Abstract: Metal thiophosphates (MTPs) are a large family of 2D materials that exhibit large structural and chemical diversity. They also show promise for applications in energy harvesting and photodetection. Strain and defect engineering have previously been demonstrated as useful mechanisms to tune several properties of MTPs such as resistivity, magnetic state, and electronic band gap. However, the effect of these stimuli on engineering tunable light emission in MTPs remains unexplored. Here, we show experimentally that structural defects in metal thiophosphate $AgScP_2S_6$ are prominent in exhibiting photoluminescence, which is likely driven by the defect-state-to-conduction-band transitions and can be further tuned by temperature-induced strain gradients. © 2024 The Author(s)

1. Introduction

Over the course of the last few decades, 2D van-der Waals layered materials have become a hotspot for material scientists, giving rise to the discovery of graphene, transition-metal dichalcogenides (TMDCs), and black phosphorus. Recently, a family of layered metal thio(seleno)phosphates (MTPs) have gathered attention owing to their unique magnetic properties [1, 2], applications in energy harvesting [3–9], and interesting nonlinear optical effects [10, 11]. While hexagonal boron nitride (hBN) is exceptional for its strong, thickness-dependent optical nonlinearities [12, 13], novel photonic avenues [14–17], and interesting optical and electronic properties [14, 15, 17–19], it is unsuitable for low-energy operations due to its wide band gap ($\sim 6 \text{ eV}$). Similarly, transition metal dichalcogenides (TMDs) have enabled exciting electronic [20–22], optoelectronic [21–26] and photonic applications [23, 27–29], but their small bandgaps ($\sim 1-2 \text{ eV}$) limit their use in high-energy devices. MTPs complete the multi-spectral library of 2D photonic materials as they possess with bandgaps between 1.6 and 4 eV, which provide the opportunity to fill the void between narrow band gap materials such as TMDs and wide band gap hBN. Physical properties of MTPs can be tuned via strain engineering, resulting in demonstrations of superconductivity [30, 31] and insulator-to-metal transitions [32–34], magnetic state tuning [35–38], and optoelectronics [39, 40]. TMDs can also form interesting hetero-structures with well-known TMDCs [41], which further expands their range of functionalities.

However, light emission properties of MTPs are much less explored, especially under symmetry-breaking strain deformations. This research direction is very promising since strain and defect engineering have been proven to be powerful and versatile mechanisms to tailor photonic properties of various material families, unlocking new functionalities in light harvesting and generation. For instance, Zhong et al [42] showed that defect engineering can play a significant role in enhancing the electrochemical performance of MnPS₃. In this work, we explore the possibility of defect engineering for enhanced visible light emission in AgScP₂S₆, a new, recently synthesized member of the MTP family.

AgScP₂S₆ is a 2D direct bandgap semiconductor, which exhibits an extraordinarily large two-photon absorption coefficient predicted to be associated with defect/virtual states [43]. Inspired by this prediction, we investigate photoluminescence (PL) in AgScP₂S₆ as an excellent probe for defects and explore the opportunities to achieve tunable light emission from MTPs via strain engineering. In this work, we show experimentally that (i) defects play a critical role in PL emission from AgScP₂S₆ bulk crystals and (ii) defect-mediated PL can be further tuned by temperature-induced strain gradients. Temperature-dependent absorption and Raman measurements have been used to characterize the defects and distinguish them from the bulk of the material.

2. Results

Figures 1a-d introduce $AgScP_2S_6$ material by presenting structural schematics of its crystal lattice, which belongs to the $P\overline{3}1c$ symmetry group. The defining common feature for compounds in the MTP family is the $[P_2S_6]^{4-}$ anion sublattice located within an individual lamella of the layered crystal. This specific compound is of the type $M^{1+}M^{3+}P_2S_6$ [43]. The sulfur atoms make up almost closed packed surfaces of each layer. From Figs. 1b,d, it can be seen that the spatial arrangement of atoms leads to octahedrally coordinated sites formed in/within the lattice, which are filled by Ag and Sc ions, or P–P dimers. Fig. 1e shows an image of the bulk crystal, which has been synthesized via a vapor transport technique [44], see the Methods section for detail.

