(Dated: July 12, 2024)

The exploration of magnetic topological insulators is instrumental in exploring axion electrodynamics and intriguing transport phenomena, such as the quantum anomalous Hall effect. Here, we report that a family of magnetic compounds $\text{Eu}_{2n+1}\text{In}_2(\text{As,Sb})_{2n+2}$ ($n = 0, 1, 2$) exhibit both gapless Dirac surface states and chiral hinge modes. Such a hybrid-order topology hatches surface-dependent quantum geometry. By mapping the responses into real space, we demonstrate the existence of chiral hinge modes along the c direction, which originate from the half-quantized anomalous Hall effect on two gapped ac/bc facets due to Berry curvature, while the unpinned Dirac surface states on the gapless ab facet generate an intrinsic nonlinear anomalous Hall effect due to the quantum metric. When $\text{Eu}_3\text{In}_2\text{As}_4$ is polarized to the ferromagnetic phase by an external magnetic field, it becomes an ideal Weyl semimetal with a single pair of type-I Weyl points and no extra Fermi pocket. Our work predicts rich topological states sensitive to magnetic structures, quantum geometry-induced transport and topological superconductivity if proximitized with a superconductor.

INTRODUCTION

Topological quantum states of matter are usually characterized by unique boundary states following the bulk-boundary correspondence [1–3]. To be specific, a topological insulator (TI) exhibits two-dimensional (2D) Dirac-type surface states [4, 5] and a higher-order TI shows 1D hinge states [6–9]. Unlike nonmagnetic topological crystalline insulators (TCI) [6, 7, 10–12], surface/hinge states in a magnetic TCI are intimately related to magnetic structures [8]. Applying a magnetic field to flip or rotate spin moments is equivalent to reversing the mass signs of the gapped surface, thus switching the chirality of hinge states and the mapped 2D Chern number [8, 13–16]. Identifying the nature of topological invariants under a combined magnetic crystalline symmetry by the translation (τ) or n -fold rotation (C_n) with time-reversal (\mathcal{T}), is evidently a central issue [17–21]. For instance, MnBi_2Te_4 is a $\tau\mathcal{T}$ protected antiferromagnetic (AFM) TI with gapless Dirac surface parallel to τ [22–24], namely a first-order topology depicted in Fig. 1a. A hybrid-order topological phase (*e.g.*, Fig. 1b-c), which exhibits both topological surface states and hinge states, is rare among intrinsic magnetic materials [14].

Furthermore, a magnetic TCI with $\tau\mathcal{T}$ or $C_n\mathcal{T}$ symmetry can generate axion electrodynamics, described by the so-called quantized θ term [25], $S_\theta = \int dt d^3x \frac{\theta e^2}{4\pi^2 \hbar c} \mathbf{E} \cdot \mathbf{B}$, where \mathbf{E} and \mathbf{B} are external electric and magnetic fields, θ is the axion field defined in a 3D system [22, 23, 26–29]. Axion insulators manifest a half-quantized anomalous Hall conductance (AHC) of $\pm \frac{e^2}{2h}$ on the gapped surface [3, 30, 31], which comes from Berry curvature, *i.e.* the imaginary part of the quantum geometry tensor [32, 33]. When two adjacent gapped surfaces hold

opposite masses, the surface quantum anomalous Hall effect (QAHE) is carried by the 1D chiral hinge mode [34]. On the other side, the real part of the quantum geometry–quantum metric–was recently discovered to generate nonlinear anomalous Hall effect (NLAHE) in magnetic conductors [35–39]. We are inspired to ask whether metallic surface states can generate a surface NLAHE due to the quantum metric in a magnetic TCI.

