_{ok}(\mathrm{d}x)$$

$$\tag{41}$$

To bound $\operatorname{KL}(\tilde{P}_k \mid F_{\star k}^{(K_o)})$, we plug in the expression for $\tilde{P}_k(\mathrm{d}x)$ in Eq. (41) and get

$$\operatorname{KL}(\tilde{P}_{k} \mid F_{\star k}^{(K_{o})}) = \int \tilde{P}_{k}(\mathrm{d}x) \log \frac{d\tilde{P}_{k}}{dF_{\phi_{k}^{\star}}}(x)$$

$$\tag{42}$$

$$= \int \frac{\pi_{ok}}{\pi_{\star k}^{(K_o)}} \cdot \frac{p_{\star}^{(K_o)}(k \mid x)}{p_o(k \mid x)}$$
(43)

$$\cdot P_{ok}(\mathrm{d}x) \left\{ \log \frac{\pi_{ok}}{\pi_{\star k}^{(K_o)}} + \log \frac{p_{\star}^{(K_o)}(k \mid x)}{p_o(k \mid x)} + \log \frac{dP_{ok}}{dF_{\star k}^{(K_o)}}(x) \right\}$$

$$\leq (1 + \epsilon_{\pi})(1 + \epsilon_z) \left\{ \int \log (1 + \epsilon_{\pi})(1 + \epsilon_z) P_{ok}(\mathrm{d}x) + \int P_{ok}(\mathrm{d}x) \log \frac{dP_{ok}}{1 + \epsilon_{\pi}(K_o)}(x) \right\}$$

$$(44)$$

$$+ \int P_{ok}(\mathrm{d}x) \log \frac{1}{dF_{\star k}^{(K_o)}}(x)$$

$$< (1+\epsilon_{\pi})(1+\epsilon_{z}) \left\{ \log(1+\epsilon_{\pi})(1+\epsilon_{z}) + \mathrm{KL}(P_{ok} \mid F_{\star k}^{(K_o)}) \right\}$$

$$(45)$$

$$<(1+\epsilon_{\pi})(1+\epsilon_{z})\left\{\log(1+\epsilon_{\pi})(1+\epsilon_{z})+\rho_{o}\right\},\tag{46}$$

where Eqs. (44) and (45) follow by applying the assumptions on the weight ratio and posterior probability ratio and Eq. (46) follows by the upper bound on $\text{KL}(P_{ok} \mid F_{\star k}^{(K_o)})$. Hence, we may set $\rho = (1 + \epsilon_{\pi})(1 + \epsilon_z) [\log(1 + \epsilon_{\pi})(1 + \epsilon_z) + \rho_o]$.

B.6. Proof of Proposition 4

It follows by the triangle inequality, Eq. (41), Hölder's inequality, and the assumption that all $h \in \mathcal{H}$ are bounded by M that

$$d_{\mathcal{H}}(\tilde{P}_k, F_{\star k}^{(K_o)}) \tag{47}$$

$$\leq d_{\mathcal{H}}(\tilde{P}_k, P_{ok}) + d_{\mathcal{H}}(P_{ok}, F_{\star k}^{(K_o)})$$

$$\begin{pmatrix} \pi_{\tau k} & n^{(K_o)}(k \mid x) \end{pmatrix}$$

$$\tag{48}$$

$$\leq d_{\mathcal{H}} \left(\frac{\pi_{ok}}{\pi_{\star k}^{(K_o)}} \frac{p_{\star}^{(K_o)}(k \mid x)}{p_o(k \mid x)} P_{ok}, P_{ok} \right) + \rho_o \tag{49}$$

$$= \sup_{h \in \mathcal{H}} \left| \int h(x) \frac{\pi_{ok}}{\pi_{\star k}^{(K_o)}} \frac{p_{\star}^{(K_o)}(k \mid x)}{p_o(k \mid x)} P_{ok}(\mathrm{d}x) - \int h(y) P_{ok}(\mathrm{d}y) \right| + \rho_o$$
(50)

