Abstract

News media has been utilized as a political tool to stray from facts, presenting biased claims without evidence. Amid the COVID-19 pandemic, politically biased news (PBN) has significantly undermined public trust in vaccines, despite strong medical evidence supporting their efficacy. In this paper, we analyze: (i) how inherent vaccine stances subtly influence individuals' selection of news sources and participation in social media discussions; and (ii) the impact of exposure to PBN on users' attitudes toward vaccines. In doing so, we first curate a comprehensive dataset that connects PBN with related social media discourse. Utilizing advanced deep learning and causal inference techniques, we reveal distinct user behaviors between social media groups with various vaccine stances. Moreover, we observe that individuals with moderate stances, particularly the vaccine-hesitant majority, are more vulnerable to the influence of PBN compared to those with extreme views. Our findings provide critical insights to foster this line of research.

1 Introduction

The pervasive impact of the COVID-19 pandemic transcends geographic and social boundaries [Haleem et al., 2020], having claimed over 7 million lives globally as of February 2024¹. Although vaccination emerges as the most efficacious defense, a substantial proportion of the population has shown vaccine hesitancy [Dror et al., 2020]. A KFF survey [Kirzinger et al., 2021] reported that more than 40% of parents in the U.S. are hesitant to get their children vaccinated due to safety and efficacy concerns. Meanwhile, hundreds of mainstream media are responsible for publishing COVID-related politically biased news (PBN), turning the vaccine campaign into a political campaign [Bolsen and Palm, 2022]. While the skepticism around vaccines isn't new, when intertwined with news media, it exacerbates polarized opinions and conspiracy theories, thereby posing substantial challenges to public health efforts [Sorell and Butler, 2022].

Figure 1: An overview of our research pipeline. On the left, it depicts news outlets disseminating COVID-related PBN to wide audiences via social media platforms. The right side illustrates the potential influence of such PBN exposure on users' vaccine stances. We define *exposure* as instances where a user engages with PBN through Retweets or Quote-tweets (Retweets with added comments). *Discussion* refers to user involvement in vaccine-related conversations after PBN *exposure*. *Change* denotes the variation in users' vaccine stances resulting from PBN *exposure*.

Recent research has examined the impact of news coverage [Le Quéré et al., 2022], political polarization [Ebeling et al., 2022], and misinformation dissemination in social media [Miyazaki et al., 2023]. However, few efforts have been focused on: (i) providing a comprehensive dataset that connects news media data with associated social media data; and (ii) understanding the causal relationship between exposure to PBN and people's vaccine stance changes. Most existing works [Joseph et al., 2022; Poddar et al., 2022; Spiteri, 2021] studied their correlation instead of causation, the latter of which is the key to understanding the impact of a PBN intervention (i.e., reading a COVID-vaccinerelated PBN) on the outcome (i.e., COVID-19 vaccine stance changes). While [Fowler et al., 2022] examined the causal relationship via surveys, it is limited to a small sample size and overlooks potential confounders such as user heterogeneity and social media features related to treatment and outcome. Modeling confounders is challenging due to the scarcity of

¹https://covid19.who.int/

observational data and domain knowledge. Moreover, little existing work differentiates the causal effect of groups with various vaccine stances. Large-scale studies on social media can complement prior research in the field to better understand how PBN shapes people's stances toward vaccines.

To address aforementioned limitations and challenges, we construct **CovNS** (<u>Cov</u>id-19 biased <u>News</u> and <u>Social</u> media dataset), the first dataset which bridges the gap between COVID-related PBN and the corresponding social media discussions. Utilizing **CovNS**, we propose a research pipeline (see Figure 1) to study the following research questions:

- **RQ1:** *How do PBN consumption and social media discussion vary with different vaccine stance groups?*
- **RQ2:** To what extent does PBN exposure contribute to the reversal and reinforcement of vaccine stances?

In summary, this study makes the following contributions to systematically address the posed research questions:

- <u>Dataset Curation</u>: We build **CovNS**, the first dataset that establishes a connection between the COVID-related PBN and the social media data, enabling future research by providing sufficient annotations.
- *Behavior Analysis*: We characterize pro-vaccine, antivaccine, and vaccine-hesitant groups on Twitter. We delve into the differences in PBN consumption preference and social media discussions across these groups.
- *Causal Effect Estimation*: We employ advanced causal learning methods to estimate the causal effect of reading PBN on users' vaccine stance changes.