Figure 2a illustrates the measured UV-Visible absorption spectrum for $AgScP_2S_6$ as a function of temperature. At room temperature (300K), the absorption was found to decrease rapidly at wavelengths larger than ~420 nm. This drop is characteristic of the band edge absorption typically observed in direct band gap semiconductors. The same trend is witnessed as temperature is decreased from 300K down to 93K. In Fig. 2b, we plot the estimated band gap energy values as a function of temperature, which are extracted from the absorption spectra by using a standard fitting procedure [45]. The band gap value obtained at ambient conditions was found to be 2.74 eV. This is consistent with the previous measurement reported in the literature [43]. From Fig. 2b, it can be seen that the band gap energy increases almost linearly with decreasing temperature.

Figure 2c shows Raman spectra of the material spanning the same temperature range. Typically in metal thiophosphates, a band below 150 cm⁻¹ is attributed to cation vibrations [46–48]. We also identify a peak at 185 cm⁻¹, most likely due to the B_{3g} mode of vibration [49], and the rotation of the PS₃ group [50]. We identify phonon modes originating from P₂S₆ units with D_{3d} symmetry (center of inversion along PS₃ groups) as A_{1g} and E_g [51–54]. Four of such prominent Raman modes are marked in the spectrum measured at 300K (Fig. 2c). (Note that we did not perform any calculation of our own to mark these modes, they have been identified by comparing data from previously published literature on metal thiophosphates). As the temperature is decreased, we observe changes in peak positions and full widths at half maximum (FWHM). We also find that the material exhibits no phase transitions at lower temperatures. The changes in Raman peak positions and FWHM are calculated with reference to the values measured at 300K and are shown in Figs. 2d and 2e, respectively. The temperature coefficients are extracted from the Raman data and presented in Table 1.

From Fig. 2d, we see that phonon modes move to higher energies as temperature is reduced, which can be explained by tighter chemical bonding in the compound leading to higher vibrational energies. In turn, the FWHM

Fig. 2. Optical and vibrational properties of $AgScP_2S_6$. (a) Absorption spectra of $AgScP_2S_6$ measured as a function of temperature under ambient pressure. (b) Band gap width values extracted from the spectra in panel (a). (c) Temperature-dependent Raman spectra measured from 300K to 93K. Four prominent Raman modes are labeled in the spectra taken at 300K. (d) Full-width at half maximum (FWHM) in cm⁻¹ as a function of temperature for the Raman peaks shown in (c). (e) Relative shifts in Raman peaks from their corresponding spectral positions measured at 300K.

of the peaks can be related to the phonon lifetime τ using the Heisenberg Uncertainty relation:

$$\frac{\Delta E}{\hbar} = \frac{1}{\tau},\tag{1}$$

where ΔE is the Raman FWHM in units of cm⁻¹, and \hbar is the Planck's constant. We identify two main contributions to the phonon lifetime: (i) phonon-phonon scattering – which is the characteristic anharmonic decay of a phonon into two or more phonons, and (ii) phonon-carrier scattering – caused by the perturbation in the translational symmetry of the crystal due to the presence of defects. It is difficult to separate the relative contributions of these mechanisms to the overall lifetime and further studies would be required to investigate their individual contributions. From Fig. 2b, it can be seen that FWHM linearly decreases as the temperature is decreased. From equation (1), it is apparent that the phonon lifetime decreases with increasing temperature. The decrease occurs due to increased thermal occupancy and interaction of phonons at higher temperatures [55], which in turn increases the rate of phonon-phonon and carrier-phonon scattering.

Raman Mode	Peak Position at 300K (cm^{-1})	$dE/dT (cm^{-1}/K)$	$d(FWHM)/dT (cm^{-1}/K)$
B _{3g}	185.0	-0.007 ± 0.001	0.009 ± 0.001
E_g	289.2	$\textbf{-0.019}\pm0.002$	0.020 ± 0.001
A_{1g}	381.9	$\textbf{-0.016} \pm 0.002$	0.021 ± 0.001
E_g	563.4	$\textbf{-0.029}\pm0.003$	0.018 ± 0.005

Table 1. Temperature coefficients of AgScP₂S₆ vibrational modes determined from Raman Spectroscopy.

