PARENDI: Thousand-Way Parallel RTL Simulation

Mahyar Emami mahyar.emami@epfl.ch EPFL Lausanne, Switzerland Thomas Bourgeat thomas.bourgeat@epfl.ch EPFL Lausanne, Switzerland James R. Larus james.larus@epfl.ch EPFL Lausanne, Switzerland

Abstract

Hardware development relies on simulations, particularly cycle-accurate RTL (Register Transfer Level) simulations, which consume significant time. As single-processor performance grows only slowly, conventional, single-threaded RTL simulation is becoming less practical for increasingly complex chips and systems. A solution is parallel RTL simulation, where ideally, simulators could run on thousands of parallel cores. However, existing simulators can only exploit tens of cores.

This paper studies the challenges inherent in running parallel RTL simulation on a *multi-thousand-core* machine (the Graphcore IPU, a 1472-core machine). Simulation performance requires balancing three factors: synchronization, communication, and computation. We experimentally evaluate each metric and analyze how it affects parallel simulation speed, drawing on contrasts between the large-scale IPU and smaller but faster x86 systems.

Using this analysis, we build PARENDI, an RTL simulator for the IPU. It distributes RTL simulation across 5888 cores on 4 IPU sockets. PARENDI runs large RTL designs up to 4× faster than a powerful, state-of-the-art x86 multicore system.

1 Introduction

Hardware developers spend as much as 24% of development time *running* simulations [22, 23]. Prominent is cycleaccurate RTL simulation, vital to debug and validate a design. Unfortunately, its slow speed hampers the design process.

Fig. 1 shows the increasing gap between single-thread performance improvements and transistor count in a package. An obvious consequence is that single-thread RTL simulation of the next generations of chips on existing machines is becoming less practical.

2010 2015 2020 2025 2030

Figure 1. Chip growth and single-thread performance [42]. The dashed line predicts the number of cores necessary to simulate a new generation at the same speed as in 2006.

One promising solution is to exploit the inherent parallelism of RTL designs by running parallel RTL simulations on parallel computers [21, 33, 56]. However, Fig. 1 shows that simulating today's chips at the same rate that we simulated chips in 2006¹ would require parallelizing simulation across hundreds or thousands of cores.

This paper investigates the problem of parallelizing the RTL simulation of large, 100-core SoCs across a few *thousand* cores. We use an actual *thousand-core* machine since simulating an architecture with thousands of cores would be too slow for a system-level study. The machine we use is the Graphcore IPU [4, 28], a 1472-core chip designed for machine learning applications. However, the IPU's high core count and fast synchronization and communication make it well-suited for large-scale RTL simulation.

Developing an effective compilation strategy for parallel RTL simulation on a thousand-core machine requires a keen understanding of the interplay between three factors: synchronization, communication, and computation. We analyze the three factors in depth to identify relations between them. These axes are not independent, so a significant challenge is to use this understanding to craft a practical partitioning algorithm that minimizes those costs.

We use these insights to build PARENDI²: the first multithousand-way parallel RTL simulator that scales simulation speed across 4 IPU chips for a total of 5888 cores. PARENDI is open-source and useable with public cloud IPUs, facilitating further research. For large designs, RTL simulation is up to $4\times$ faster than Verilator (the fastest multi-thread RTL simulator) running on large x86 systems.

The contributions of this work are:

- A quantitative study of thousand-way parallel RTL simulation.
- A new communication- and duplication-aware partitioning strategy for large-scale RTL simulation.
- PARENDI, the first open-source³ RTL simulator to parallelize RTL code to thousands of cores.
- An evaluation of PARENDI on the IPU compared to Verilator on x86 showing a 2.8× geomean (4.0× max) speedup.

The paper is organized as follows: §2 describes the IPU architecture and its programming model. §3 discusses our parallel simulation methodology. §4 is a high-level study of parallel RTL simulation performance. §5 outlines PARENDI's

¹The release of Intel Core 2 Duo and the unofficial end of Dennard's scaling. ²PARENDI is the female Zoroastrian angel of abundance. ³https://github.com/epfl-vlsc/parendi

design. §6 evaluates and compares PARENDI on the IPU and Verilator on x86. §7 surveys related work. And, §8 concludes.

2 Graphcore IPU Background

A Graphcore IPU consists of 1472 tiles (physical cores) interconnected by a high-bandwidth network on the chip (the IPU exchange) with an 11 TiB/s all-to-all bandwidth [4]. The IPU is a multiple-instruction, multi-data (MIMD) architecture where each tile runs an independent instruction stream. This sets the IPU apart from SIMD or SIMT GPUs, where groups of threads (warps) execute the same instruction on different data. Furthermore, the IPU is a message-passing machine, where tiles can only access their own private memories and must explicitly communicate through the exchange fabric. The total on-chip memory in an IPU is about 900 MiB, with each tile having direct access to 624 KiB.

Fig. 2 shows a Graphcore M2000 IPU server. The M2000 is a 1U server with 4 IPUs, connected via a dedicated 320 GiB/s on-board exchange fabric, totaling 5888 independent tiles. Multiple M2000 boards may also be connected to form systems of 16 or 64 IPUs with dedicated networking. This work uses a single M2000 board as the compilation target.

An IPU system (with any number of IPUs) is programmed using the bulk-synchronous parallel (**BSP**) [54] programming model in C++, with the *poplar* SDK and *popc*, a clangbased C++ compiler. The next section describes BSP and shows how to apply this execution model to RTL simulation. The IPU *natively* supports BSP communication and synchronization, which enables efficient fine-grained parallelism.

3 Parallel RTL Simulation

Hardware description languages (HDL) like SystemVerilog can express digital sequential circuits. An HDL program describes stateful *clocked* elements called registers that are interconnected (by wires) via stateless combinational logic (e.g., addition). An HDL register is associated with a clock, and its value is updated at clock ticks. The collection of clocked register updates and combinational logic defines the abstraction of the register transfer level (RTL).

We focus on cycle-accurate RTL simulation, in which combinational logic has zero delay. Furthermore, we perform a full-cycle simulation (activity-oblivious) to evaluate the entire circuit at each RTL cycle. The alternative method is to simulate the circuit in an event-driven fashion (activity-aware). However, full-cycle simulators perform better—sometimes by orders of magnitude—as the cost of tracking value changes in RTL is high [14].