Our observations reveal that the three vaccine stance groups demonstrate significantly *different* user behaviors. Meanwhile, exposure to left-leaning and right-leaning news sources generally causes social media users to be more provaccine and anti-vaccine, respectively. Notably, users who are hesitant about vaccination show a greater *vulnerability* to the influence of PBN, underscoring the significant challenges faced in promoting vaccination campaigns.

2 Related Work

In this section, we review three existing bodies of literature that lay the foundation for this work: (*i*) long-standing literature on the political bias in news media in the United States; (*ii*) fast-rising literature on the COVID-19 vaccine stance; and (*iii*) well-established work on applying causal inference methods on COVID-related problems.

2.1 Political Bias in News Media

Political bias in news media has been studied extensively in the areas of political science, social science, etc [Eberl *et al.*, 2017]. It is an inherent bias of journalists and media outlets that makes them intentionally report biased news articles in order to serve a political agenda. The alteration of the news content usually operates in two ways: (i) *issue framing*, i.e., presenting an issue in a way that will likely get the most agreement from supporters; and (ii) *issue filtering*, i.e., selectively omit information that supports an alternative opinion on the other political side [Iyengar, 1994]. As a result, readers

were manipulated by misleading or false viewpoints and narratives. Prior work examining political bias using both qualitative and quantitative methods, has shown that U.S. news media differs ideologically and can create a highly polarized social environment [Budak *et al.*, 2016]. During the COVID-19 pandemic, much scholarly attention has been devoted to understanding the influence of PBN on public health. For example, some have shown that misleading information downplays the severity of COVID [Teng *et al.*, 2022], false claims prevent people from knowing the fact [Seo *et al.*, 2022], and conspiracy communities use PBN to distance users from science [Sharma *et al.*, 2022].

2.2 COVID-19 Vaccine Stance

Various studies have investigated the COVID-19 vaccine stance in social media. Among them, some works contributed to providing labeled datasets regarding COVID-19 vaccine stance [Mu et al., 2023; Glandt et al., 2021] These works use either manual or algorithmic annotations to label a post as anti-vaccine, pro-vaccine, or vaccine-hesitant. There exist other works that focus on building machine learning models to predict the COVID-19 vaccine stance, using linguistic features [Poddar et al., 2022], auxiliary information [Tahir et al., 2022], or large language models [Riaz et al., 2022]. Besides, another line of research has been devoted to collecting COVID-vaccine-related datasets from news media. [Semeraro et al., 2022] collected 5,745 news from 17 Italian news media. [Joseph et al., 2022] collected 750k articles from over 300 local news outlets to analyze relations between news coverage and offline behaviors.

However, little prior work provided labeled datasets of COVID-vaccine-related PBN and social media discussion. To bridge this gap, our dataset combines both social media (e.g., tweets) and news media (e.g., news articles) data with multilevel manual and algorithmic annotations on news articles, posts, and users.

2.3 Causal Analysis of COVID-Related Factors

Well-established literature is built around learning causality with machine learning and big data [Guo *et al.*, 2020]. Much of the recent work examined the causal relationships among COVID-related factors. For instance, [Hsiang *et al.*, 2020] and [Ma *et al.*, 2022] estimated the causal effect of different government efforts (e.g., COVID-19 policies) on offline statistics (e.g., number of infections and deaths). Other studies investigated the causal impact of online COVID-19 misinformation on one's mental health [Verma *et al.*, 2022] or vaccine hesitancy [Pierri *et al.*, 2022]. [Fowler *et al.*, 2022] conducted a survey to study the effect of exposure to politicized media coverage on people's negative emotional responses.

However, there is little understanding of the impact of consuming COVID-related PBN on social media users' willingness toward the COVID-19 vaccine uptake. As a remedy, we work on this problem by exploiting advanced causal machinelearning methods on the collected real-world dataset and proposed causal graphs.

Figure 2: An example of the data collection process. We first collect a set of COVID-related news triplets containing articles from leftleaning, center-leaning, and right-leaning outlets from *Allsides* (top). We then obtain associated *Twitter* data (bottom).

