We report on simulations of counter-propagating laser-produced plasmas in an inertial confinement fusion (ICF) hohlraum surrogate, aiming to replicate observations reported by Le Pape et. al in recent work [1]. The conditions of the colliding plasmas are relevant to ICF hohlraums used for indirect-drive ignition, and are obtained both with and without low-density He-gas fill. We compare experimental diagnostics to outputs from simulations using the 1D-2V Vlasov-Fokker-Planck kinetic code iFP and the xRAGE radiation-hydrodynamics code. These include the inferred radial lineouts of inferred ion number fraction and ion and electron temperatures, as well as the reported experimental Thomson-scattering (TS) spectra (compared via synthetic TS diagnostics). We observe that 1D kinetic simulations capture the plasma states reported in the experimental diagnostics quite well. Counter-intuitively, the kinetic simulations capture the gas-fill experiment (expected to be more 'hydro-like') better than the vacuum experiment, while the reverse is observed for hydrodynamic simulations. This is attributed to the presence of non-trivial multi-dimensional hydrodynamic effects which are more dominant in the vacuum experiment. These effects are somewhat inhibited in the gas-fill experiment, permitting quasi-1D kinetic plasma transport to play more of a role in producing plasma interpenetration. Differences between the effects of Maxwellian vs. non-Maxwellian ('full f') synthetic TS diagnostics are investigated for the kinetic simulations. We find non-Maxwellian TS spectra differ non-trivially from Maxwellian spectra, which suggests caution may be warranted when applying Maxwellian TS models to infer plasma conditions via backward modeling when kinetic effects may be present.

I. INTRODUCTION

Plasma flow interpenetration is a phenomenon of particular interest inside the hohlraum of inertial confinement fusion (ICF) indirect-drive capsule implosions. Specifically, the coronal plasma produced from the laserablated high-Z hohlraum walls (e.g., gold) can interact with the ambient fill gas (if present) as well as the coronal plasma produced from the ablating capsule (e.g., highdensity carbon). While hydrodynamic phenomena such as Kelvin-Helmholtz (KH) or Rayleigh-Taylor (RT) instabilities may be present in high-gas-fill hohlraums [2, 3], transport-driven (i.e., due to finite mean-free-path effects) interpenetration may play a significant role as well, particularly in low-gas-fill and vacuum hohlraum environments where the coronal plasma from the capsule ablator and gold wall may interact [4–7]. Notably, transportdriven interpenetration is particularly difficult to account for in radiation-hydrodynamics (rad-hydro) simulations when long-mean-free-path (kinetic) rather than shortmean-free-path (hydro-like) effects are dominant, as radhydro models cannot correctly capture kinetic transport.

Recently, Le Pape *et al.* presented experimental results from a study at the OMEGA laser facility exploring counter-propagating plasmas in a surrogate ICF indirectdrive hohlraum environment [1]. The experiments collided laser-driven carbon and gold plasmas with and without a background helium gas fill, and were intended to create a quasi-one-dimensional environment. Their stated goal was to investigate the effects of the presence of the background gas on the plasma interpenetration, varying the environment from one dominated by kinetic effects to one where hydro-like effects dominate.

To date, the state-of-the-art for ICF simulations is radiation-hydrodynamics codes (for example, the **xRAGE** Eulerian hydro-code [8–10]). However, in regimes where kinetic effects are present such as the hot, low-density region in a hohlraum interior, kinetic modeling may be necessary to correctly capture the physical trajectory of the system. The iFP Eulerian Vlasov-Fokker-Planck code has been developed to explore kinetic physics in ICF environments [11–13]. Given their purported quasi-onedimensional nature and hohlraum relevance, the experiments of Le Pape *et al.* are a good candidate for validating and characterizing physics performance of iFP, in comparison to **xRAGE**.

In the Le Pape experiments, the primary diagnostic tool was the OMEGA facility's Optical Thomson Scattering (OTS) diagnostic [14], wherein a low-power laser is scattered from the plasma and collected as a spectrum. From the spectrum of scattered light, the plasma conditions may be determined. However, while Thomson Scattering (TS) is commonly used to diagnose such experiments, there are a few limitations. Notably, the plasma conditions which produced the scattering may only be inferred by using a backward model of the TS process and the assumed plasma environment. Further, backward models typically assume that the plasma distribution functions are Maxwellian. While this has historically been a necessary limitation (because fitting an arbitrary distribution function is much more difficult than fitting

^{*} andeste@lanl.gov

moments of Maxwellian distribution), it is known that non-Maxwellian features can produce non-trivial modifications to resulting TS spectra (see e.g., Refs. [15–17]). We note that recent work has expanded the capability of inferring non-Maxwellian distributions from arbitrary TS spectra (see e.g., Ref. [18]).