Parallel RTL simulation is better suited to *message-passing* computation (and architectures) than shared-memory. First, the fine-grained parallelism is challenging to execute on a shared-memory multiprocessor due to costly synchronization [21, 56]. Second, the RTL tasks have a high level of finegrained point-to-point communication: Independent tasks communicate only a few bytes of data to neighbors in the RTL design, which must all go through the LLC. Last, the RTL can have a high reuse distance in data and instructions, which makes caches perform poorly. Most data and instructions are accessed once per simulated RTL cycle, which could span millions of machine cycles. Large designs, which do not fit in the caches of a shared-memory machine, must prefetch code and data at every RTL cycle.

3.1 BSP RTL Simulation

We apply Valiant's bulk-synchronous parallel (**BSP**) [54] model to coordinate parallel RTL simulation. The appeal of BSP is that it vastly reduces synchronization overhead: to two global barriers per RTL clock cycle.

BSP is a message-passing model that consists of two phases: (i) computation and (ii) communication. In the computation phase, parallel *processes* run, reading shared variables but only modifying private data. Computation ends with a barrier, followed by the communication phase, in which the new private values propagate to other processes. The communication phase also ends with a barrier, after which a new computation phase starts.

Fig. 3 shows an example *data dependence graph* of an RTL circuit. In the graph, each RTL register is split into two values: a read-only value (*current*, at the beginning of the clock) and a write-only value (*next*, at the end). The read-only values (current) are at the top (e.g., read1) and feed into stateless combinational logic (circles) that computes next register values (e.g., write1).

The dashed lines in Fig. 3 *partition* the data dependence graph into BSP *processes* p1 and p2. Each process reads a set of RTL registers and computes new values for one or more (e.g., write1 in p2). Processes may have overlapping computations; for instance, a3 is present in both p1 and p2. These internal nodes are wire computations, which can be safely duplicated across processes. As a result, we only communicate register values in bulk at the end of the computations.

Figure 3. BSP Simulation of an RTL data dependence graph. The graph has three fibers (f1, f2, f3), partitioned into two processes (p1, p2), running on two threads (node a3 is duplicated on each). The run on the right shows the computation and communication phases, separated by barriers.

The right side of Fig. 3 shows the evaluation of the example. The two parallel processes synchronize at a barrier (dashed vertical lines). The first barrier marks the end of the computation, after which we exchange next values (write1, write2, and write3) and update the current values accordingly (read1, read2, and read3). We finish the communication with a barrier and conclude one RTL simulation cycle.

A parallel RTL compiler needs to find a partition of the RTL data dependence graph that minimizes time spent running each simulation cycle. p1 and p2 are not the only possible partitions of Fig. 3. We call the atoms of BSP simulation *fibers*. A fiber is the smallest BSP process that uniquely computes the new value of a *single* register. For instance, Fig. 3 consist of three registers; hence there exists three fibers f1, f2, and f3, which can be partitioned by assigning f1 to p1 and the other two fibers to p2.

Lastly, BSP is one of many possible parallel simulation methods. We could use finer partitions that slice fibers in the data dependence graph to expose more parallelism to avoid duplicating work. Verilator [46–48], the fastest RTL simulator and our baseline, takes the latter approach [44].

4 Analysis of BSP RTL Simulation

This section identifies and measures the principal factors affecting BSP RTL simulation performance. This analysis uses both carefully crafted microbenchmarks and illustrative integration benchmarks. We run the experiments on a Graphcore M2000 quad-IPU system and an Intel Xeon Gold 6348 56-core dual-socket processor (see Table 2 for details).

Parallel RTL simulation performance depends on the synchronization, communication, and computation cost. In the BSP model, the sum of the three is the time to simulate one cycle, so the simulation rate (in thousand RTL cycles per second or kHz) is

$$r_{cycle} = \frac{1}{t_{sync} + t_{comm} + t_{comp}},\tag{1}$$

where t_{sync} , t_{comm} , and t_{comp} are the per simulated RTL cycle synchronization, communication, and computation latencies. We must reduce their sum to increase the simulation rate.

Below, we explore how each component behaves as we increase parallelism through measurements. Our analysis reveals salient architectural features of both the IPU and x86, providing insight into compilation strategies.

4.1 Synchronization Latency

BSP requires two global synchronizations per simulated clock cycle, so t_{sync} costs two barriers. Therefore, t_{sync} is independent of the simulated design but depends on the number of hardware threads used for simulation.

To show how much an increase in t_{sync} affects simulation performance, we simulate a set of xorshift32 pseudorandom number generators (PRNG), each performing 3 XORs and 3 shifts [35]. The simulated PRNGs are independent; hence, $t_{comm} = 0$, but $t_{sync} > 0$ as we still need to synchronize all PRNGs with the RTL clock.

We simultaneously increase the number of PRNGs and the number of computation units—tiles (IPU) or threads (x86). In doing so, we keep the amount of work per tile (thread) constant. Therefore, if t_{sync} is small compared to the rest, we should observe a near-constant simulation rate. Note that each PRNG consists of one fiber, and we sequentially execute multiple fibers on one tile (thread).

We use the IPU's built-in barrier and increase the tiles from 64 to 5888 by 64. On x86, we use a user-space barrier (atomic fetch-and-add), sweeping the threads from 1 to 56.

Fig. 4 shows the measured rate on the IPU (normalized to the rate with 64 tiles) and on x86 (normalized to the rate with 1 thread). Each line shows the performance with a fixed quantity of fibers per tile: 7, 56, and 448 on the IPU and 736, 5888, and 47104 on the x86. The total work with 5888 tiles on IPU is the same as 56 threads on x86. However, we normalized each experiment to itself; as a result, we are not comparing absolute simulation rates between the machines.

Figure 4. IPU and x86 PRNG rates

With 7 fibers per tile on the IPU, performance decreases by almost 50% due to increased synchronization overhead among an increasing number of tiles. Synchronization latency becomes less noticeable as the work per tile increases (e.g., 448 fibers). This agrees with our definition of r_{cycle} : the larger t_{comp} is, the less sensitive r_{cycle} is to changes in t_{sync} . The cost of synchronization on x86 is high, particularly with few fibers per thread. With 736 fibers per thread, performance drops by more than 75%.

The IPU has native hardware support for global synchronization, taking only a few hundred IPU cycles. By contrast, x86 barrier synchronization requires expensive atomic memory accesses that could consume a few thousand cycles with all 56 threads.

Fig. 4 implies a simple rule-of-thumb. To mask synchronization overhead on x86, we need hundreds of thousands of instructions per thread (each fiber is roughly 6 instructions), whereas on the IPU, a few thousand instructions adequately hide synchronization overhead. The IPU potentially allows fine-grain parallelism, whereas the x86 does not.