$$= \sup_{h \in \mathcal{H}} \left| \int \left(\frac{\pi_{ok}}{\pi_{\star k}^{(K_o)}} \frac{p_{\star}^{(K_o)}(k \mid x)}{p_o(k \mid x)} - 1 \right) h(x) P_{ok}(\mathrm{d}x) \right| + \rho_o$$
(51)

$$\leq \int P_{ok}(\mathrm{d}x) \cdot \sup_{h \in \mathcal{H}} \sup_{x \in \mathcal{X}} |h(x)| \left| \frac{\pi_{ok}}{\pi_{\star k}^{(K_o)}} \frac{p_{\star}^{(K_o)}(k \mid x)}{p_o(k \mid x)} - 1 \right| + \rho_o \tag{52}$$

$$\leq M\left(\epsilon_{\pi} + \epsilon_{z} + \epsilon_{\pi}\epsilon_{z}\right) + \rho_{o}.$$
(53)

Hence, we may take $\rho = M (\epsilon_{\pi} + \epsilon_{z} + \epsilon_{\pi} \epsilon_{z}) + \rho_{o}$.

Appendix C: Connection to Likelihood-based Inference

For the Kullback–Leibler divergence case, we can relate the structurally aware loss to the conditional negative log-likelihood. Let \tilde{X}_k be a random element selected uniformly from

23

 $X^{(k)}(z_{1:N})$. Then the conditional negative log-likelihood given $z_{1:N}$ is

$$-\log p(x_{1:N} \mid \theta, z_{1:N}) = \sum_{k=1}^{K} \sum_{x \in X^{(k)}(z_{1:N})} -\log f_{\phi_k}(x)$$
(54)

$$=\sum_{k=1}^{K} |X^{(k)}(z_{1:N})| E\{-\log f_{\phi_k}(\tilde{X}_k)\}$$
(55)

For the sake of argument, if \tilde{X}_k were distributed according to a density \tilde{p}_k , then the Kullback–Leibler divergence between \tilde{p}_k and f_{ϕ_k} would be

$$\begin{aligned} \operatorname{KL}(\tilde{p}_k \mid f_{\phi_k}) &= E\{\log \tilde{p}_k(\tilde{X}_k)\} - E\{\log f_{\phi_k}(\tilde{X}_k)\} \\ &= -\mathcal{H}(\tilde{p}_k) - E\{\log f_{\phi_k}(\tilde{X}_k)\}, \end{aligned}$$

where $\mathcal{H}(p) = \int p(x) \log p(x) dx$ denotes the entropy of a density p. Then the negative conditional log-likelihood for each is equal to the Kullback–Leibler divergence, up to an entropy term that depends on the data (i.e., \tilde{p}_k) but not the parameter ϕ_k :

$$-\log p(x_{1:N} \mid \theta, z_{1:N}) \approx \sum_{k=1}^{K} |X^{(k)}(z_{1:N})| \left\{ \mathrm{KL}(\tilde{p}_k \mid f_{\phi_k}) + \mathcal{H}(\tilde{p}_k) \right\}.$$

Thus, we can view the structurally aware loss as targeting the negative conditional loglikelihood but (a) using a consistent estimator $\widehat{\mathrm{KL}}(X^{(k)}(z_{1:N}) | f_{\phi_k})$ in place of $\mathrm{KL}(\tilde{p}_k | f_{\phi_k})$ and (b) "coarsening" the Kullback–Leiber divergence using the map $t \mapsto \max(0, t - \rho)$ to avoid overfitting.

Appendix D: Kullback-Leibler Divergence Estimation

D.1. Theory and Methods

Following Wang, Kulkarni and Verdú (2009), we derive and study the theory of various onesample Kullback-Leibler estimators on continuous distributions. Estimating Kullback-Leibler between continuous distributions is nontrival. One common way is to start with density estimations.