	Fields	Stats	Labels
Twitter	Tweets	243,412,961	VS
	User metadata (e.g., id)	36,172	VS
Allsides	Stories (news triples)	732	VS
	News articles	2,196	VS, PL
	News metadata (e.g., url)	2,196	-
	News Media	160	PL

Table 1: Overview of **CovNS**. Note that VS = vaccine stance; PL = political leaning.

3 Bridging News Media and Social Media

In this section, we introduce how we build the dataset, including detailed data collection, annotation, and selection process. Figure 2 exemplifies the data collection process. We rely on two resources: *Allsides*² and *Twitter*, to collect PBN and social media data, respectively. We obtain human-annotated labels such as political leaning from *Allsides*. We then annotate the vaccine stances for the collected data using manual and algorithmic labeling strategies. At last, we apply filters to compose a high-quality dataset for our experiment. Table 1 provides an overview of **CovNS**.

3.1 Data Collection

PBN from Allsides. We gather COVID-related PBN from *Allsides*, a website that assesses the political bias of prominent media outlets, and presents different versions of similar news stories from sources of the political right, left, and center. It shows readers news coverage and diverse perspectives from all across the American political spectrum. In addition, it also provides a neutral summary to recapitulate the story and discuss how different news outlets spin or manipulate the facts. Note that *Allsides* currently only focuses on English

news from American media outlets.

For each news story, we collect the triplets of PBN { $\mathcal{N}_L, \mathcal{N}_C, \mathcal{N}_R$ } denoting news articles from leftleaning, center-leaning, and right-leaning news media, respectively. They are associated with corresponding titles { $\mathcal{T}_L, \mathcal{T}_C, \mathcal{T}_R$ }, contents { $\mathcal{C}_L, \mathcal{C}_C, \mathcal{C}_R$ }, and URLs { $\mathcal{U}_L, \mathcal{U}_C, \mathcal{U}_R$ }. We also collect meta-information such as publication date, topics, media name, and URLs of banners or pictures for each news article. In total, there are 732 COVID-related news triplets (i.e., 2,196 news articles) from 160 U.S. media outlets.

Social Media Data from Twitter. We construct a largescale Twitter dataset using the official academic research API. Following previous work on collecting news articles in social media [Shu *et al.*, 2020], we use the <u>URL</u> of original PBN as the search query on Twitter to collect all the available social media discourses such as tweets, retweets, and replies. Moreover, we collect historical tweets and profile information from users who have participated in the discussion about COVID-related PBN. Overall, this dataset consists of 243,412,961 historical tweets from 36,172 unique accounts.

3.2 Data Annotation

Two sets of labels are essential to analyze the relationship between PBN consumption and vaccine stance changes of social media users: political leaning and <u>vaccine stance</u>.

We adopt labels on political leaning (*left, lean-left, center, lean-right*, or *right*) from *Allsides*. For each news article, the rating process includes (*i*) editorial review, (*ii*) blind bias survey, (*iii*) independent review, (*iv*) third-party review, (*v*) community feedback, and (*vi*) confidence level.³ However, both data sources (*Allsides* and *Twitter*) do not provide human-annotated labels on COVID-19 vaccine stances. As it is a time-consuming and labor-intensive task to annotate vaccine stances for the entire collected dataset with 2,196 news articles and 243,412,961 tweets, we follow the method mentioned in [Lyu *et al.*, 2022] and leverage a human-in-the-loop machine-learning strategy to minimize the manual annotation effort meanwhile maintaining high-quality labels.

Specifically, we first identify common COVID-related keywords (*covid*, *coronavirus*, and *SARS-CoV-2*) to filter out news articles and tweets unrelated to COVID-19. After that, we invite two annotators in the area to inspect the headline and content to assign one of the four labels for each news article:

- Pro-vaccine, i.e., news that promotes the willingness of vaccine acceptance and uptake;
- Anti-vaccine, i.e., news that discourages the willingness of vaccine acceptance and uptake;
- Mixed, i.e., news that contains controversial opinions about COVID-19 vaccines; and
- *Other*, i.e., news that contains general COVID-19 information, but are unrelated to vaccines.