In this study, we simulate the plasma interpenetration experiments using both xRAGE (in axisymmetric twodimensional geometry) [6, 8–10] and the mature iFP kinetic ICF capsule implosion code (one-dimensional in physical space, two-dimensional in velocity-space). We compare them to the experimental results in Ref. [1]. We generate synthetic TS spectra both for xRAGE (using a Maxwellian TS forward-model) and iFP (using both Maxwellian and non-Maxwellian "full-f" TS forwardmodels). We observe a number of interesting features. Firstly, while the experiment was performed in as close to a one-dimensional (cylindrically-symmetric) manner as possible, there are significant multi-dimensional features present (primarily seeded by the oblique incidence of the lasers on the carbon and gold) that challenge its utility for 1D validation. Nevertheless, we find that quasi-onedimensional kinetic simulations recover the features of the experimental TS spectra much better than the hydrodynamic simulations. We also find that the hydrodynamic simulations capture the number density profiles of the no-gas-fill experiment (which *ought* to be more kinetic) very well, but not the gas-fill experiment (which ought to be more hydro-like). An analysis suggests this is likely a result of significant multi-dimensional effects producing *apparent* interpenetration. Further, the degree of apparent interpenetration is probably significantly increased by the 300ps time-averaging of the OTS diagnostic [1], as the expanding gold and carbon coronae are moving very quickly, particularly in the vacuum case with no gas fill (estimates from Ref. [1] of flow speed indicate the carbon/gold fronts could traverse between ~ 50 -200µm during the OTS averaging window). Finally, we compare Maxwellian and non-Maxwellian synthetic TS spectra for the iFP simulations and observe non-trivial differences between them, with the potential to introduce errors into subsequent Maxwellian backward-modeling to infer the moments.

The rest of this paper is organized as follows. Firstly, we give an overview of the plasma interpenetration experiments described in Ref. [1]. Next, we summarize the capabilities of the radiation-hydrodynamics code xRAGE and outline the simulation parameters used for the rad-hydro simulations. Following this, we give an overview of the iFP Vlasov-Fokker-Planck code, summarizing its capabilities and the setup and parameters of the kinetic simulations. Then, we briefly discuss the models used for Thomson scattering and how the synthetic TS spectra are created. The next section presents our simulation results, with comparison to the reported experimental data of Ref. [1]. Finally, we summarize the work and conclude.

Figure 1. Cartoon of the Le Pape experimental setup (see e.g., Ref. [1]) showing the view from the side (top) and view from either end (bottom). The relative positions of the inner HDC puck and outer gold ring are shown, with approximate positioning of the target support stalk and drive lasers. Note that the target support stalk is not included in either Vlasov-Fokker-Planck or rad-hydro simuations. Figure is not to scale though dimensions of HDC puck and inner diameter of the gold band are included.

II. PLASMA INTERPENETRATION EXPERIMENT OVERVIEW

We aim to validate computer simulations against the plasma interpenetration experiments performed by Le Pape et al.[1]. These experiments investigated the effects of gas fill on plasma interpenetration in quasione-dimensional conditions relevant to an ICF indirectdrive (ID) hohlraum. The experimental setup was of a 1200µm-diameter high-density-carbon (HDC) puck, 800µm in length (which mimics an ICF capsule with HDC ablator), surrounded by a 25µm thick gold band, which was 3200µm-diameter (outer surface) and also 800µm in length (to mimic the ICF hohlraum wall). Two versions of the experiment were performed, one with a vacuum between the HDC and the gold, and another with a lowdensity (0.15 mg/cm^3) He4 gas bag. Fig 1 gives a basic cartoon of the experimental setup, showing relative sizes and positions of the inner HDC puck and outer gold ring. Approximate pointing of the drive lasers is also shown, highlighting the oblique incidence angle of the laser illumination.

To drive the ablation and plasma creation, the surface of the HDC and the inner surface of the gold band were both illuminated with 351nm laser light. The main laser pulse for both vacuum and gas-fill cases was 300J in a 1ns flat-top, resulting in 400TW/cm² laser intensity on the

carbon and gold surfaces. In the gas-fill case, the pulse was stepped with 70J in a pre-pulse to burst the gas-bag.

The experiments were diagnosed using Thomsonscattering (TS) with a 40J, 1ns probe, using 263.23nm light, with an approximately 50µm focus. To determine the plasma conditions, the usual assumed-Maxwellian TS backward-model was used (see Refs. [1] and [19] for details). The conclusion in Ref. [1] was that the introduction of a low-density helium gas-fill produced a transition from an apparently kinetic interpenetration regime to one dominated by more hydro-like effects due to the inhibiting effect of the background helium fill.

III. OVERVIEW OF HYDRO SIMULATIONS

The experimental setup reported by Le Pape *et al.* was replicated in a two-dimensional axisymmetric geometry using xRAGE [6, 8–10]. xRAGE is the LANL flagship Eulerian multi-physics hydro-code with adaptive mesh refinement (AMR). It includes a laser ray-tracing package with plasma heating via inverse-bremsstrahlung and cross-beam-energy-transfer (CBET) modeling. Also incorporated are non-local thermal equilibrium (NLTE) radiation transport and emission/opacity modeling as well as a plasma physics module including NLTE variable ionization and ion and electron heat conduction, as well as plasma transport (viscosity).