Consider a general case on $\mathcal{X} = \mathbb{R}^D$. Suppose $y_{1:N} = (y_1, \ldots, y_N) \in \mathcal{X}^{\otimes N}$ are independent, identically distributed from a continuous distribution P with density p. For r > 0, one can estimate the density $p(y_n)$ by

$$P(V_D(r)) \approx p(y_n) V_D(r), \tag{56}$$

where $V_D(r) = \pi^{D/2} r^D / \Gamma(D/2 + 1)$ is the volume of a *D*-dimensional ball centered at y_n of radius *r*. Fix the query point y_n . The radius *r* can be determined by finding the *k*-th nearest neighbor $y_{n(k)}$ of y_n , i.e., $r_{k,n} = ||y_{n(k)} - y_n||$, where $|| \cdot ||$ denotes the Euclidean distance. Therefore, the ball centered at y_n with radius $r_{k,n}$ contains *k* points and thus $P(V_D(r_{k,n}))$ can be estimated by k/(N-1). Plugging this estimate back to Eq. (56) yields the *k*-nearest-neighbor density estimator for $p(y_n)$,

$$\hat{p}_N(y_n) = \frac{k/(N-1)}{V_D(r_{k,n})}.$$
(57)

To estimate Kullback-Leibler divergence, Wang, Kulkarni and Verdú (2009) studied various two-sample estimators given two sets of samples $y_1, \ldots, y_N \sim P$ and $z_1, \ldots, z_M \sim Q$ where the distributions P and Q are unknown. However, in the context of our method, we want to estimate the Kullback-Leibler divergence with one set of samples $y_{1:N}$ and one known distribution from our assumed model Q. Hence, we modify the two-sample k-nearest-neighbor estimators from (Wang, Kulkarni and Verdú, 2009) to create one-sample Kullback–Leibler estimators.

Given samples $y_1, \ldots, y_N \sim P$, where P is unknown, and a known distribution Q with density q, we can use Eq. (57) to obtain the one-sample k-nearest-neighbor estimator

$$\widehat{\mathrm{KL}}_{k}^{\mathrm{b}}(y_{1:N} \mid Q) = \frac{1}{N} \sum_{n=1}^{N} \log\left\{\frac{\hat{p}_{N}(y_{n})}{q(y_{n})}\right\} = \frac{1}{N} \sum_{n=1}^{N} \log\left\{\frac{k/(N-1)}{V_{D}(r_{k,n})q(y_{n})}\right\}.$$
(58)

Following the proof of Wang, Kulkarni and Verdú (2009, Theorem 1), we can show that for fixed k

$$\lim_{n \to \infty} E[\widehat{\operatorname{KL}}_{k}^{\mathsf{b}}(y_{1:N} \mid Q)] = \operatorname{KL}(P \mid Q) + \log k - \psi(k), \tag{59}$$

where $\psi(k) = \Gamma'(k)/\Gamma(k)$ is the digamma function. Eq. (59) suggests that this canonical Kullback–Leibler estimator is asymptotically biased. However, using Eq. (59), we can define the consistent (asymptotically unbiased) estimator

$$\widehat{\mathrm{KL}}_{k}^{\mathrm{u}}(y_{1:N} \mid Q) = \widehat{\mathrm{KL}}_{k}^{\mathrm{b}}(y_{1:N} \mid Q) - \log k + \psi(k).$$
(60)

Another way to eliminate the bias is to make k data-dependent, which we call *adaptive* k-nearest-neighbor estimators. Following the proof of Wang, Kulkarni and Verdú (2009, Theorem 5), we can show that $\widehat{\operatorname{KL}}_{k_N}^{\mathrm{b}}(y_{1:N} \mid Q)$ is asymptotically consistent by choosing k_N to satisfy mild growth conditions.

Proposition 5. Suppose P and Q are distributions uniformly continuous on \mathbb{R}^D with densities p and q, and $\operatorname{KL}(P \mid Q) < \infty$. Let k_N be a positive integer satisfying

$$\frac{k_N}{N} \to 0, \qquad \frac{k_N}{\log N} \to \infty.$$

If $\inf_{p(y)>0} p(y) > 0$ and $\inf_{q(y)>0} q(y) > 0$, then

$$\lim_{n \to \infty} \widehat{\mathrm{KL}}_{k_N}^{\mathrm{b}}(y_{1:N} \mid Q) = \mathrm{KL}(P \mid Q)$$
(61)

almost surely.