²https://www.allsides.com/unbiased-balanced-news

³https://www.allsides.com/media-bias/ media-bias-rating-methods

Before annotating, we inform the annotators of a few examples of each category. With the collected annotations, we calculate Cohen's Kappa Score (k) to assess the inter-annotator agreement for the selected PBN dataset. We get k = 0.83, which is considered "almost perfect" agreement according to [Cohen, 1960]. To further obtain the ground truth, we only considered the annotations that both annotators agreed on. This results in 410 *pro-vaccine*, 395 *anti-vaccine*, 409 *mixed*, and 772 *other* news articles.

For our large-scale Twitter dataset, we finetune a pretrained CT-BERT [Müller et al., 2020] on three publicly available Twitter datasets for COVID-19 vaccine stance detection [Glandt et al., 2021; Cotfas et al., 2021; Jiang et al., 2023]. The final downstream task is designed to be a binary classification, i.e., infer the stance of COVID-vaccinerelated tweets as pro-vaccine (+1) or anti-vaccine (-1). Our final model achieves a high F1 score and accuracy, yielding respectively 0.833 and 0.845. To further evaluate our dataset's final model, we adopt a set of COVID-vaccinestance-related keywords from CoVaxxy [DeVerna et al., 2021] to extract relevant tweets. Then we manually check the machine-generated stance labels. Specifically, we randomly select 500 COVID-vaccine-related tweets (250 pro-vaccine and 250 anti-vaccine) from our dataset and manually annotate them. Algorithmic and manual annotations have a "almost perfect" agreement with Cohen's Kappa Score k = 0.84. This suggests that the final model is capable and reliable in labeling the rest COVID-vaccine-related tweets in our dataset.

3.3 Data Selection

To compose a high-quality dataset for the experiment, we apply filters to obtain a set of COVID-vaccine-related PBN with *extreme political bias* and relatively *high social media engagement* from 2021/06 to 2022/06. Particularly, we exclude PBN that is (*i*) unrelated to COVID-19 vaccines; (*ii*) from lean-left and lean-right news media; and (*iii*) with fewer than 100 related social engagements (retweets and replies).

As bot accounts are active on Twitter, we apply Botometer [Yang *et al.*, 2022] to filter out malicious bots in our dataset. After that, we apply additional filters to exclude users (*i*) whose locations are outside the United States; and (*ii*) who do not have at least one COVID-vaccine-related tweet before and after consuming COVID-vaccine-related PBN in seven days. After doing so, the subset contains 250 news triplets and 89,535,833 tweets from 17,643 unique users.

4 RQ1. Behavior Analysis of Three Vaccine Stance Groups

People with different vaccine stances can have different news consumption behaviors, e.g., pro-vaxxers read more news from the left-leaning media. How they react to a PBN reading intervention may also differ significantly. Therefore, it is critical to identify groups with different vaccine stances to mitigate potential selection and sampling bias. In this section, we (i) categorize users into anti-vaccine, pro-vaccine, and vaccine-hesitant groups and then (ii) compare their PBN consumption behaviors and social media discussions.

Figure 3: Ratio of left-, right-, and center-leaning news media of pro-vaccine, anti-vaccine, and vaccine-hesitant groups.

Vaccine Stance Groups. Based on a study from the SAGE working group [MacDonald and others, 2015], *vaccine hes-itancy* occurs on the continuum between two extremes, i.e., completely accepting (pro-vaccine) and refusing all vaccines (anti-vaccine). Intuitively, vaccine-hesitant users change their stances more frequently compared to anti-vaxxers and pro-vaxxers. Therefore, we first calculate the monthly COVID-vaccine stance changes:

$$stance = \frac{P_{before} - A_{before}}{P_{before} + A_{before}}.$$
 (1)

Note that P_{before} and A_{before} denote the number of pro-vaccine and anti-vaccine tweets before a user reads PBN, respectively. Similar to [Mitra *et al.*, 2016], we then determine three types of vaccine stance groups based on the following criteria:

- *pro-vaccine group*, users whose monthly COVID-19 vaccine *stance* are always greater than 0.8;
- *anti-vaccine group*, users whose monthly COVID-19 vaccine *stance* are always less than -0.8; and
- *vaccine-hesitant group*, users whose monthly COVID-19 vaccine *stance* are changing between 0.8 and -0.8.

In total, we identify 2,377 pro-vaccine, 1,238 anti-vaccine, and 10,428 vaccine-hesitant users.