The hydro simulations were performed using AMR with a minimum/maximum spatial resolution of (1.0 µm / 32.0 µm). The numerical laser pulse was set to replicate the pulse shape and energy reported by Le Pape *et al.*[1], including the initial foot of the laser pulse intended to break the He4 gas-bag. Further, the laser geometry was arranged as fielded in the OMEGA laser facility. In the vacuum case, the He4 was set to an ultra-low density gas fill ($\rho_{He4} = 10\mu g/cc$) to mimic vacuum conditions.

xRAGE simulations of gas-fill and vacuum cases were run with and without the hydrodynamic plasma transport model. While there were minor differences in the vacuum case, plasma interpenetration was enhanced in the gasfill case. For the results presented herein, the plasma transport model was used.

IV. OVERVIEW OF VLASOV-FOKKER-PLANCK SIMULATIONS

The plasma interpenetration experiment was also simulated using the plasma kinetic code iFP [11–13]. iFP is a 1D-2V (one physical space dimension in x, and two velocity-space dimensions, $v_{\parallel} \times v_{\perp}$) Eulerian Vlasov-Fokker-Planck code, which solves the coupled Vlasov-Rosenbluth-Fokker-Planck equations for multiple ion plasma species. Electrons are modeled as a quasineutral (zero charge density) and ambipolar (zero current density in 1D) fluid with a separate temperature from the ions. The mesh is adaptive using a mesh-motion technique that minimizes a gradient-based monitor function. The boundary locations are allowed to move according to the same mesh motion strategy, which allows iFP simulations to contract or expand with a given prescribed boundary (e.g., in the case of a spherically symmetric ICF capsule implosion, the interface between pusher and fuel may be tracked). This gives iFP a capability similar to arbitrary Lagrangian-Eulerian (ALE) meshing strategies. An extended variable-Coulomb logarithm model was implemented in order to deal with the gold plasma conditions reaching into a moderate coupling regime (due to high density and large effective charge state) [20].

For the simulations reported in this study, the physical space geometry was planar, rather than the cylindrical symmetry of the original experiments. This is justified by the domain of interest ranging from radii sufficiently outside the initial carbon surface $(r > 600 \mu m)$ to radii sufficiently inside the initial gold surface ($r < 1600 \mu m$), such that geometric effects are not expected to dominate the system evolution. Based on a simple estimate of a volume of adiabatic expansion of plasma into vacuum, we expect a difference of at most $\sim 30\%$ in position of the blowoff fronts between (one-dimensional) planar and cylindrical geometry is possible, but without dramatic effects to the overall radial profiles of plasma quantities. Clearly, there will be differences resulting from multi-dimensional flow that cannot be captured in the one-dimensional case. We expect that these differences would primarily manifest as differences in apparent plasma interpenetration (due to adjacent counter-propagating plasma flows).

iFP's initial and boundary conditions were sourced from the two-dimensional xRAGE simulations. This was done by extracting radial lineouts between the carbon and gold surfaces, which were averaged along the axial direction. For the vacuum case, hydro profiles were averaged over $\pm 400 \mu m$ in the axial direction, the entire axial extent of the gold ring. This was determined as the best choice for this case, due to the significant axial variation in the plasma state observed in the hydro simulations (i.e., 'fingering' of the gold and carbon plasmas into the vacuum or ultra-low-density helium), which will be shown later in Sec. VI. Further, this axial averaging range was chosen to capture these multi-dimensional hydrodynamic 'apparent' interpenetration effects in the iFP driving boundary conditions. For the helium gasfill case, the axial average was computed over $\pm 25 \mu m$, much narrower than the vacuum case. This is the stated width of the experimental TS diagnostics (see Ref. [1]), and – as will be shown later – the gas-fill simulations are somewhat less multi-dimensional than the vacuum case.

The initial conditions for the iFP simulations were specified as Maxwellian distributions for the ions based on the profiles of moments (density, velocity, temperature) from the hydro simulations at approximately the start of the main laser pulse. Due to the presence of the pre-pulse used to burst the gas bag the iFP simulations are initialized at t = 0.85ns in the gas-fill case, while in the vacuum case they are initialized at t = 0.28ns. The iFP boundary conditions on both the gold and carbon boundaries were prescribed by tracking the location of the maximum electron temperature (T_e) in the coronal blowoff within $\pm 50\mu$ m of the 50% critical surface (i.e., where $n_e = 0.5n_{crit}$, with n_{crit} the density at which the plasma frequency equals the laser frequency). This allows the iFP simulations to capture the effect of the laser drive from the hydro simulations without modeling the laser ray-trace and deposition itself. The ions are modeled as having a fixed effective average ionization for each species: $Z_{He} = 2.0$, $Z_C = 5.6$, and $Z_{Au} = 32.0$. These ionization levels were chosen from the ionization data in the rad-hydro simulations.