Recently, Eu-based Zintl compounds $\text{Eu}_{2n+1}\text{In}_2(\text{As,Sb})_{2n+2}$ ($n = 0, 1, 2$) emerged with unusual magnetic structures revealed by neutron diffraction, resonant elastic X-ray scattering, muon spin-rotation, or magnetotransport [40–51]. These materials can be magnetic TCI candidates due to the interplay of AFM order and strong spin-orbit coupling (SOC). In EuIn_2As_2 , a pure helix order formed at 17.5 K evolves to a ‘broken helix order’ below 16 K (Fig. 1d) [41–45], although an earlier theory study assumed a collinear AFM order [15]. In $\text{Eu}_3\text{In}_2\text{As}_4$, an AFM order was conformed below $5 \sim 6.5$ K in experiments [50, 51]. In $\text{Eu}_5\text{In}_2\text{As}_6$, a collinear AFM order formed at 14 K (Fig. 1f) evolves to a complex coplanar order below 7 K accompanied with the anisotropic susceptibility [46–49]. Their magnetic structures of three compounds exhibit $C_2\mathcal{T}$ symmetry but break $\tau\mathcal{T}$ and \mathcal{PT} , different from the conventional AFM phase (*e.g.*, MnBi_2Te_4) but similar to ‘altermagnets’, a collinear AFM order studied recently [52–56]. Additionally, $\text{Eu}_3\text{In}_2\text{As}_4$ was recently grown from InAs nanowires in a mutual-exchange method [50] and inherits the ideal proximity with a superconductor [57]. Thus, this system will serve as a potential platform to study topological superconductivity due to the interplay between chiral hinge states/Dirac surface states and the s -wave superconductivity.