Figure 3 shows the defects in bulk crystals of $AgScP_2S_6$ (Fig. 3a) and illustrates the difference in the Raman spectra (Fig. 3b,c) collected from the bulk (red) and defect regions (blue). These microscopic defects are introduced during the process of material growth. We find that most of the observed defects are structural (physical),

i.e. they have the same overall Raman spectrum signature as the rest of the material (compare the normalized spectra in Fig. 3c).

However, the Raman signal from the 'defect region' within the red circle in Figs. 3a-b, plotted prior to background subtraction, is weak. This local Raman signal attenuation may be caused by the Raman scattering process interference with the material photoluminescence under the laser pump excitation. PL interference is one of the common underlying mechanisms contributing to the Raman lines suppression and may play such a role in AgScP₂S₆, as this material exhibits a PL spectrum overlapping with the Raman spectrum. Using a hypothesis that the inverse correlation between Raman and PL signals can help to identify the comparatively more photoluminescent areas on the sample, we find and map these areas via Raman imaging spectroscopy.

An example of a Raman map taken around a structural defect region is shown in Fig. 3b. The mapping is done at the strongest Raman peak at $\sim 291 \text{ cm}^{-1}$ marked by a light blue square in Fig. 3c. The area shown in the red circle in Fig. 3b exhibits the weakest Raman intensity, which spatially overlaps with the structural defect at this location, as shown in Fig. 3a.

Fig. 3. Raman signals collected from structural defects reveal defect-induced photoluminescence. (a) Example of a structural 'peacock-like' defect region (area marked by the red circle). (b) Raman map of the spatial area shown in the image in (a) plotted for the Raman peak at 289 cm⁻¹ marked by the blue square in (c). (c) Raman signature for a structural defect (blue), compared with the bulk (red).

To test our hypothesis that these Raman-weak structural defects exhibit strong PL emission as compared to the rest of the material, we correlate our findings with the PL spectra collected from both the bulk region and the defect region, which are measured as a function of temperature. PL measurements have been performed under three distinct operational scenarios – (i) at a laser excitation energy higher than the band gap (325 nm, 3.81 eV $> E_g = 2.74 \text{ eV}$), (ii) at an excitation within the band gap (532 nm, 2.33 eV $< E_g = 2.74 \text{ eV}$), and (iii) PL spectra obtained by directly exciting a structural defect (of $\sim 50 \ \mu\text{m}$ in diameter) with the 325 nm laser line having $\sim 10 \ \mu\text{m}$ diameter laser spot. The results are shown and compared in Fig. 4.

Figure 4a reveals PL quenching with exponential decrease in intensity as the temperature is decreased from 300K to 93K. This trend is explained by the evolution of the bandgap size with temperature, which has been extracted from the temperature-dependent absorption measurements and plotted in Fig. 2b. The bandgap widens with decreasing temperature, decreasing the probability of interband transitions and leading to the decrease in the bulk PL signal observed in Fig. 4a. The PL spectra can be deconvoluted into two bands peaking at 476 nm and 575 nm approximately. The behavior of the peak positions for these bands, relative to the peak position measured at 300K, are shown in Fig. 4b. Both luminescent bands follow a similar trend – red-shifting on average at lower temperatures.

Figure 4c summarizes the PL spectra collected in the case when we perform the same PL spectral experiment with the 532 nm laser line. Here, we see a completely opposite trend from than observed in Fig. 4a, with PL emission intensity exponentially increasing with decreasing temperature. In the next paragraph, we propose a rationale for this finding. Again, we can deconvolute the PL spectra in Fig. 4c to get two luminescent bands peaking at roughly 594 nm and 617 nm. We track the relative peak positions of these bands in Fig. 4d. It can be seen that the two bands move further apart with decreasing temperature, with the 594 nm band red-shifting and the 617 nm band blue-shifting.