Proof. Let p and q are densities of P and Q respectively. Consider the following decomposition

of the error

$$\begin{aligned} \left| \widehat{\mathrm{KL}}_{k_{N}}^{\mathrm{b}}(y_{1:N} \mid Q) - \mathrm{KL}(P \mid Q) \right| \\ &\leq \left| \frac{1}{N} \sum_{n=1}^{N} \log \left\{ \frac{\hat{p}_{N}(y_{n})}{q(y_{n})} \right\} - \frac{1}{N} \sum_{n=1}^{N} \log \left\{ \frac{p(y_{n})}{q(y_{n})} \right\} \right| + \left| \frac{1}{N} \sum_{n=1}^{N} \log \left\{ \frac{p(y_{n})}{q(y_{n})} \right\} - \mathrm{KL}(P \mid Q) \right| \\ &\leq \frac{1}{N} \sum_{n=1}^{N} \left| \log \hat{p}_{N}(y_{n}) - \log p(y_{n}) \right| + \left| \frac{1}{N} \sum_{n=1}^{N} \log \left\{ \frac{p(y_{n})}{q(y_{n})} \right\} - \mathrm{KL}(P \mid Q) \right| \\ &= e_{1} + e_{2}. \end{aligned}$$
(62)

It follows by the conditions that $k_N/N \to 0$ and $k_N/\log N \to \infty$ and the theorem given in Devroye and Wagner (1977) that \hat{p}_N is uniformly strongly consistent: almost surely

$$\lim_{N \to \infty} \sup_{y} |\hat{p}_N(y) - p(y)| \to 0.$$
(63)

Therefore, following the proof of Wang, Kulkarni and Verdú (2009), for any $\epsilon > 0$, there exists N_1 such that for any $n > N_1$, $e_1 < \epsilon/2$. For e_2 , it simply follows by the Law of Large Numbers that for any $\epsilon > 0$, there exists N_2 such that for any $n > N_2$, $e_2 < \epsilon/2$. By choosing $N = \max(N_1, N_2)$, for any n > N, we have $|\widehat{\operatorname{KL}}_{k_N}^b(y_{1:N} | Q) - \operatorname{KL}(P | Q)| < \epsilon$.

D.2. Empirical Comparison

We now empirically compare the behavior of these k-nearest-neighbor Kullback–Leibler estimators. Consider two multivariate Gaussian distributions $P = \mathcal{N}(\mu_1, \Sigma_1)$ and $Q = \mathcal{N}(\mu_2, \Sigma_2)$. The theoretical value for the Kullback–Leibler divergence between P and Q is

$$\mathrm{KL}(P \mid Q) = \frac{1}{2} \left[\log \frac{|\Sigma_2|}{|\Sigma_1|} - d + tr(\Sigma_2^{-1}\Sigma_1) + (\mu_2 - \mu_1)^T \Sigma_2^{-1} (\mu_2 - \mu_1) \right], \tag{64}$$

where $|\cdot|$ is the determinant of a matrix and $tr(\cdot)$ denotes the trace. We generate samples $y_{1:N}$ from P and estimate $\widehat{\mathrm{KL}}(y_{1:N} \mid Q)$ with the three estimators above: the canonical fixed k estimator in Eq. (58) with $k \in \{1, 10\}$, the bias-corrected estimator in Eq. (60) with $k \in \{1, 10\}$ and the adaptive estimator with $k_N = N^{1/2}$.