In this work, we predict that $\text{Eu}_{2n+1}\text{In}_2(\text{As,Sb})_{2n+2}$

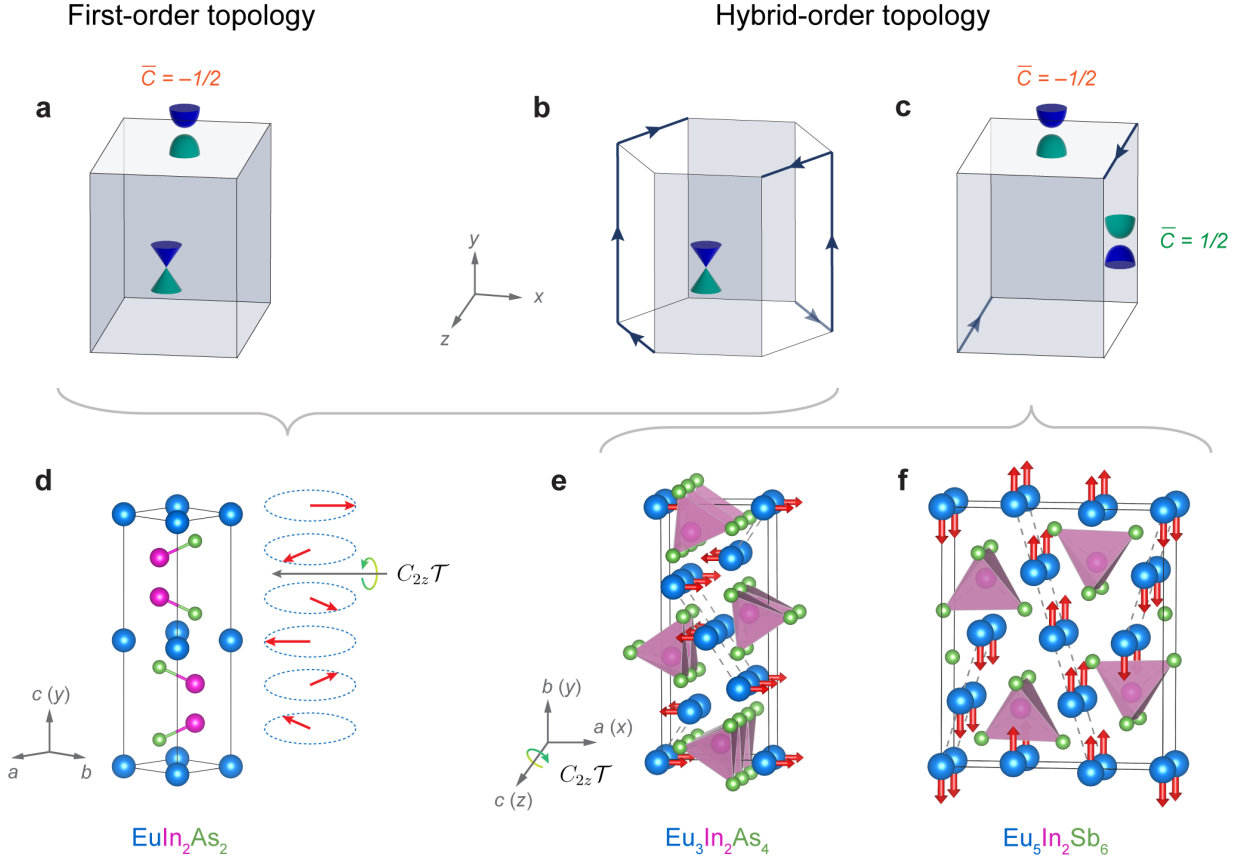

FIG. 1. Symmetry protected boundary states, crystal and magnetic structures. **a** The first-order topology with gapless surfaces (dark) protected by $\tau_y\mathcal{T}$ symmetry, exemplified by MnBi_2Te_4 . **b,c** The hybrid-order topology with unpinned Dirac surface states (dark) and chiral hinge states (thick lines) under $C_{2z}\mathcal{T}$ symmetry, exemplified by $\text{Eu}_{2n+1}\text{In}_2(\text{As,Sb})_{2n+2}$. **b** and **c** show two kinds of sample geometry. **d** EuIn_2As_2 (space group: $P6_3/mmc$): Broken helix spin order (in- ab -plane) below 16 K [43–45]. Six layers of Eu atoms (dashed ellipses) form a period. **e** $\text{Eu}_3\text{In}_2\text{As}_4$ ($Pnmm$): AFM order predicted by calculations. The thin dashed lines mark a set of sublattices. **f** $\text{Eu}_5\text{In}_2\text{Sb}_6$ ($Pbam$): Collinear magnetic order between 7 and 14 K [48, 49]. Below 7 K, the spin order becomes coplanar but $C_{2z}\mathcal{T}$ symmetry still survives. For $\text{Eu}_3\text{In}_2\text{As}_4$ and $\text{Eu}_5\text{In}_2\text{Sb}_6$, the $C_{2z}\mathcal{T}$ axis passes through the cell center.

compounds possess hybrid-order topology characterized by the coexistence of chiral hinge modes and unpinned Dirac surface states protected by a $C_2\mathcal{T}$ -related topological invariant [18–21]. Taking $\text{Eu}_3\text{In}_2\text{As}_4$ for an example, we demonstrate the axion insulator state with a surface QAHE. On the gapless surface, we find the NLAHE due to the quantum metric from Dirac states. In addition, the AFM bulk can exhibit the anomalous Hall effect despite vanishing net magnetization, because the magnetic lattice violates $\tau\mathcal{T}$ and \mathcal{PT} . If the magnetic order turns into ferromagnetic (FM) by applying a magnetic field, $\text{Eu}_3\text{In}_2\text{As}_4$ exhibits an ideal Weyl semimetal phase. We further derive a topological phase diagram based on a material-specific effective model to reveal possible topological states for these compounds in different magnetic orders. Finally, we discuss possible unique Majorana modes when the material is in proximity to an ordinary superconductor.