4.2 Communication Latency

Similar to t_{sync} , we expect t_{comm} to increase as we increase parallelism, as additional tiles (threads) mean more inter-tile (thread) messages. Unlike synchronization, communication depends on the specifics of an RTL design and the partitioning of fibers to tiles (threads). We summarize these considerations into two parameters: bytes sent from each tile (*b*) and number of tiles in the simulation (*m*).

To first order, we could expect $t_{comm} = \frac{m \times b}{bw}$, where bw is the bandwidth of communication and $m \times b$ corresponds to the total communication volume. Additional parallelism can increase communication latency as it also increases communication volume. Therefore, at some point, the increases in t_{comm} negate the gains from parallelism.

Alternatively, it could be that t_{comm} is almost independent of *m* and only depends on *b*. Then, performance increases *monotonically* with parallelism, without increasing t_{comm} .

We found that communication within a single IPU mostly depends on b, and communication between IPUs depends on $m \times b$. We demonstrate this using two experiments.

First, we consider 2m tiles on one IPU. We *randomly* partition the 2m tiles into two sets of m tiles and send a fixed number of bytes in both directions.

The left plot in Fig. 5 shows the measured IPU cycle counts (averaged over 10 random bi-partitions). Note that the cycle counts include t_{sync} as determining when all messages have been exchanged requires synchronization. The horizontal axis is the number of bytes each tile sends and receives (*b*). The vertical axis is the number of tiles (*m*). On-chip t_{comm} increases in only the direction of increasing *b* as shown by the arrow in the left of Fig. 5.

In the second experiment, one tile in each pair resides on one IPU and the other on another IPU, so all traffic goes off-chip. The right of Fig. 5 reports the results.

The off-chip exchange shows a vastly different behavior: t_{comm} increases with increasing parallelism *and* bytes per tile as it depends on $m \times b$ (the diagonal arrow delineates

Figure 5. Measured communication cycles on the IPU, onand off-chip.

the direction of change). Furthermore, the increase is more pronounced compared to the on-chip latency.

At the plots' darkest points, we consume 13% and 82% of the maximum measured communication bandwidth, onand off-chip, respectively (7.7 TiB/s and 107 GiB/s). The onchip experiment is far from saturating the bandwidth, so the latency is insensitive to the tile count. By contrast, the offchip experiment runs near the fabrics's maximum bandwidth, so additional tiles increase contention and communication latency.

In conclusion, the difference between the communication fabrics implies that minimizing off-chip communication volume should be a first-class concern.

Before analyzing t_{comp} , we discuss a subtle technicality of BSP communication. A common programming practice to reduce t_{comm} is to overlap it with computation (i.e., software pipelining), which is particularly valuable when a tile (thread) executes multiple fibers so final values are produced throughout the computation. Cycle-accurate semantics of RTL simulation requires double buffering. Overlap has some value on x86, though it is difficult to implement on the IPU. The IPU's exchange fabric is *statically scheduled*; hence, the communication phase must begin with a synchronization to ensure all tiles are at the same point in execution. As a result, we ignored the potential effects of overlap.

4.3 Computation Latency

At first glance, optimizing t_{comp} is similar to the classical *multiprocessor independent task scheduling* or *makespan min-imization* problem [25]. In this problem we consider a set of tasks (fibers) $F = \{f_1, ..., f_n\}$ with corresponding execution times $t_i, ..., t_n$. The goal is to schedule these tasks on *m* tiles (threads) to minimize the maximum execution time across all tiles. This problem is NP-hard [53], but polynomial-time approximation schemes exist [25, 43].

In the classical problem, tasks (fibers) contain no duplicated work. However, in BSP RTL simulation, two fibers might compute a common intermediate value (for example the value produced by a3 in Fig. 3). This is an opportunity to collocate the two fibers in the same process, however it complicates the partitioning problem.

Each fiber is a set of computation nodes (the nodes in Fig. 3). If we denote the execution time of a BSP process using $\tau(.)$, then a process made up of fibers f_i and f_j would have $\tau(f_i \cup f_j) = t_i + t_j - \tau(f_i \cap f_j)$ since we only need to execute the shared code once in a process. Moreover, merging fibers reduces communication (t_{comm}) so $\tau(f_i \cup f_j) \leq t_i + t_j - \tau(f_i \cap f_j)$.

The scheduled execution time is called a submodular function, and this variant of the scheduling problem is called submodular load balancing (SLB). SLB is inherently more difficult than classical scheduling in the sense that it is hard to get even modest approximation guarantees ($\sqrt{n/log(n)}$ [49]).

(a) Stragglers impose a lower bound on tcomp. Fibers sorted for visualization.

(b) Fiber computation cycles in pico, bitcon, and rocket.

(c) Reducing t_{comp} through parallel execution (base-2 log scale). Dashed lines show a perfect scaling.

Figure 6. Straggler fibers and performance scaling regions.

When fewer tasks exist than tiles (threads) ($n \le m$), the optimal solution is to assign one fiber to each tile (thread). It

		Par	ENDI			Verilator on ix3

Table 1. Simulation rate in kHz. **par** is the tile- or threadcount used to achieve the rate in **kHz**.

is impossible to improve t_{comp} beyond max_i t_i as the slowest fiber (the straggler) bounds t_{comp} from below. Encountering this bound on x86 hardware is unlikely: even relatively small designs have a few hundred fibers, an order of magnitude more than available cores. However, a single IPU chip has 1472 tiles, sufficient for small to medium-sized designs so that a straggler fiber can be the limit on the IPU.

Fig. 6a summarizes the SLB problem: mapping fibers to tiles results in a linear regions were we could reduce t_{comp} almost linearly by using more tiles. The reductions gradually become less significant, and we plateau at max_i t_i with sufficient tiles. In Fig. 6a m_{crit} represents the minimum number of tiles needed to reach max_i t_i (lowest value of t_{comp}). To maximize simulation rate, we only need m_{crit} tiles; having more would not help as the straggler is the limit.

To put this into perspective, consider 3 small RTL designs: (i) a multi-cycle RISC-V pico core [40], (ii) a bitcoin miner [38], and (iii) a *small* rocket pipelined RISC-V core [10]. These small designs contain more fibers than x86 systems core: 111, 270, and 1211 fibers, respectively. We run each benchmark using PARENDI, which we describe later in §5.