We generate samples from a weakly correlated multivariate Gaussian distibution. Set $P = \mathcal{N}(\mu, \Sigma)$ with $\mu = (1, ..., 1) \in \mathbb{R}^D$ and $\Sigma_{ij} = \exp\{-(i - j)^2/\sigma^2\}$, where large σ results in high correlations and vice versa. Let $\sigma = 0.6$ and set $Q = \mathcal{N}(0, I_D)$. We test the performance of each estimator with varying $N \in \{100, 1000, 5000, 10000, 20000, 50000\}$ and varying dimensions $D \in \{4, 10, 25, 50\}$.

As shown in Fig. 6, when D = 4, the adaptive estimator with $k_N = N^{1/2}$ outperforms and shows reliable estimation when sample size is large ($N \ge 5000$). This scenario resembles the setup in our simulation and real-data experiments. We therefore use the adaptive estimator with $k_N = N^{1/2}$ for our experiments in Section 6.

When the dimension increases, the stability of all k-nearest-neighbor estimators drops due to the sparsity of data in high dimensions. This reveals a limitation of all k-nearest-neighbor estimators. Although proposing estimators for divergence is beyond the scope of the paper, we test one possible adaption in Section 6.2 to use the k-nearest-neighbor estimators in high dimensions by assuming independence across coordinates.

Fig 6: Absolute error against sample size for canonical 1-nearest-neighbor estimator (blue), canonical 10-nearest-neighbor estimator (green), bias-corrected 1-nearest-neighbor estimator (yellow), bias-corrected 10-nearest-neighbor estimator (orange) and adaptive k_N -nearest-neighbor estimator with $k_N = N^{1/2}$ (pink). Each panel corresponds with a different dimension $D \in \{4, 10, 25, 50\}$. Gray dotted lines indicate no error.

Fig 7: For the mixture of skew-normals example from Section 2 and Section 6.1, each panel shows the expected logliklihood $\hat{E}_{\alpha}(\text{loglik} | \text{data})$ against the expected number of clusters which excludes tiny clusters of size less that 2% of whole dataset denoted as $\hat{E}_{\alpha}(k_{2\%} | \text{data})$. We select α as the elbow point in the plots.

Appendix E: Additional Calibration Figures

E.1. Simulation Study

The coarsened posterior requires calibration of the hyperparameter α , which determines the degree of misspecification. For all scenarios considered in Section 2 and Section 6.1, we select α using the *elbow method* proposed by Miller and Dunson (2019). In this section, we include all calibration figures for the coarsened posterior following the code provided by Miller and Dunson (2019).

As shown in Fig. 7, we calibrate α as the turning points where we see no significant increase in the log-likelihood if α increases. With these elbow values for α , we can see for all cases except the small-large case, the coarsened posterior consistently estimates the number of clusters (even after removing mini clusters with size < 2%) as $\hat{K} = 3 > K_o = 2$.

E.2. Flow Cytometry Data

In this section, we include loss and F-measure plots of our model selection method on all test datasets 7–12. See Miller and Dunson (2019, Section 5.2) for a discussion of the exact calibration procedure for the coarsened posterior.

Recall that to calibrate ρ , we select ρ that optimizes the F-measure across first 6 datasets. To incorporate this prior knowledge on test datasets, we suggests selecting the value of K that has has stable penalized loss and is closest to the optimal ρ . We compare our selection \hat{K} with the ground truth K_o labeled by experts. For each dataset, there is always one cluster labeled as unknown due to some unclear information for cells. With automatic clustering algorithm, it is natural for the algorithm to identify those unlabeled points and assign them to other clusters, which results in $K_o - 1$ clusters. So we treat both K_o and $K_o - 1$ as ground truth in our analysis. As shown in Figs. 8 and 9, our selection method results in highest F-measure for datasets 8–12. Dataset 7 is challenging and even the ground truth does not produce a large F-measure.

Fig 8: Calibration and F-measure plots for test datasets 7–9 in flow cytometry experiments. Left: The black dashed lines indicate the optimal ρ calibrated on training datasets 1–6. The cross mark indicates the selection for number of clusters. Right: F-measure against the number of clusters. The dashed line shows the number of clusters selected by our method and the red star indicates the ground truth K_o .