RESULTS

Magnetic order and bulk band structure. We first focus on $\text{Eu}_3\text{In}_2\text{As}_4$ to demonstrate the hybrid-order topology and resultant properties. As illustrated in Fig. 1e, the Zintl compound $\text{Eu}_3\text{In}_2\text{As}_4$ crystallizes in an orthorhombic lattice with the inversion symmetric space group $Pnmm$, including a two-fold rotation C_{2z} , and nonsymmorphic symmetries $\{C_{2x,2y}|\tau\}$, where τ is the translation of one-half of a body diagonal $(\frac{a}{2}, \frac{b}{2}, \frac{c}{2})$. All atoms are located at $z = 0$ and $z = 0.5$ planes, and one In atom and four As atoms form a tetrahedron. The tetrahedrons $([\text{In}_2\text{As}_4]^{6-})$ constitute a 1D chain by sharing their corners along the c axis, between which the divalent Eu^{2+} cations ($\mathbf{S} = \frac{7}{2}$) are dispersed. Three Eu atoms (linked by the dashed line) with the two nearest neighboring tetrahedrons form a sublattice. Within one unit cell, two sublattices are related by $\{C_{2x,2y}|\tau\}$ operations.

The exact spin structure has thus far not been resolved in experiments, so we carry out the calculations to examine the magnetic ground state of $\text{Eu}_3\text{In}_2\text{As}_4$. Inspired by the collinear spin order of the sister compound $\text{Eu}_5\text{In}_2\text{As}_6$ [48, 49], we investigated several collinear magnetic structures (Supplementary Table III). We found an AFM phase with the easy axis in ab -plane (Fig. 1e) is energetically favored, consistent with recent magnetometry measurements [50, 51]. The Eu^{2+} cations exhibit FM coupling along the c -axis while two sublattices are AFM coupled. The in- ab -plane magnetic structure preserves $C_{2z}\mathcal{T}$ symmetry.

The nonmagnetic phase gives a trivial semiconducting band structure while magnetic orders lead to nontrivial topology. The band structure of $\text{Eu}_3\text{In}_2\text{As}_4$ with an AFM a order (easy axis along a) is shown in Fig. 2a. Localized $\text{Eu-}4f$ orbitals appear below the Fermi energy between -2.5 eV and -1.5 eV. Without SOC, a trivial bandgap of 52 meV is found at Γ point and spin splitting appears along $\Gamma - S$ (see Supplementary Fig. S9). The inclusion of SOC induces an inverted gap of nearly 10 meV at Γ with band inversion and an indirect global gap of 5 meV (Fig. 2b), which is larger than the energy scale of magnetic order temperature ($T_N \sim 5$ K) or induced superconductivity gap. The spin double-degeneracy is lifted along $\Gamma - X$, $\Gamma - Y$, and $\Gamma - Z$, similar to an alternanget, but remains along $X - S - Y$ because of antiunitary operators $\{C_{2x}|\tau\}\mathcal{T}$ and $\{M_x|\tau\}\mathcal{T}$. Details of symmetry analysis can be found in the Supplementary Sec. III.

Surface and hinge states. The antiunitary symmetry $C_{2z}\mathcal{T}$ helps understand the bulk-surface-hinge correspondence. Let us begin with a \mathcal{T} -preserved \mathbb{Z}_2 TI where all surfaces present Dirac surface states. For an orthorhombic crystal (Fig. 1c), magnetism opens a surface gap on bc and ac facets, *i.e.*, introduces a mass term in the Dirac equation. Because they transform to each other by $C_{2z}\mathcal{T}$, two bc facets (also two ac facets) exhibit opposite masses. For four hinges between ac and bc facets along the c direction, we can always find two diagonal hinges at the domain boundary between surfaces with opposite signs of mass, leading to chiral hinge modes inside the surface gap. $C_{2z}\mathcal{T}$ symmetry is preserved on the ab plane and leads to crystalline symmetry-protected unpinned Dirac surface states. The surface Dirac cone can only be pushed away from time-reversal-invariant momenta (*e.g.* $\bar{\Gamma}$) rather than gapped out. Two chiral hinge states terminate at gapless (001) surfaces while the equilibrium current persists, different from an ordinary TI or TCI that shows only surface or hinge states. Consequently, three surface Chern numbers ($\bar{C} = \pm\frac{1}{2}, 0$) can be realized on different surfaces, offering a road for designing the direction-selective QAHE and quantized circular dichroism effect [58].