Fig. 6b shows fiber computation latency (t_i for each f_i) of the three benchmarks (in IPU machine cycles). Fig. 6c illustrates the corresponding scheduled execution times with the dashed diagonal representing a perfect linear reduction. We normalize machine cycle counts to the minimum parallel execution: 1 tile in pico and bitcoin, 2 tiles in rocket (a single tile cannot hold sufficient code and state for rocket).

First, t_{comp} in Fig. 6c follows the trend of Fig. 6a: imbalanced fibers yield a small linear scaling region. pico is the most imbalanced and settles to a final t_{comp} extremely quickly. rocket is slightly more scalable but also leaves the linear region early. bitcoin performs the best as its fibers are quite balanced. Second, we see that t_{sync} and t_{comm} increase as we use additional tiles. However, the t_{comp} reduction is always larger, and the sum of the three decreases overall.

Table 1 compares the wall-clock simulation rate of the IPU, using PARENDI, against an Intel Xeon 6348 (see Table 2 for details), using Verilator. We show the simulation rate using a single tile (except for rocket which needs more memory than available in one tile) and the maximum number of tiles, where we assign one fiber per tile. For x86, we report the single-thread and best multi-thread performance.

None of the three small benchmarks show any speedup on x86 from parallelism since the synchronization cost is too high (see §4.1). The results in Table 1 do not mean that Verilator cannot speed up RTL simulation. In §6, we show that Verilator does an excellent job of parallelizing code. However, our analysis of t_{sync} shows that a simulated design on the x86 must be large enough to mask synchronization overhead, and these three benchmarks are small.

Verilator's inability to scale these three benchmarks confirms our claim that the straggler fiber is not a performance limit on x86 as synchronization latency limits performance earlier. On the other hand, stragglers are a fundamental concern for PARENDI when compiling small designs. Table 1 shows that PARENDI does not manage to match Verilator's single-thread performance for pico and rocket, despite modest gains from parallelism. However, it does outperform Verilator for bitcoin, where the balanced fibers scale well.

Last, single-tile execution of pico and bitcoin on the IPU are approximately 84× and 37× slower than x86, respectively. Consequently, the IPU has to *massively* scale RTL simulation even to match Verilator's single-thread performance.

5 PARENDI Compiler

PARENDI is a Verilog compiler for the IPU systems. It is based on Verilator to take advantage of its optimizations and the maturity of its codebase. However, PARENDI contains significant changes that target the IPU (message-passing) rather than the x86 (shared memory). PARENDI also includes new scheduling and partitioning strategies and IPU-specific optimizations—about 8K lines of code.

PARENDI generates a C++ BSP program that uses Graphcore's *poplar* programming framework. The code defines each tile's computation and how the tiles communicate.

At a high level, PARENDI's primary responsibility is to partition RTL across the tiles of an IPU system. The user selects the number of tiles; for example, a user could ask PARENDI to produce code for 736 tiles (half an IPU) or 2944 tiles (2 IPUs). PARENDI tries to maximize the simulation rate by finding an appropriate partitioning of fibers to the tiles. We briefly describe our partitioning strategy.

5.1 Partitioning

After generating a data dependence graph (see Fig. 3), we determine the fibers by collecting the nodes that transitively feed into each sink node by crawling the graph in reverse.

Once we form the set of fibers, we must solve the SLB problem introduced in §4.3. It is crucial to recognize the interdependence between computation (t_{comp}) and communication latency (t_{comm}) . Additionally, each tile has a finite memory. Consequently, our partitioning algorithm must consider duplication, communication, and memory limitations.

We solve this problem in multiple steps, each pursuing a different goal. At each algorithm step, we *merge* fibers into *processes*. On the IPU, a process is a collection of fibers that will eventually run on a tile (e.g., see the processes in Fig. 3). There are four stages in our algorithm:

- 1. Reduce data memory footprint.
- 2. Minimize off-chip communication.
- 3. Reduce *t_{comm}* while keeping *t_{comp}* unchanged in each IPU.
- 4. Match the number of fibers to available hardware parallelism.

In the first stage, we merge fibers referencing the same RTL array. We do this to save memory, at the cost of increasing

 t_{comp} , but only for *very* large arrays (e.g., \geq 128 KiB, tunable) so as to not limit parallelism.

The second stage minimizes off-chip exchanges if PARENDI is compiling for more than one IPU. We do this by partitioning a hypergraph of fibers. In this hypergraph, hypernodes represent fibers, and hyperedges represent RTL registers. If two fibers access the same register (read or write), their corresponding hypernodes share a hyperedge. The hyperedge weights are the number of words in an RTL register, and hypernodes are unweighted.

For *k* IPUs, we use the KaHyPar [45] library to find a *k*-way balanced partition of the hypergraph that minimizes the *cut* (hyperedges crossing the partitions). KaHyPar produces *k* roughly equally-sized sets of fibers. However, each set may contain more than 1472 fibers, in which case, we must further merge fibers to fit the available tiles.

In the third stage, we *conservatively* merge *tiny* fibers to reduce communication within each target IPU without increasing computation latency. Intuitively, we crawl right to the left in the right subplot of Fig. 6a towards m_{crit} . If we reduce the number of fibers to fit the tiles in an IPU without crossing m_{crit} , then we can use the optimal $t_{comp} = \max_i t_i$ and a pseudo-optimal t_{comm} .

We create one process for each fiber and estimate its execution cost. Recall from §4.3 that the cost of a process is submodular with respect to its fibers. We use a dense bitset data structure to represent duplication across fibers and efficiently compute intersection and union in the submodular cost function $-\tau(f_i \cup f_i) = t_i + t_i - \tau(f_i \cap f_i)$.

In addition, we use another bitset to calculate the memory usage after merging, accounting for deduplication.

In each iteration, we select the process with the shortest execution time and try to merge it with a process with which it communicates, so long as their merged time does not surpass the worst existing execution time (straggler).

If we cannot perform the merge because of overflowing memory or exceeding the straggler execution time, we consider merging the two smallest processes. If that fails, we skip the candidate process and move to the next one. We merge processes until we process all of them or reach the desired tile count.

The final stage only runs if the third stage fails to reach the desired tile count. We follow the same strategy as in the third stage but allow an increase in the worst-case execution time. However, we still disallow out-of-memory merges.

At the end of this stage, the number of processes must fit the available hardware. Otherwise, the compilation fails because the design is too large to fit the hardware resources.