Case (iii) is shown in Fig. 4e, where we excite a structural defect of $\sim 50 \,\mu\text{m}$ in diameter with the laser spot of $\sim 10 \mu\text{m}$ in diameter. PL emission from the defect is quenched as the temperature decreases to 213K, consistent with the trend we expect for a 325 nm laser excitation. However, in the temperature range 183-93K, we observe

a substantial increase in PL intensities. This supports our hypothesis of defect states lying within the band gap, which make possible defect-to-band transitions excited by the 325 nm laser pump. The increase in the PL signal is accompanied by interference effects manifested as Fabry-Perot fringes, which can be attributed to the structural defect acting as a resonant cavity. We hypothesize that the increase in PL can be either due to unexplained defect-carrier statistics or due to the temperature-induced 'wrinkling' of the defect creating strain gradients, which modify both the defect geometry and the electron band structure. The latter hypothesis is supported by the emergence of new photoluminescent bands (forming a prominent double-peak feature) seen in the PL spectra collected at 123K and 93K.

Fig. 4. Structural defects create local PL centers. PL intensity as a function of temperature for (a) the bulk material, (e) a structural defect under 325 nm laser excitation. (c) PL intensity as a function of temperature for the bulk material under 532 nm excitation. Peak positions of the PL spectral lines corresponding to (a), (c) are shown in (b), (d) respectively.

3. Experimental Section

3.1. Material Synthesis

We synthesized AgScP₂S₆ via conventional vapor transport methods [44]. Briefly, we combined Ag foil (Johnson Matthey, 99.99%), Sc metal (Alfa Aesar pellet, 99.999%, rolled thin) P chunks (Alfa Aesar Puratronic, 99.999+%), and S pieces (Alfa Aesar Puratronic, 99.999%) together in a near-stoichiometric ratio (we used 10% excess P) in an evacuated quartz ampoule (2mm wall thickness, 22 mm OD, 10 cm in length) together with ~100 mg I2 crystals (Alfa Aesar, 99.8%). We placed the sealed ampoule in a single-zone tube furnace, heated to 750°C over a period of 20 hours, held at that temperature for 100 hrs, and cooled over a period of 20 hrs. The resulting crystals were of maximum size of 5 mm × 5 mm in area and ~200 μ m in thickness. Sample compositions were determined by subjecting at least three distinct single-crystal specimens of each batch to multiple-spot scanning electron microscopy/energy-dispersive X-ray spectroscopy (SEM/EDS) analysis (9-12 spots total per batch) using a Thermo Scientific UltraDry EDS spectrometer joined with a JEOL JSM-6060 SEM. The compositions were stoichiometric, within error.

3.2. Instruments and Methods

For observing defect-assisted Photoluminescence (PL), the samples were excited with a near-UV (325 nm) Kimmon-Koha IK3201R-F model laser. PL data was collected using a Triax 320 monochromator from ISA Yobin Yvon-Spex equipped with a Spectrum One CCD detector. A Cary 5000 spectrophotometer was used to obtain absorption spectra in the UV-Visible range. Raman spectral data were acquired using a Monovista CRS+ system from S&I Ltd, equipped with a 0.75 m long monochromator. The resolution was approximately 0.5 cm⁻¹. The

setup was operated on Trivista Software. A 532 nm laser was used, set at a power density of 7.5 mW/ μ m². Raman, Absorption and PL data were collected at both room temperature and low temperatures under ambient pressure. Low temperature measurements were performed on Linkam FTIR600 table under steady N₂ flow to prevent air and moisture from freezing. Line positions and FWHM in the Raman spectra were established by fitting the observed spectra with Lorentzian curves. Gaussian curves were used to deconvolute the observed PL data and to measure peak positions.

4. Conclusions and Outlook

Structural defects have been characterized and shown to be the main contributor towards low-temperature PL emission in $AgScP_2S_6$. However, the origin of these defect states needs further studies. We plan to take further steps to characterize these defects using advanced techniques such as EPR (Electron Paramagnetic Resonance) and to systematically engineer the defects by using energetic electron beams as reviewed in [56]. To explore the possibility of using strain gradients to create new PL bands and to increase emission intensity, we are developing a fabrication pipeline to create such gradients in MTP materials using nano-pillars and gratings on a CMOS platform. This will be a crucial step towards our final goal of achieving strain-tunable photon sources by using materials from the MTP family.