The simulations where run on a 192-cell grid in physical space, with 128x64 cells in $v_{\parallel} \times v_{\perp}$ space. The velocity-space domain is $v_{\parallel} \in \pm 10v_{th}$ and $v_{\perp} \in [0, 10v_{th}]$. For both vacuum and gas-fill simulations, the average timestep size was 40-50fs, with a final time around 1.7ns, corresponding to roughly 35,000-40,000 timesteps. Finally, we note that, for both the iFP and xRAGE simulations of the "vacuum" case, there is in fact an ultra-low-density He gas-fill present (roughly $10\mu g/cm^3$). While both xRAGE and iFP can run with an arbitrarily small He-fill density, xRAGE simulations are significantly cheaper with a small but finite He-fill. For consistency with xRAGE, we retain the same ultra-low He fill density in iFP. iFP scoping simulations both with and without the He-fill for the "vacuum" case (though retaining an ultra-low "floor" fill for both carbon and gold in both cases) found no appreciable differences.

V. THOMSON SCATTERING (TS) AND SYNTHETIC SPECTRA

A key element of our comparison to the experimental data is the generation of synthetic TS spectra using the simulated plasma states. The model for the Thomson scattering power spectrum $S(\mathbf{k}, \omega)$ is given by:

$$S(\mathbf{k},\omega) = \frac{2\pi}{k} \left| 1 - \frac{\chi_e}{\epsilon} \right|^2 f_{e,0}\left(\frac{\omega}{k}\right) + \sum_j \frac{2\pi}{k} \frac{Z_j^2 n_j}{n_e} \left|\frac{\chi_e}{\epsilon}\right|^2 f_{j,0}\left(\frac{\omega}{k}\right).$$
(1)

In this equation, \mathbf{k} and ω are the wavevector and frequency, $\epsilon = 1 + \chi_e + \sum_i \chi_i$ is the dielectric function, and χ_s is the susceptibility for species s. The one-dimensional marginal distribution function (i.e., integrated along the perpendicular velocity components) of species s along the wavevector \mathbf{k} is given by $f_{s,0}$. The species s number density is given by n_s , with the species effective charge given by Z_s .

The susceptibility χ_s is given by:

$$\chi_s(\mathbf{k},\omega) = \int_{\infty}^{\infty} d\mathbf{v} \frac{4\pi q_s^2 n_{s,0}}{m_s k^2} \frac{\mathbf{k} \cdot \partial f_{s,0} / \partial \mathbf{v}}{\omega - \mathbf{k} \cdot \mathbf{v}}.$$
 (2)

In the typical TS backward-model for fitting to experimental data, the marginal one-dimensional distribution functions $f_{s,0}$ along the wavevector **k** are assumed to be Maxwellian distributions:

$$f_{s,0} \to f_{M,s,0} = \frac{n_s}{\pi^{3/2} v_{th,s}^3} e^{\frac{-(\mathbf{v}-\mathbf{u})^2}{v_{th,s}^2}}.$$
 (3)

Here, $v_{th,s} = \sqrt{2T_s/m_s}$, with T_s the species temperature and m_s its mass. This assumption greatly simplifies the calculation of the susceptibilities, as Eq. (2) may be simplified as in App. D of Ref. [19].

In the case of a non-Maxwellian distribution function, however, the susceptibility integral must be performed numerically, with care being taken to avoid the pole at $\omega = \mathbf{k} \cdot \mathbf{v}$. This may be expressed as:

$$\int_{-\infty}^{\infty} d\mathbf{v} \frac{\partial f_{s,0}}{\partial \mathbf{v}} = \int_{-\infty}^{\frac{\omega}{k} - \delta} d\mathbf{v} \frac{\partial f_{s,0}}{\partial \mathbf{v}} + \int_{\frac{\omega}{k} + \delta}^{\infty} d\mathbf{v} \frac{\partial f_{s,0}}{\partial \mathbf{v}} + \int_{\frac{\omega}{k} - \delta}^{\frac{\omega}{k} + \delta} d\mathbf{v} \frac{\partial f_{s,0}}{\partial \mathbf{v}} + \int_{\frac{\omega}{k} - \delta}^{\frac{\omega}{k} + \delta} d\mathbf{v} \frac{\partial f_{s,0}}{\partial \mathbf{v}} + \int_{\frac{\omega}{k} - \delta}^{\frac{\omega}{k} - \delta} d\mathbf{v} \frac{\partial f_{s,0}}{\partial \mathbf{v}} + \int_{\frac{\omega}{k} - \delta}^{\frac{\omega}{k} - \delta} d\mathbf{v} \frac{\partial f_{s,0}}{\partial \mathbf{v}} + \int_{\frac{\omega}{k} - \delta}^{\frac{\omega}{k} - \delta} d\mathbf{v} \frac{\partial f_{s,0}}{\partial \mathbf{v}} + \int_{\frac{\omega}{k} - \delta}^{\frac{\omega}{k} - \delta} d\mathbf{v} \frac{\partial f_{s,0}}{\partial \mathbf{v}} + \int_{\frac{\omega}{k} - \delta}^{\frac{\omega}{k} - \delta} d\mathbf{v} \frac{\partial f_{s,0}}{\partial \mathbf{v}} + \int_{\frac{\omega}{k} - \delta}^{\frac{\omega}{k} - \delta} d\mathbf{v} \frac{\partial f_{s,0}}{\partial \mathbf{v}} + \int_{\frac{\omega}{k} - \delta}^{\frac{\omega}{k} - \delta} d\mathbf{v} \frac{\partial f_{s,0}}{\partial \mathbf{v}} + \int_{\frac{\omega}{k} - \delta}^{\frac{\omega}{k} - \delta} d\mathbf{v} \frac{\partial f_{s,0}}{\partial \mathbf{v}} + \int_{\frac{\omega}{k} - \delta}^{\frac{\omega}{k} - \delta} d\mathbf{v} \frac{\partial f_{s,0}}{\partial \mathbf{v}} + \int_{\frac{\omega}{k} - \delta}^{\frac{\omega}{k} - \delta} d\mathbf{v} \frac{\partial f_{s,0}}{\partial \mathbf{v}} + \int_{\frac{\omega}{k} - \delta}^{\frac{\omega}{k} - \delta} d\mathbf{v} \frac{\partial f_{s,0}}{\partial \mathbf{v}} + \int_{\frac{\omega}{k} - \delta}^{\frac{\omega}{k} - \delta} d\mathbf{v} \frac{\partial f_{s,0}}{\partial \mathbf{v}} + \int_{\frac{\omega}{k} - \delta}^{\frac{\omega}{k} - \delta} d\mathbf{v} \frac{\partial f_{s,0}}{\partial \mathbf{v}} + \int_{\frac{\omega}{k} - \delta}^{\frac{\omega}{k} - \delta} d\mathbf{v} \frac{\partial f_{s,0}}{\partial \mathbf{v}} + \int_{\frac{\omega}{k} - \delta}^{\frac{\omega}{k} - \delta} d\mathbf{v} \frac{\partial f_{s,0}}{\partial \mathbf{v}} + \int_{\frac{\omega}{k} - \delta}^{\frac{\omega}{k} - \delta} d\mathbf{v} \frac{\partial f_{s,0}}{\partial \mathbf{v}} + \int_{\frac{\omega}{k} - \delta}^{\frac{\omega}{k} - \delta} d\mathbf{v} \frac{\partial f_{s,0}}{\partial \mathbf{v}} + \int_{\frac{\omega}{k} - \delta}^{\frac{\omega}{k} - \delta} d\mathbf{v} \frac{\partial f_{s,0}}{\partial \mathbf{v}} + \int_{\frac{\omega}{k} - \delta}^{\frac{\omega}{k} - \delta} d\mathbf{v} \frac{\partial f_{s,0}}{\partial \mathbf{v}} + \int_{\frac{\omega}{k} - \delta}^{\frac{\omega}{k} - \delta} d\mathbf{v} \frac{\partial f_{s,0}}{\partial \mathbf{v}} + \int_{\frac{\omega}{k} - \delta}^{\frac{\omega}{k} - \delta} d\mathbf{v} \frac{\partial f_{s,0}}{\partial \mathbf{v}} + \int_{\frac{\omega}{k} - \delta}^{\frac{\omega}{k} - \delta} d\mathbf{v} \frac{\partial f_{s,0}}{\partial \mathbf{v}} + \int_{\frac{\omega}{k} - \delta}^{\frac{\omega}{k} - \delta} d\mathbf{v} \frac{\partial f_{s,0}}{\partial \mathbf{v}} + \int_{\frac{\omega}{k} - \delta}^{\frac{\omega}{k} - \delta} d\mathbf{v} \frac{\partial f_{s,0}}{\partial \mathbf{v}} + \int_{\frac{\omega}{k} - \delta} d\mathbf{v} \frac{\partial f_{s,0}}{\partial \mathbf{v}} + \int_{\frac{\omega}{k}$$

with the integral around the pole expressed as [21]:

$$\int_{\frac{\omega}{k}-\delta}^{\frac{\omega}{k}+\delta} d\mathbf{v} \frac{\partial f_{s,0}/\partial \mathbf{v}}{\omega - \mathbf{k} \cdot \mathbf{v}} = -i\pi \left. \frac{\partial f}{\partial \mathbf{v}} \right|_{\frac{\omega}{k}} + 2\delta \left. \frac{\partial^2 f}{\partial \mathbf{v}^2} \right|_{\frac{\omega}{k}}.$$
 (5)