5.2 IPU-Specific Optimizations

PARENDI extends Verilator's optimizations with a few IPUspecific ones. We briefly describe the most important ones.

Differential exchange. RTL arrays are common structures in hardware designs, e.g., in a register file or a cache

bank. If a process reads an array, it needs a full copy on its tile. We avoid sending whole arrays by using static analysis to determine the number of updates to an array, though not their location or condition (e.g., a 2-port SRAM with byte-strobes). With this analysis, we only send the changes instead of an entire array.

Aggressive block splitting. We extend Verilator's V3Split pass, favoring parallelism over code bloat, to maximally split all clocked code blocks.

Aggressive inline. PARENDI ensures that the simulation program on the IPU is free of function calls. Inlining can increase code size and produce excessive instruction cache pressure on x86, especially in RTL simulation, where nearly every instruction executes only once per RTL cycle, except for code in functions invoked multiple times. An IPU tile has no instruction cache but a 624 KiB local memory, of which 200 KiB holds executable code. So, a single IPU chip has \approx 300 MiB of on-chip instruction memory space, which allows PARENDI to aggressively inline code.

5.3 Limitations

Currently, PARENDI has some limitations as compared to Verilator. For instance, PARENDI can simulate an RTL design with one top-level clock and an arbitrary number of driven ones (e.g., gated or divided). In principle, PARENDI *could* support multiple top-level clocks, but we leave this feature for future work. Verilator, on the other hand, has recently added support for timing-accurate simulation with arbitrary clocking.

PARENDI supports only a Verilog test driver, whereas Verilator allows both C++ and Verilog drivers. We do this for pragmatic reasons: to achieve good performance, host interactions must be infrequent, and a C++ testbench requires interactions at every simulated RTL cycle.

PARENDI's compilation fails if there is a combinational loops in the design⁴.

6 Evaluation

We use the following set of benchmarks to evaluate PARENDI:

- mc [52] is stock option price predictor.
- vta [37] is an ML accelerator. We configure vta with BlockIn/Out=64, larger than the default FPGA configuration to expose more parallelism.
- srN is a N × N Constellation [60] mesh NoC that consists of N × N 3 small Rocket cores [10] (64-bit, no FPU, no VM), generated using the Chipyard [9] SoC generator (3 nodes in the NoC connect to uncore components). We change N from 2 to 15.
- 1rN is similar to srN, but we use large cores with an FPU and VM. We change N from 2 to 10.

Verilator

Note that srN is different from rocket in §4.3. The latter is a bus-based design, whereas srN uses a NoC.

These benchmarks reflect today's chip designs, including accelerators and multicore systems. By making the mesh bigger in srN and lrN, we can see how PARENDI performs with larger chips.

We wrap all benchmarks with simple drivers in Verilog, free of unnecessary DPI calls⁵. This is different from Chipyard's default simulation flow which heavily relies on DPI calls that hook the simulation to various services provided by the RISC-V frontend server in software. The advantage is that without linking heavy-weight software to simulation, we ensure that our evaluation does not include unwanted performance degradation (both in PARENDI and Verilator).

Baseline. We use Verilator as our baseline. Recent opensource work that attempts to improve RTL simulation performance through parallelism has limited usability. Verilog is a complex language, so academic works, including ours, make concessions and focus on techniques, ideas, and feasibility of approach rather than full language coverage and usability. We discuss a few technical limitations of earlier work to explain why we could not use them as a baseline in §7.

Evaluation Setup. Table 2 summarizes the hardware setup in our evaluation. For our baseline, Verilator, we use two modern data center processors: ae4 is the latest generation of AMD server lineup that offers very large caches and a high core count. The 64 cores on one socket are arranged in *chiplets* [1], each containing 8 cores. ix3 is a recent Intel lineup with less cache and fewer cores. Unlike the AMD

⁴In some situations, designs can have false combinational loops created by dependencies within wide signals

⁵Some PLI calls like \$readmemh, \$display, \$value\$plusargs, and etc. still exist.

machine, $i \times 3$ is not a chiplet-based design. For PARENDI, we use an M2000 server with 4 IPUs⁶.

We use Verilator v5.006 (PARENDI is forked from the same version) with all optimizations enabled (-03).

To find the best simulation performance for each design on PARENDI, we consider only 1472, 2944, 4416, and 5888 tiles (1, 2, 3, and 4 IPUs, respectively). On Verilator, we parallelize each design from 2 to 32 threads with a step of 2. We compile all the designs on an Intel Xeon 6132 with 1.5 TiB of memory.

Compile time and memory usage. Table 2 also shows the minimum and maximum compilation time and memory usage during compilation. Verilator compiles small designs very quickly but struggles with large ones, taking close to 8 hours to generate multi-threaded code. PARENDI, is relatively slower for small designs but faster for bigger ones, only taking 40 minutes in the worst case. Besides, Verilator uses 1043 GiB of memory to compile sr15. Because of this, we use a dedicated machine with 1.5 TiB of memory and only consider parallelizing up to 32 threads. Overall, we spent more than 2 weeks compiling code with Verilator.

We traced this issue to the V3VariableOrder, which approximates the traveling salesman problem to optimize shared-variable layout across threads (not needed in PARENDI). This pass runs irrespective of the optimization level. By manually disabling it we noticed an improvement in compile time and memory usage, but about a 30% performance decrease. So, we keep V3VariableOrder enabled.

6.1 PARENDI Vs. Verilator

Fig. 7 reports PARENDI's speedup against Verilator (on ix3 and ae4). Overall, PARENDI outperforms Verilator: geometric mean speedups are 2.81 and 2.75 compared to ix3 and ae4. Table 3 shows detailed performance numbers on each platform. We also report a few size metrics for each benchmark: number of data dependence graph nodes, fibers, x86 instructions needed to simulate one RTL cycle on a single thread, and Verilator's code footprint. Furthermore, for multi-IPU points, we report the size of the variables exchanged in KiB (actual exchange volume is higher due to fanout).

6.2 Verilator's Performance

Table 3 shows Verilator's best speedup relative to itself. Clearly, Verilator speeds up RTL simulation quite well when the design is large, by more than $20 \times$. We expand on a few points from Table 3 to better understand interesting trends.

High sync. cost. Fig. 8 shows that smaller designs only see limited speedups. From §4.1, we expected this behavior: synchronization cost cancels the gains from parallelism.