Such a magnetic TCI is equivalent to a 3D strong Stiefel-Whitney insulator with vanishing Berry curvature

due to $C_{2z}\mathcal{T}$ symmetry[19, 20, 59, 60]. We can define a \mathbb{Z}_2 -type topological invariant $\Delta_{3D} = w_2(\pi) - w_2(0)$, where $w_2(k_z)$ is the second Stiefel-Whitney number defined on a 2D plane. The first Stiefel-Whitney number w_1 is equivalent to the quantized Berry phase and thus $w_1 = 0$ in our case. A nontrivial w_2 characterizes a double band inversion, which is well-defined only when $w_1 = 0$. We can calculate w_2 by tracing the Wilson loop spectra φ , where w_2 is the number of crossings at $\varphi = \pi \bmod 2$. Fig. 2c indicates AFM a phase as a 3D strong Stiefel-Whitney insulator ($\Delta_{3D} = 1$) with $w_2(0) = 1$ and $w_2(\pi) = 0$. The Stiefel-Whitney insulator can exhibit an odd number of surface Dirac cones [18, 20].

We perform the Green's function calculations using Wannier functions extracted from DFT calculations to verify the surface and hinge states. A single gapless Dirac cone exists on the (001) surface, shown in Fig. 2d. Because there is no additional symmetry to constrain the Dirac point besides $C_{2z}\mathcal{T}$, the Dirac point is unpinned from $\bar{\Gamma}$ or any high-symmetry line. The Dirac point positions can be continuously shifted by synchronously rotating or slightly titling the magnetic moments on the ab plane (Supplementary Fig. S5), for which $C_{2z}\mathcal{T}$ is maintained. In this case, the in-plane magnetic moments act as a vector potential perturbation that keeps the gapless nature of the surface Dirac cone.

The hinge modes of two adjacent side facets are analyzed by building a half-infinite slab model, containing 34 unit cells plus half a unit cell (34.5) along the b axis, which respects $C_{2z}\mathcal{T}$ and is thick enough to suppress inter-facet and inter-hinge interactions. The obtained spectrum includes the states from bulk, one (100) surface, two (010) surfaces, and two hinges. In Fig. 2e, an up-moving in-gap state clearly emerges as we expect. By projecting it into each layer, we find that the spectral weight is mainly distributed at hinge ② (Fig. 2g), confirming it as a hinge mode in the real space. These exotic boundary states attract us to next consider what kind of transport signals or physical quantity they carry on the surface.

Surface quantum geometry. To resolve a local response in real space, we can introduce the non-Abelian quantum geometric tensor in terms of two band (n, m), and depose it as [61],

$$Q_{nm}^{ij} \equiv \mathcal{A}_{nm}^i \mathcal{A}_{mn}^j = g_{nm}^{ij} - \frac{i}{2} \Omega_{nm}^{ij}, \quad (1)$$

where $\mathcal{A}_{nm}^i = i \langle n | \partial_{k_i} | m \rangle$ is the Berry connection, g_{nm}^{ij} and Ω_{nm}^{ij} are the quantum metric and Berry curvature. Then the local AHC in a slab is identified by the layer-resolved Chern number $\sigma_{\text{slab}}^{ij}(l) = \frac{e^2}{h} \mathbb{C}(l)$ [31]

$$\sigma_{\text{slab}}^{ij}(l) = \frac{e^2}{\pi h} \text{Im} \sum_{n=1}^{N_c} \sum_{m=N_c+1}^{\infty} \int_{\mathbf{k}} \frac{\langle n | \hat{P}_l \partial_{k_i} \mathcal{H} | m \rangle \langle m | \partial_{k_j} \mathcal{H} | n \rangle}{(\varepsilon_n - \varepsilon_m)^2}, \quad (2)$$

FIG. 2. Hinges ① / ② is adjacent by the bc facet and ac facet. **g** The intensity of the in-gap states (pointed in **e**) projected onto each layer (unit cell), showing a localization behavior at hinge ②. #0 and #35 represent two hinges.

where N_c is the number of occupied bands, $\hat{P}_l = |l\rangle\langle l|$ is the projector onto l -th layer.