To compute the synthetic TS spectrum for a given location in space and time, we must specify the scattering angle, which is determined from the experimental TS geometry. In the case of the Le Pape experiments, the scattering angle is 60° . From the simulations, we have the moments of each of the plasma species (density n, velocity \mathbf{u} , and temperature T) for the Maxwellian TS case, and the full distribution function f in the case of non-Maxwellian TS analysis. Note that for the non-Maxwellian analysis of the 1D-2V iFP simulations, we technically ought to compute the marginal distribution $f_{s,0}$ along the wavevector \mathbf{k} (see also the term $\mathbf{k} \cdot \partial f_{s,0}/\partial \mathbf{v}$). However, for simplicity, we take the distribution $f_{s,0}$ to be the perpendicularly integrated marginal distribution,

$$f_{s,0} = 2\pi \int_0^\infty d\mathbf{v} v_\perp v_\perp f_s(v_\parallel, v_\perp). \tag{6}$$

While this is not strictly correct, our primary aim is to observe whether accounting for non-Maxwellian features in the TS analysis for this experiment may have a significant impact on the resulting synthetic spectra. As will be shown later, non-Maxwellian features indeed have an impact, which introduces uncertainty in the inferred moments from the standard Maxwellian TS backward model.

To mimic the experimental TS spectra more accurately, the synthetic spectra were convolved in a number of ways. First, we note that the experimental TS spectra in Ref. [1] are taken at "the end on the main laser pulse for a 300ps duration". Thus, we perform a temporal averaging on our synthetic spectra according to

$$\bar{S}(\boldsymbol{k},\omega) = \frac{1}{t_1 - t_0} \int_{t_0}^{t_1} S(\boldsymbol{k},\omega,t) dt, \qquad (7)$$

which we approximate on the discrete output via the trapezoidal rule,

$$\bar{S}(\boldsymbol{k},\omega) = \sum_{k=1}^{N} \frac{S(\boldsymbol{k},\omega)_{k-1} + S(\boldsymbol{k},\omega)_{k}}{2(t_{N} - t_{1})} (t_{k} - t_{k-1}).$$
(8)

Further, to capture effects of uncertaintly in the scattering angle, we average over a range of angles, e.g., $\theta \in [60^{\circ} - \Delta\theta, 60^{\circ} + \Delta\theta]$. Typically $\pm 7^{\circ}$ is used here, with a 1° resolution. To capture the effects of finite resolution in physical space and in the spectrum, we employ a Gaussian blurring kernel convolution in both the spatial and spectral axes. Typical values for characteristic width of the kernels are 50µm and 0.5Å, respectively.

VI. RESULTS AND DISCUSSION

A. Comparison of experimental and synthetic Thomson scattering spectra

Our primary targets for comparison are the experimental OTS spectra (Figs. 2(a) and 2(e) in Ref. [1]) and synthetic TS spectra generated from the rad-hydro (Maxwellian spectra) and Vlasov-Fokker-Planck (non-Maxwellian spectra) simulations. These comparisons are shown in Figs. 2 and 3, showing spectra for the vacuum and gas-fill experiments/simulations, respectively. Here, the position index employs the same convention as in Ref. [1], measured from the initial inner surface of the gold, towards the carbon. We see that the iFP simula-

Figure 2. Comparison of experimental OTS spectra (left) to synthetic spectra generated from iFP simulations (center) and **xRAGE** simulations (right) for the vacuum case. The synthetic spectrum for iFP is computed starting at the end of the main laser pulse (t = 0.88ns after main pulse start) with 300ps temporal averaging with ~12ps resolution. The **xRAGE** spectrum is computed using the same axial-averaging as was used to generate the iFP initial and boundary-conditions (±400µm around axial centerline for this case).

Figure 3. Comparison of experimental OTS spectra (left) to synthetic spectra generated from iFP simulations (center) and **xRAGE** simulations (right) for the gas-fill case. Synthetic iFP and **xRAGE** spectra are computed starting at the end of the main laser pulse (t = 1.55ns after pre pulse start) with 300ps temporal averaging ~12ps resolution. The **xRAGE** spectrum is computed using the same axial-averaging as was used to generate the iFP initial and boundary-conditions ($\pm 25\mu$ m).

tions actually produce synthetic TS spectra which agree remarkably well with the qualitative features of the experimental spectra, though much better for the gas-fill case than the vacuum case. For the rad-hydro synthetic spectra, neither gas-fill nor vacuum case matches particularly well. We offer an explanation for this later in the manuscript.

Figure 4. Comparison of non-Maxwellian (left) and Maxwellian (right) synthetic TS spectra for the vacuum case from iFP simulations.