News Consumption Behavior. Next, we compare the selection bias of three types of news sources in the pro-vaccine group, anti-vaccine group, and vaccine-hesitant group in Figure 3. A notable observation is that the pro-vaccine and anti-vaccine groups display a highly <u>unbalanced distribution</u> compared to the vaccine-hesitant group. Left-leaning and right-leaning news dominate among the pro-vaccine (around 75%) and anti-vaccine groups (around 91%), respectively. Mean-while, users in the vaccine-hesitant group read news mainly from center-leaning (around 43%) and left-leaning (around 35%) media outlets.

Sociel Media Discussion. We further use topic modeling on the collected COVID-vaccine-related tweets to investigate topics each group is interested in after reading PBN. The text is pre-processed by punctuation removal, URL removal, stop words removal, hashtag removal, tokenization, stemming, and lemmatization. The cleaned data is then fed into BERTopic [Grootendorst, 2022], a state-of-theart topic modeling technique that leverages Sentence-Bert (SBERT) [Reimers and Gurevych, 2019] for text embedding, UMAP [McInnes *et al.*, 2018] for dimensionality reduction, HDBSCAN [McInnes *et al.*, 2017] for clustering, and a classbased TF-IDF for topic representation. To verify the quality

Figure 4: Overall (a) and monthly (b) percentage of Twitter discussions associated with five COVID-vaccine-related topics among the pro-vaccine group, anti-vaccine group, and vaccine-hesitant group.

of the result from BERTopic, we manually inspect representative tweets (i.e., tweets nearest to the cluster centroid) for each topic cluster. Finally, we merge over-partitioned clusters to obtain the final list of COVID-related topic clusters.

In Table 2, we identify five major COVID-vaccinerelated topics: "vaccine refusal", "vaccine acceptance", "conspiracy theory", "scientific fact", and "political narrative". We illustrate a large variation in the results across these topics in Figure 4a:

- The pro-vaccine group prefers discussions about "vaccine acceptance" (46.5%) and "scientific argument" (23.3%).
- The anti-vaccine group tends to post "conspiracy theories" (42.4%) and "vaccine refusal" (35.6%).
- The vaccine-hesitant group tends to discuss "scientific arguments" (36.0%) and "politics" (28.8%).

Figure 4b shows how the discussion changes over time in each stance group. We find that:

- "Vaccine acceptance" (green) and "scientific argument" (blue) discussions have grown steadily in the pro-vaccine and vaccine-hesitant groups.
- Percentages of tweets about "conspiracy theories" (purple) and "vaccine refusal" (red) show a rapid increase between 2022/04 and 2022/05 in the anti-vaccine group.
- The trending around "political discussion" (grey) of the three groups shows a similar pattern.

5 RQ2. Estimating Causal Effect of Reading PBN on Stance Change

One of the primary challenges in causal effect estimation with observational data is controlling for confounders. In this research question, we (i) identify two types of social media features as <u>potential confounders</u>: users' statistical profile feature (e.g., <u>number of tweets</u>) and textual content feature (e.g.,

historical tweets) [Veitch et al., 2020; Cheng et al., 2022a]. With the identified potential confounders, we (i) estimate the causal effect of reading COVID-vaccine-related PBN on Twitter users' vaccine stance changes. We hypothesize that reading COVID-vaccine-related news from left-leaning and right-leaning media will cause people's COVID-19 vaccine stance to shift toward pro-vaccine and anti-vaccine, respectively. To validate this hypothesis, we begin by formulating the problem as a causal effect estimation task. We use causal graphs [Pearl, 2009] to represent the two scenarios we $\overline{\text{consider} - (1)}$ when the causal effect is confounded only by observed variables (see Figure 5a); and (2) when there exist unobserved confounders (see Figure 5b). With them, we apply state-of-the-art causal learning methods to quantitatively estimate the causal effect using data from CovNS. We also compare the results obtained by the causal learning models and that from a correlation-based model.

Potential Confounders. We consider the following profile features as potential confounders:

- The log-transformed number of historical tweets, likes, followers, and friends;
- The 2020 U.S. presidential election results of the location, (0 = blue state, 1 = red state);
- The age (months) of the account;
- The Twitter account is verified or not, (0 = unverified, 1 = verified); and
- The proportion of COVID-vaccine-related tweets, i.e., a continuum between 0 and 1.