By constructing a slab along the y direction, $\mathcal{C}_y(l)$ and $\mathcal{C}_{int} = \sum_l \mathcal{C}_y(l)$ in Fig. 3a show a saturation behavior of the half-quantized surface AHC. Such a local signal is known to be the direct evidence of the axion insulator [31]. The first ten layers are enough to stabilize \mathcal{C}_{int} at 0.4976 (corresponds to the penetration length of the hinge state), while the internal layers from #10 to #20 (bulk) tame the oscillation and do not contribute to σ^{zx} of the entire slab. Since the spin moments of the top and bottom layers hold the same direction, the half-quantized surface AHC from the first and last ten layers together

gives rise to a $\mathbb{C} = -1$ Chern insulator.

Besides the surface AHC, it is worth noting that $C_{2z}\mathcal{T}$ does not exclude all the bulk Hall tensors. When the system is doped to be a conductor, a finite AHC $\sigma_{\text{bulk}}^{zx}$ will also emerge despite the compensated magnetization (Supplementary Fig. S10), offering a signature of unusual antiferromagnet or altermagnet.

On the $C_{2z}\mathcal{T}$ -preserved ab facet, the linear AHC σ^{xy} vanishes but the second-order Hall conductivity is permitted ($\sigma^{ij;k} = \mathcal{J}^k/E^i E^j$) [39]. In a similar vein, the layer-resolved second-order Hall conductivity can be given by

$$\sigma_{\text{slab}}^{ii;j}(l) = \frac{e^3}{\hbar} \text{Re} \sum_{n,m \neq n}^{\infty} \int_{\mathbf{k}} \frac{2 \langle n | \hat{P}_l \partial_{k_j} \mathcal{H} | n \rangle \langle n | \partial_{k_i} \mathcal{H} | m \rangle \langle m | \partial_{k_j} \mathcal{H} | n \rangle - \langle n | \hat{P}_l \partial_{k_i} \mathcal{H} | n \rangle \langle n | \partial_{k_i} \mathcal{H} | m \rangle \langle m | \partial_{k_j} \mathcal{H} | n \rangle}{(\varepsilon_n - \varepsilon_m)^3} \frac{\partial f_n}{\partial \varepsilon_n}, \quad (3)$$

The Eq. 3 includes the Fermi surface contribution from the scattering time-independent quantum metric dipole (χ^{QMD}). In Fig. 3b, a localized intrinsic NLAHE is found in a slab stacked along the c direction. Due to the

inversion symmetry, the total second-order conductivity (χ_{int}) is zero and the Dirac cone from the top and bottom surfaces are oppositely tilted. Since $C_{2z}\mathcal{T}$ does not restrict the shape of the Dirac cone, an in-plane