Comm. cost is non-uniform. From §4.1 and Fig. 4, we know that large designs are not limited by synchronization

cost and Fig. 9 shows Verilator's significant speedup for the largest designs. However, on ae4, speedups stagger after 8 threads (chiplet boundary), whereas on ix3, we see a significant drop after 28 threads (socket boundary). Therefore, the non-uniform communication latency within and across these boundaries has a noticeable performance impact and parallel simulators should be aware of them.

Architecture matters. Fig. 10 shows no clear winner between the two machines. In general, ae4 wins for the smaller designs, whereas ix3 performs better for huge ones up to 28 threads. But in some cases, ae4 shows superlinear gains up to the chiplet boundary. Such gains are exciting but not uncommon in RTL simulation: using more cores relieves the private cache and boosts performance [13, 14, 21, 34, 56]. By using more cores, there is more *aggregate* private cache capacity (L1 and L2). Therefore, we can essentially fully contain the working set within the private caches and increase simulation speed superlinearly. However, ultimately, superlinear gains disappear as we exhaust the cache capacity.

Overall, our analysis in §4 assumed a BSP execution model. Yet, we can still qualitatively apply it to Verilator (non-BSP), as we showed when t_{sync} and t_{comm} surface as bottlenecks.

6.3 PARENDI's Performance

RTL simulation on IPU follows different trends than x86. We expand on a few key differences. On x86, we identified two points of performance collapse: synchronization and communication. We show that on IPU, only off-chip communication becomes a bottleneck, which is in principle similar to off-chiplet or -socket communication.

Single-IPU scaling. On x86, we cannot use *all* the cores to increase simulation speed reliably: synchronization or communication cost may undo all the gains from parallelism. On the other hand, simulation performance on a single IPU monotonically increases as we use more tiles. Fig. 11a shows the simulation rate for three select designs as a function of the fraction of the IPU used.

Unlike a general-purpose machine, we cannot compile a moderately large design to a single tile on the IPU (not enough memory). Consequently, we cannot see speedup numbers relative to a single tile, unlike Verilator. Therefore, we consider using 184 tiles ($\frac{1}{8}$ of an IPU), 368, ..., and 1472 tiles only. Note that this is a fundamentally different starting point than a single thread on x86, as at this point, most significant gains from parallelism have already diminished; however, we still see improvements.

Fig. 11b shows the breakdown of simulation time for each of the designs in Fig. 11a. The vertical axis is normalized to simulation time using $\frac{1}{8}$ of the IPU in each benchmark. Communication (t_{comm}) and synchronization (t_{sync}) remain roughly constant while computation time (t_{comp}) decreases with more tiles. However, in sr3, the reduction in t_{comp} slows to a halt which happens due to fiber imbalance (see §4.3).

⁶The M2000 is not the fastest IPU machine available. BOW-2000 has the same architecture and tile count but clocked at 1.85 GHz (a 37% increase). M2000 and BOW-2000 are available in the public cloud [2].

Figure 7. IPU's speedup versus multi-thread Verilator.

Figure 8. Verilator's speedup diminish quickly for smaller designs as synchronization is costly.

Figure 9. Non-uniform communication (crossing chiplets or sockets) affects speedups in larger designs.

Figure 10. ae4 and ix3 have different scaling profiles: superlinear on one and sublinear on another.

Performance monotonically increases with more parallelism on the IPU due to low-cost communication and synchronization, which is not the case on x86. On x86, a hardware developer must tune the simulator's parallelism for each specific design *and* the machine they use (e.g., ix3 or ae4). However, a developer can confidently use all 1472 tiles on the IPU and operate at peak speed.

Multi-IPU scaling. Within one IPU, communication is relatively cheap, which enables good scaling. However, crossing IPU boundaries is expensive, as mentioned in §4.2. Therefore, preserving performance monotonicity across IPUs is challenging: fundamentally, crossing IPUs is the same as crossing chiplets or sockets since off-chip communication latency increases abruptly (see Fig. 5). However, non-uniform communication surfaces much later on the IPU: after 1472 tiles rather than 8 or 28 threads. Fig. 12 shows how the simulation speed scales across multiple IPUs. Even for very large

(a) Simulation speed scales monotonically on one IPU. We start from 184 tiles (1/8 of an IPU) and scale performance to a full IPU (1472 tiles).

Figure 11. Speedup of simulation within one IPU and the breakdown of simulation time.

Figure 12. Performance scaling across multiple IPUs.

designs, maximum parallelism may not yield the best result, and using fewer IPUs has marginal gains in specific cases.

The speedups are also much smaller off-chip: going from 1472 tiles to 5888 tiles in 1r9 improves performance by 60%, despite leveraging 4× more tiles. However, even a 60% gain is quite interesting: on x86 it is difficult to scale beyond 28 threads (ix3), but on the IPU, we keep increasing performance all the way to 5888 tiles (210× more parallel).

Performance resilience. We showed that PARENDI can scale the simulation rate of a single design within and across IPUs (strong scaling). However, can we maintain a constant simulation rate as we scale the design size (weak scaling)?

Fig. 13 shows the maximum simulation rate of PARENDI and Verilator as a function the mesh size in srN and 1rN. Neither PARENDI nor Verilator can perfectly keep the simulation rate constant, but PARENDI shows more resilience. For instance, in the right of Fig. 13, there is a long segment in which PARENDI simulates larger and larger designs at the same rate. Verilator's rate slowly drops in the same region; therefore, the speedup (PARENDI vs. Verilator) increases.

Figure 13. PARENDI vs. Verilator in coping with increasing design size. The left axis shows the best simulation rate in base-2 logarithmic scale. Right axis shows the gmean speedup of PARENDI against Verilator (dashed lines).

While fiber imbalance severely limits the performance of a small or medium RTL design, thereby limiting strong scaling, it actually *enables* better weak scaling. We use Fig. 14 to show how this happens. Consider an SoC with *N* cores and a sizable imbalance between its fibers, as shown on the left. If we double the size of the SoC, we double the number of its fibers. Because a small portion of fibers have significantly more execution time, we can tolerate increasingly larger designs, e.g., simulate an SoC with twice the number of cores but keep the simulation rate constant. Fig. 14 shows how we absorb the extra fibers (different colors) needed to simulate a larger design into the existing tiles without increasing the execution time. However, the tiles start to balance out at some point, and increasing the design size will drop the simulation rate (e.g., tripling the number of SoC cores).

6.4 Partitioning Strategies

So far, we have used the partitioning strategy outlined in §5.1. This section considers alternative strategies for partitioning fibers within and across IPUs.