B. Comparison of Maxwellian and non-Maxwellian synthetic TS spectra for iFP simulations

Next, we compare the effects of considering a non-Maxwellian model vs. a traditional Maxwellian model for computing synthetic TS spectra. In Figs. 4 and 5, we compare Maxwellian and non-Maxwellian spectra for the vacuum and gas-fill iFP simulations, respectively. We see that, overall, there are noticeable differences, primarily in the center of the domain where long-mean-free-path effects are more dominant. Figs. 7 and 6 compare lineouts from Maxwellian and non-Maxwellian synthetic spectra at representative locations in the domain where differences are greatest for the vacuum and gas-fill simulations, respectively. We observe non-trivial differences in the spectral lineouts which may affect the inferred plasma state at these locations using traditional TS backwardmodeling. From this, we note that caution is advised when utilizing standard Maxwellian TS models to infer plasma conditions in cases where long-mean-free-path effects are expected to be significant.

C. Comparison of spatial moment profiles

Finally, we compare the spatial profiles of the plasma moments. To compare the **xRAGE** and iFP moment profiles with the experimentally inferred profiles (see Fig. 3 of Ref. [1]), we apply similar averaging to that used for the Thomson scattering diagnostics, specifically a 50µm Gaussian blurring kernel in space, with 300ps temporal averaging. In addition, the simulation data is interpolated to radial locations of the given experimental mo-

Figure 5. Comparison of non-Maxwellian (left) and Maxwellian (right) synthetic TS spectra for the gas-fill case from iFP simulations.

Figure 6. Comparison of non-Maxwellian (blue) and Maxwellian (red) synthetic TS spectra for the vacuum case from iFP simulations, at 300µm (left) and 450µm (rigth) from the initial gold interface. Lineouts are taken from the spectra in Fig. 4.

ment profiles. The timing for the moment profiles is the same as for the prior TS spectra, namely starting at 0.88ns and 1.55ns after main laser pulse start for the vacuum and gas-fill cases, respectively. From the previous discussion, we expect fundamental limits in our ability to match experimental data solely based on differences between Maxwellian and non-Maxwellian TS spectra.

For the species temperature profiles, we see in Fig. 8 that iFP simulations follow the experimental trends generally better than the rad-hydro simulations (noting **xRAGE** does not allow for ion temperature separation). We note here that the individual ion species temperature profiles have been reported only in regions where the relative ion number fraction of each species is greater than 10^{-3} . This is particularly the case with the iFP temperature profiles, where the gold temperature profile is clipped around 500-550µm in both cases.

For both cases, iFP is in relatively good agreement with the available inferred experimental data for carbon

Figure 7. Comparison of non-Maxwellian (blue) and Maxwellian (red) synthetic TS spectra for the gas-fill case from iFP simulations, at 500µm (left) and 675µm (rigth) from the initial gold interface. Lineouts are taken from the spectra in Fig. 5.

Figure 8. Temperature radial lineouts for iFP and xRAGE simulations, compared to experimental data inferred from a Maxwellian TS model. The plots are oriented using the same convention as Fig. 3 of Ref. [1], with the initial gold surface on the left and carbon on the right. The abcissae are spatial positions with respect to the initial inner surface of the gold band. The vacuum case is above, while the gas-fill case is below. We note that the agreement here is much more qualitative in broad trends. Generally, the iFP simulations recover the high gold and carbon temperatures in the vacuum case and the lower electron temperature.

and gold, capturing the general trends. We note that, for the gas-fill case, the regions where iFP ion temperatures are much higher tend to correspond to regions of lower density, where experimental data are not available. Note also that iFP captures the broadly 'flat' electron temperature profiles of the experimental data, and are roughly in line with the electron temperature magnitude.

We observe that, in general, the iFP ion and electron temperatures appear overall higher than the experimentally inferred and the simulated **xRAGE** temperatures. We hypothesize that this is due to iFP not having a radiation package, as radiation in this context would tend to cool electrons and therefore the plasma. For the conditions observed here, we estimate that including radiation with

Figure 9. Species relative fraction as a function of radial position for iFP and **xRAGE** simulations, compared to experimental data inferred from a Maxwellian TS model. The plots are oriented using the same convention as Fig. 3 of Ref. [1], with the initial gold surface on the left and carbon on the right. The abcissae are spatial positions with respect to the initial inner surface of the gold band. The vacuum case is above, while the gas-fill case is below.

a temperature approximately equal to the electron temperature would reduce ion and electron temperatures by as much as $\sim 60\%$. For example, in the gas-fill case, radiation emission would cool electrons from 2keV to 750eV, which is much closer to the experimentally inferred values. Testing this hypothesis will be the subject of future work.

Figure 9 compares the species relative number fractions for the vacuum (above) and gas-fill (below) cases for experiments (left), iFP (center), and xRAGE (right). Here, carbon is shown in red, gold in blue, and helium (when present) in black. The abcissae are measured relative to the inner surface of the outer gold band. We observe that, counter-intuitively, **xRAGE** compares quite favorably to the experimental number fraction profiles for the vacuum case, while iFP does not capture nearly as much apparent interpenetration of the gold and carbon. In the gas-fill case, **xRAGE** shows much sharper boundaries between the gold, carbon, and helium regions, indicating very little apparent interpenetration. In this case iFP shows a much more significant degree of interpenetration of the helium into both carbon and gold, and is much closer to the experimentally inferred number fraction profiles.