For the textual feature, we extract the text embedding of the most recent one-week historical tweets before a user reads PBN from the fine-tuned CT-BERT. These statistical and textual features can reflect user characteristics, which are related to users' online behaviors. Therefore, we select these important social media features as potential confounders for discovering the causal relation in the next phase.

Modeling Causal Relations. We define the causal effect we aim to estimate – reading COVID-vaccine-related PBN (*treatment*) denoted by T on one's COVID-vaccine stance shifting (*outcome*) denoted by Y. We represent the causal relations among variables with two different causal graphs [Pearl, 2009] to consider two possible scenarios (see Figure 5). We consider four different settings in terms of how the values of T and Y are defined (see Table 3). Then, with *do*-calculus [Pearl, 2009], we define the causal estimand, i.e., the average treatment effect (ATE):

$$ATE = E[Y|do(T=1)] - E[Y|do(T=0)], \quad (2)$$

where E[Y|do(T = t)] is the expectation of Y when T is intervened to take value t. As aforementioned, we consider the user characteristics, i.e., a set of selected profile features and user history, are related to one's PBN consumption behavior (T) and change in COVID-19 vaccine stance (Y).

In scenario 1, we let the confounder W be these user characteristics. Thus, by conditioning on them, we can block the backdoor path (treatment-confounder-outcome) to handle confounding bias. With Figure 5a, we assume that there is no

backdoor path between T and Y by conditioning on the observed user characteristics W. This leads to the identification of ATE through backdoor criterion [Pearl, 2009]:

$$P(Y|do(T)) = \int P(Y|T, W)P(W)dW.$$
 (3)

In this scenario, we estimate ATE with two state-of-theart causal learning methods. Double machine learning (DML) [Chernozhukov et al., 2018] – DML estimates heterogeneous treatment effects from observational data with machine learning algorithms. It contains two predictive tasks (i.e., predict the treatment and outcome from the confounder) to ensure unbiased estimates of the causal effect. We use a linear DML in this study. Causal Forest (CF) [Athey et al., 2019] – CF is widely adopted for causal effect estimation, which performs recursive partition in the confounder space s.t. each leaf of a tree in CF corresponds to a homogeneous subpopulation with similar causal effect. Compared to linear DML, CF models the relationship between the confounder and the treatment with a tree-based model and infers the causal effect of a test instance by looking up the treatment effect of the subpopulation this instance is mapped to.

Scenario 1 relies on a strong causal assumption that all confounders are observable/measurable (i.e., the unconfoundedness assumption [Pearl, 2009]). However, in practice, some confounders are hidden or unmeasurable. For example, one's education and occupation may not be explicitly stated in the user profile. We cannot hope to measure all possible confounders. A common practice is to adopt the "proxy variables" [Cheng et al., 2022b]. For example, some textual clues from historical tweets can implicitly reflect users' education levels and jobs. Therefore, in scenario 2, we further relax the unconfoundedness assumption and consider the observed user characteristics X as the *proxies* of the latent confounder W. The causal graph is illustrated in Figure 5b. Then we can leverage proximal causal inference methods [Miao et al., 2018] to identify ATE. Specifically, we consider Causal effect variational autoencoder (CEVAE) [Louizos et al., 2017] as the estimator. CEVAE leverages deep variational autoencoders (VAE) to learn the representation of the latent confounder given the observed proxy variables.

For comparison, we include a correlation-based method. Specifically, we implement a simple *logistic regression on treatment* that predicts the outcome Y with the treatment T as its input. It can be considered as a generalized version of the naive estimator [Rubin, 1978] that does not control the effect of confounding variables.

Figure 5: Two causal DAG of our studied problem. The left one (a) assumes all confounding variables are observed. The right one (b) uses proxies to approximate latent confounders.

Setting	Treatment (T)	Outcome (Y)
1	0: read <i>center</i> news 1: read <i>left</i> news	0: unchanged stance 1: move toward pro-vax
2	0: read <i>center</i> news 1: read <i>left</i> news	0: unchanged stance 1: move toward anti-vax
3	0: read <i>center</i> news 1: read <i>right</i> news	0: unchanged stance 1: move toward pro-vax
4	0: read <i>center</i> news 1: read <i>right</i> news	0: unchanged stance 1: move toward anti-vax

Table 3: Experiment settings for the causal study.