6.4.1 Single-IPU Partitioning. We presented a bottomup strategy in §5.1 that conservatively merges smallest fibers to make processes. Recent work proposes casting this problem as a hypergraph partitioning problem where hypergraph nodes represent clusters of computation and hyperedges represent duplicated clusters across fibers [56]. The goal of this proxy problem is to find a balanced partitioning of clusters while minimizing duplication. We implemented this strategy in PARENDI as an alternative for users. Fig. 15 compares our default bottom-up (**B**) strategy with hypergraph partitioning

Figure 14. Fiber imbalance allows us to keep simulation rate constant in face of increasing design size.

(H) on a single IPU (1472-way partitioning). The vertical axis shows the normalized number of IPU machine cycles per RTL cycle (i.e., reciprocal of rate; lower is better). Interestingly, neither strategy is uniformly better. Bottom-up performs best with srN, whereas hypergraph partitioning performs better with lrN in some cases.

Figure 15. Comparison of our method with the hypergraph partitioning from repcut [56]. We compare our bottom-up (**B**) fiber merge strategy with the hypergraph (**H**) used in repcut. The vertical axis shows IPU machine cycles per RTL cycle, normalized to **B** (lower is better).

6.4.2 Multi-IPU Partitioning. Fig. 16 compares three strategies for multi-device partitioning over 4 IPUs:

- Pre: partition fibers across IPU before they are merged into processes (default PARENDI strategy)
- Post: partition processes across IPU, i.e., after fibers are merged into processes
- None: do not partition fibers or process, i.e., multi-IPU oblivious

Not partitioning fibers or processes across IPUs yields objectively inferior performance as expected. However, partitioning fibers works better than partitioning processes, too. This is because, during the merge, we may suboptimally absorb some *good cuts* and land in a region of the design space that is only locally optimal. Conversely, partitioning fibers before the merge helps us better optimize globally.

Figure 16. Normalized simulation rate for 4-IPU partitioning strategies. Partitioning fibers **pre** merge performs better than partitioning processes **post** merge. Being oblivious to the muli-IPU setup (**none**), yields vastly inferior results.

Table 3. st-, **mt-kHz** are single- and multi-thread Verilator performance (blue is best of ix3-ae4). **kHz** is best PARENDI rate. **gain** is Verilator's self-relative speedup (underscored superlinear). **#T** is threads or tile count of parallel rate. **Speedup** is PARENDI vs. Verilator (green ≥ 2 and red < 1). **gmean** is reported across machines and benchmarks. **MiB** is Verilator's binary size. **#I** is the million number of x86 instructions per RTL cycle (Verilator). **#N** is thousands of data dependence graph nodes. **#F** is thousands fibers. **Int.** and **Ext.** are KiBs on- and off-chip cut size (less than actual communication volume due to fanout).

6.5 Fastest Simulation is Cheapest

A detailed cost analysis of our approach is out of the scope of this work. However, it is worth noting that at the time of writing, GCore offers IPU-POD4 classic instances (M2000, used in our evaluation) for \$2.13 per hour [2]. On the other hand, a 32-core Dav4 instance from Microsoft Azure (AMD EPYC 7452) costs \$1.536 per hour [3]. More powerful machines, like the HB-series instances that are still one generation older than the ae4 cost as much as \$2.8-\$3.36 per hour.

The IPU's performance advantage for large designs makes it a more cost-effective solution than any existing cloud VM. Let us consider simulating 1r10 for one billion cycles. This takes 7.26 hours on the IPU and 44.30 hours on ae4. Clearly, IPU's faster simulation rate offsets its hourly cost (\$17 on the IPU vs. \geq \$69 on cloud VMs). To be competitive with the IPU, a cloud VM (with many cores) should cost about 6× less than the IPU to offset the performance disadvantage. Our analysis is quite forgiving to simulation on ae4, because it does not consider the cost of compiling, which is again much lower on the IPU (see Table 2). However, far more critical than the hourly cost is the time savings the IPU offers to verification engineers, whose hourly wage is at least an order of magnitude more than machine costs.

6.6 Discussion

Fast simulation requires a simulator architecture and implementation that accommodates the fine-grain parallelism of RTL simulation and exploits the features of the underlying hardware platform. Verilator fails to scale because its frequent fine-grain synchronization does not match the costly synchronization and communication on the x86. PARENDI scales far better, albeit from much lower single-core performance, because an IPU efficiently supports the BSP model and offers high-bandwidth communication. However, Graphcore's high off-chip communication latency creates a constraint that requires effective partitioning of the RTL design to minimize cross-chip communication.

When we started this project, we expected no speed gains from multiple IPUs, planning to use more IPUs when we ran out of memory. We were surprised to see speedups with even 5888 cores and believe that additional improvements in partitioning can increase performance further. We explain why speedups exist even with thousands of cores by drawing and analogy between VLSI design's clock rate and simulation rate. First, optimizing circuit performance for synthesis, placement, and routing, requires a good *floorplan* that is aware of physical constraints such as pin placement: Therefore, a good design facilitating floorplanning, facilitates optimizing off-chip communication in its simulation—there is a natural minimal cut. Second, the critical path length in VLSI caps the clock rate, as does the straggler fiber and its cone of logic limit simulation rate. Again, a good circuit design minimizes the critical path (length), indirectly minimizing the critical cone of logic (area); as such, faster circuits should simulate faster at scale.

Our work on thousand-core simulation is valuable for x86 simulation as well: it would benefit from a chiplet- and socket-aware partitioning methodology to better exploit the x86's memory hierarchy. Furthermore, by knowing the coarse cost of synchronization and communication, we may be able to achieve performance monotonicity on an x86, as we did for an IPU.

7 Related Work

PARENDI is the first RTL simulator to parallelize code across a few thousand cores. Prior work parallelizes RTL for tens of cores on CPUs and GPUs and a few hundred cores on specialized architectures. Other work simulates thousandcore SoCs through software or FPGA emulation.

Tens of cores. RepCut [56] is a BSP RTL simulator (fullcycle) for the firrtl [26] intermediate representation on x86. It shows that BSP can produce superlinear speedups within and across sockets (we discovered a similar effect with chiplets). They sped simulation up to 32 cores (48-core machine) but showed no gains beyond that limit.