Note that there is a general trend of **xRAGE** appearing to have greater species interpenetration than iFP in the vacuum case while this reverses for the gas-fill case. This is not due to interpenetration of the plasma species, but rather to multi-dimensional hydrodynamic effects, 'fingers' of carbon and gold plasmas passing *past* each other, producing *apparent* interpenetration. In fact, these sorts

Figure 10. Mass density contour snapshots for 2D axisymmetric xRAGE simulations. The vacuum case is shown on top, and the gas-fill case on bottom. Snapshots are taken at the end of main laser pulse (1.55ns for gas-fill and 0.88ns for vacuum). Note the presence of significant multi-dimensional features at gold (right-hand side) and carbon (left-hand side) fronts, particularly for the vacuum case.

of features can be observed in the two-dimensional axisymmetric xRAGE simulations in Fig. 10, where the vacuum case (top) exhibits much more multi-dimensionality than the gas-fill case (bottom), which is inhibited by the presence of the helium gas-fill. iFP, which cannot capture these multidimensional effects, but *can* capture plasma interpenetration due to kinetic plasma transport, shows less interpenetration than xRAGE in the vacuum case, and *more* interpenetration than xRAGE in the gas-fill case.

Finally, we also note in Fig. 9-top (vacuum case) that the interface between the carbon and gold is offset to the right (radially inward) in the experimental and **xRAGE** number fraction profiles relative to the apparent interface for iFP. In general, this is the sort of trend we expect from the use of planar geometry in the iFP simulations relative to the cylindrical geometry of the experiment and **xRAGE** simulations. That is, we expect the blowoff from the gold surface will be somewhat faster in the cylindrical geometry than in planar (converging from a larger to a smaller radius), while we expect the opposite from the

Figure 11. End-on self-emission radiograph from vacuum experiment showing presence of azimuthal features in blowoff [22].

carbon surface blowoff (expanding from smaller to larger radius). Taking the approximate iFP gold-carbon interface as \sim 400µm, and the experimental/**xRAGE** interface to be \sim 500-600µm, we observe a difference of \sim 20-30%, which is in good agreement with the previously stated estimate. The differences in the interface locations are less extreme in the gas-fill case, being inhibited significantly by the presence of the helium.

VII. SUMMARY AND CONCLUSIONS

In this study, we have presented a validation exercise with the laser-driven plasma-interpenetration hohlraum surrogate experiments described in Ref. [1] using both kinetic Vlasov-Fokker-Planck (iFP) and multi-physics radiation-hydrodynamics (xRAGE) models.

The validation exercise is a priori hampered by the fact that these experiments remain inherently threedimensional, despite the significant efforts of the authors of Ref. [1] to minimize high-dimensional effects. This is clear from the two-dimensional rad-hydro simulations depicted in Fig. 10, as well as from self-emission imaging from the experiments (see Fig. 11). Nevertheless, useful understanding has been gained from this exercise, which we have reported here.

We have observed that, in general, synthetic TS spectra from the Vlasov-Fokker-Planck model agree much better with the experimental data than those from the radiation-hydrodynamics model. We have also observed non-trivial differences in synthetic TS spectra generated from Vlasov-Fokker-Planck simulations using fully kinetic ('high-fidelity') forward models vs. the usual Maxwellian ansatz. This suggests caution is warranted when interpreting inferred plasma quantities from Maxwellian backward models of experimental TS spectra when kinetic effects may be present.

When comparing experimentally inferred moment profiles to those from simulations, the picture is murkier. xRAGE's radial species-fraction profiles compare better (counter-intuitively) for the vacuum experiment (which is more kinetic) than the He gas-fill experiment (more 'hydro-like'), while failing to predict temperature lineouts altogether. Conversely, iFP achieves better agreement with the number fraction profiles of the gas-fill experiment than the vacuum experiment, while agreeing reasonably closely with experimentally inferred temperature profiles on both experiments. The apparent contradiction in the species-fraction comparison resolves when

accounting for the extreme multidimensional nature of the vacuum experiment (due to 'fingering' of carbon and gold plasmas passing *past* each other, producing *apparent*

interpenetration) vs. the relatively quiet gas-fill experi-

Overall, despite iFP's limitations (1D planar, no radi-

ation package, no laser package), we conclude that iFP

compares more favorably with key signatures of the ex-

perimental data than xRAGE, despite the latter featur-

ing more accurate geometry (two-dimensional cylindrical

symmetry), a consistent laser-drive package, radiation-

diffusion modeling, as well as tabular dynamic ionization

modeling. This suggests that high-fidelity modeling of

these experiments in multiple dimensions including ki-

netic plasma and radiation transport effects is warranted

ment, in which the He-fill inhibits such behavior.