Estimating Causal Effects. Figure 6 shows the comparison of the overall estimated ATE by different methods and that of the pro-vaccine group (6b), anti-vaccine group (6c), and vaccine-hesitant group (6d). The estimated ATE from DML, CF, and CEVAE are similar (p > 0.05).

- Comparing the results from settings 1 and 2, we observe that reading PBN from left-leaning media causes individuals to be more pro-vaccine. In contrast, results from settings 3 and 4 show that consuming PBN from right-leaning media causes people to be more anti-vaccine.
- Results from logistic regression (LR) on treatment are outliers in all experiments (p < 0.001). For example, the estimated ATEs of LR in setting 3 show that reading rightleaning PBN will make people more pro-vaccine, which is opposite to the results from causal learning models. A possible explanation is that the results of correlation-based observational studies usually suffer from spurious correlation due to confounding bias, especially when the confounding effect is important [Austin, 2011].
- In addition, we find that the magnitudes of the estimated ATE of the vaccine-hesitant group are higher

Figure 6: The overall estimated ATE and that of each (pre-treatment) stance group: we compare correlation-based (red) and causal learning models (green) in 4 experimental settings. We ran each model 10 times to report the mean values (histograms) and standard deviations (error bars). Note that the ATE inferred by the causal learning methods are similar (p > 0.05 for t-test) while they are significantly different from the one estimated by the correlation-based model (p < 0.001 for t-test).

than the pro-vaccine group and anti-vaccine group, indicating that vaccine-hesitant people are more likely to change their vaccine stances after consuming PBN.

6 Implications

RQ1. Users with varying stances on vaccines display unique patterns of PBN consumption and social media discussion. Future research should consider the disparity when studying vaccine-related problems in social media.

- Compared to the vaccine-hesitant people, the pro-vaccine and anti-vaccine group members are more likely to read PBN from <u>far-left</u> and far-right news media, respectively. Intensive exposure to highly biased news may explain the occurrence of extreme COVID-19 vaccine stances.
- As "scientific arguments" and "political narratives" usually contain debatable opinions, the vaccine-hesitant group member is able to gather <u>diverse information</u> from both sides. Thus, their stances may move back and forth.
- The pattern of increasing interest in "vaccine acceptance" and a decline in "vaccine refusal" indicates that the vaccinehesitant group is becoming more positive about the vaccine.

RQ2. The exposure to COVID-vaccine-related news from left- and right-leaning media causes one's COVID-19 vaccine stance shift toward pro- and anti-vaccine respectively, especially for users in the vaccine-hesitant group. This suggests that it is possible for malicious people to manipulate public opinion through PBN interventions.

• The similar estimated causal effects from causal learning models indicate that the unobserved confounding variables may have limited impacts on the treatment and outcome.

- Comparing the magnitudes of the estimated ATE (see Figure 6a), we observe that left-leaning news (setting 1 and 2) is more *influential* than right-leaning news (setting 3 and 4). We speculate that vaccine-hesitant people are more likely to become pro-vaxxers than anti-vaxxers over time through the influence of PBN.
- As reading left-leaning news has a very small causal effect (around 0.1) on anti-vaxxers' vaccine stance changes (see Figure 6c), it is unlikely to alter anti-vaxxers to provaxxers through PBN reading interventions. Meanwhile, pro-vaxxers are difficult to become anti-vaxxers by consuming PBN (see Figure 6b). This indicates that people with extreme views about vaccines tend to reinforce their existing stances. On the other hand, the vaccine-hesitant majority are vulnerable to the influence of PBN and, thus, may frequently reverse their minds.

7 Conclusions

This paper investigates the impact of PBN consumption on the vaccine stance changes of social media users. We construct **CovNS**, which contains data from both news media and social media. We compare the PBN consumption behavior and social media discussion between three vaccine stance groups. By identifying potential confounders, we leverage state-of-the-art causal inference methods to estimate the causal effect. Our experiments and analyses have implications for fostering the research of vaccine hesitancy in social media. We conclude that consuming left-leaning and right-leaning news causes people to be pro-vaccine and antivaccine, respectively. More importantly, there is only a small possibility for anti-vaxxers to become pro-vaxxers via PBN reading interventions on social media, and vice versa.