We did no use RepCut as a baseline for a few reasons. First, RepCut is a firrtl compiler and cannot parse arbitrary Verilog, and to our knowledge, there is no reliable way of converting Verilog to firrtl, so a design not written in Chisel [12] cannot be compiled using RepCut, but can be compiled with Verilator (and PARENDI) as firrtl can be lowered to Verilog. Second, a comparison between RepCut and Verilator (or PARENDI) is biased by the quality of lowering firrtl to Verilog, which can affect performance [6]. Third, RepCut uses the firrtl Scala compiler, which is now replaced by the CIRCT implementation. Consequently, Rep-Cut cannot ingest the designs srN and 1rN generated by Chipyard [7]. Last, RepCut is not engineered to handle large designs; it generates a single C++ header file that takes days to compile with gcc [5].

There is considerable research on parallel event-driven methods with finer granularity than full-cycle simulation. Past work employs intelligent concurrency techniques on x86 to avoid computation/communication [8, 30, 32, 59]. SAGA [55] applies static scheduling to SystemC [39] and achieves a 16× parallel speedup on GPUs. GCS [16–18] employs *levelization* [57, 58] to accelerate gate-level simulation on GPUs. Levelization splits the combinational logic into synchronous levels of computation, each separated by a barrier (similar to BSP but at a lower level). PARENDI could leverage levelization to break stragglers into concurrent pieces at the cost of increased synchronization and communication.

Hundreds of cores. Hundred-core general-purpose machines are recent, so work on hundred-core simulation is for GPUs or specialized architectures.

Since RTL is irregular, GPU acceleration typically yields low thread utilization. For instance, Qian et al. [41] proposes a GPU-accelerated event-driven simulator with one thread per GPU core (i.e., $\frac{1}{32}$ warp utilization). RTLFlow [33] more fully uses a GPU by running independent simulations using multiple test vectors for a single design. RTLFlow performs similarly to Verilator with 1K test vectors but runs 40× faster with 64K tests. RTLFlow is limited by available GPU memory: sr15 touches about 42 MiB of data each cycle; which means \geq 42 GiB of memory with 1K test vectors.

Manticore [21] is a 225-core architecture specifically for RTL simulation and prototyped on an FPGA. Like PARENDI, Manticore uses BSP for RTL simulation, running on a dense and deeply pipelined architecture. Manticore's Yosys-based frontend lacks support for Verilog packed arrays that are used abundantly in 1rN and srN. Since FPGAs have limited memory, very large designs do not fit on Manticore, these large designs would unlikely fit into Manticore's limited resources. Nevertheless, our evaluation shares three benchmarks with Manticore: the bitcoin, mc, and vta. We provide raw performance numbers in kHz (see Table 1 and Table 3) so that our results can be directly compared to the reported numbers in Manticore [21] and future work. On PARENDI, bitcoin is 40% slower, but mc and vta are 40% and 63% faster, respectively. Owing to Manticore's huge register file, it achieves a higher single-core performance than the IPU despite being clocked at only 475 MHz. Therefore, a small design like bitcoin runs faster on Manticore, whereas vta and mc that are larger and more parallel do better on PARENDI because Manticore has only 225 cores.

Nexus [15] is an FPGA-based parallel RTL simulator with 240 8-bit processors in a systolic array. Like Manticore, Nexus suffers from limited SRAM resources on FPGAs. ASH [20] extends the Swarm architecture [27] with prioritized dataflow to accelerate RTL simulation. It consists of 256 simple x86 cores with dedicated task queues to enable efficient event-driven simulation, showing 32× speedup over Verilator. However, ASH is neither silicon proven nor prototyped on FPGAs.

Thousands of cores. Previous work on thousand-way parallel simulation differs from PARENDI since it does not start from RTL but rather C++ processor models (i.e., an architectural simulator). An RTL simulator parallelizes a model (the code), whereas an architectural simulator *implements*

parallel models. Hence, the simulator developer must parallelize the code rather than a compiler. Moreover, many architectural simulators compromise modeling accuracy to enable efficient parallel execution [19, 36, 50, 61], which is incompatible with RTL's rigid semantics.

Some architectural simulators use multiple machines to simulate large systems [24, 34, 36]. The primary motivation for distributed simulation is to leverage a cluster of machines' computing and memory resources, similar to PARENDI. Metro-MPI [34] is a hybrid example that generates C++ processor models from RTL using Verilator and stitches them with a C++ driver. Their methodology requires design expertise to manually and correctly partition designs. PARENDI could leverage a methodology similar to Metro-MPI to allow users to guide its partitioning for improved performance or decreased compile time.

Emulating large systems on FPGAs is an alternative. Capacity and compile time are significant challenges in FPGAbased emulation. Some systems, such as FireSim [29] and DIABLO [51] simulate warehouse-scale computers, but the individual FPGAs are limited in size (e.g., 8-core processor).

Other emulation platforms connect tens of FPGAs to make one giant logical FPGA [11, 31] that circumvents resource limits. These systems face problems similar to softwarebased RTL simulation, such as partitioning, but also suffer from extended compilation time (hours to days) to map logic to FPGA primitives. However, they can emulate large systems as fast as 1 MHz at a high cost.

8 Conclusion

A thousand-way parallel RTL simulation is becoming necessary. Current simulation techniques can adequately exploit only tens of cores in general-purpose processors due to their high synchronization and communication costs.

We used a 1472-core computer, the Graphcore IPU, to study the feasibility and challenges of a thousand-way parallel simulation. Our study analyzed three dimensions of parallel simulation: synchronization, communication, and computation. Using the results of this analysis, we implemented PARENDI, an RTL compiler that can compile an RTL simulation to use 5888 cores effectively.

Despite the IPU's almost 84× single-core performance disadvantage compared to recent, powerful x86 machines, PARENDI simulations run up to 4× faster for large designs. Our work demonstrated that a thousand-way parallel RTL simulation is practical and beneficial. It opens new avenues for future research to improve simulation performance beyond what is possible today.

9 Acknowledgements

We are grateful to Graphcore for lending us the M2000 hardware. We thank the the Graphcore staff and engineers, especially Mark Pupilli, Dario Domizioli, Peter Birch, Svetlomir Hristozkov, Marie-Ann Le Menn, and David Bozier. They helped us throughout the project development, from getting us started to detailed explanations of the inner workings of poplar and popc, and providing feedback on our work.

At EPFL, Sahand Kashani and Rishabh Iyer's feedback on the writing and paper's narrative helped us make tangible improvements. Furthermore, Sanidhya Kashyap generously allowed us to use their machines to benchmark Verilator. Last but not least, we thank Jiacheng Ma, who accidentally made us realize the potential of using the IPUs for RTL simulation.