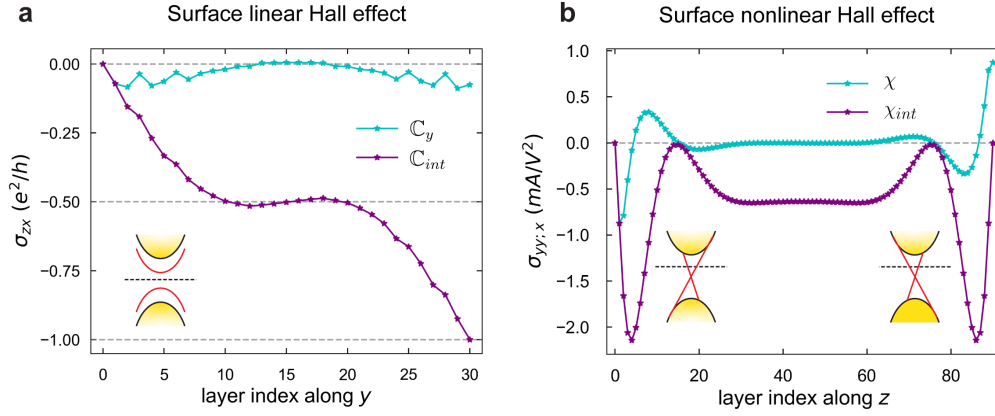

FIG. 3. Surface anomalous Hall effect. **a** Local Chern number and integrated Hall conductance as a function of layers in a 29.5-unit-cell slab. **b** Intrinsic second-order Hall conductivity from the quantum metric dipole in a 90-unit-cell slab. The Fermi level lies in the surface gap in **a** and cuts through the surface Dirac cone in **b**.

nonlinear response $\sigma^{yy;x}$ will appear on the surface. Breaking inversion with different chemical potentials for the top and bottom surface states is expected to induce a net NLAHE in the thin film, which can be probed in transport experiments. In addition, both the surface AHE and surface NLAHE discussed above can also be measured by the nonlocal transport, for example, by using a device configuration proposed in Ref. [62].

Weyl semimetal phase. When all the spin moments align along the a axis under an external field (FMA, $\mathbf{m} \parallel a$), we find two type-I Weyl points with opposite chiralities along $\Gamma - X$ connected by inversion symmetry in Fig. 4a,b. In the projected (001) Fermi surface, two Weyl nodes separated 0.074 \AA^{-1} along k_x are connected by a surface Fermi arc. In the FMB phase (Supplementary Fig. S7), the Weyl nodes are shifted to locate along the $\Gamma - Y$ direction. Thus, the FMA/ b phase is an ideal Weyl semimetal, which exhibits a single pair of type-I Weyl points without extra trivial Fermi pockets at the Fermi energy. In the FMC phase, the mirror M_z will protect a nodal ring on the $k_z = 0$ plane and drumhead-like surface states, as shown in Fig. 4c,d.

Effective model and topological phase diagram.

We build a general topological phase diagram by constructing a $k \cdot p$ model using the invariant theory [63], to more intuitively understand the role of magnetic order in the topological band structure. Since $\{C_{2y}|\tau\}$ is a key symmetry to relate two sublattices and the AFM order, three sets of Pauli matrices should be introduced to describe this system:

- spin σ : $|\frac{1}{2}\rangle$ and $|\frac{1}{2}\rangle$
- orbital τ : $|\text{In } s\rangle$ and $|\text{As } p_z\rangle$
- sublattice ζ : $|A\rangle$ and $|B\rangle$

and the basis are labeled by $|\Lambda_\alpha, \uparrow(\downarrow)\rangle$, where $\Lambda = \text{In}, \text{As}$; $\alpha = A, B$; $\uparrow(\downarrow) = \frac{1}{2}(-\frac{1}{2})$. According to the band representation (parity \pm) and wavefunction at Γ , we can have the orbital basis $|\text{In}_A^+ s\rangle, |\text{In}_B^+ s\rangle, |\text{As}_A^- p_z\rangle, |\text{As}_B^- p_z\rangle$. The symmetry operators are given by $\hat{T} = i\sigma_2\tau_0\zeta_0\mathcal{K}$, inversion $\hat{I} = \sigma_0\tau_3\zeta_0$, $\hat{C}_{2z} = -i\sigma_3\tau_0\zeta_0$ and $\{\hat{C}_{2y}|\tau\} = -i\sigma_2\tau_3\zeta_1$, where \mathcal{K} is the complex conjugate operator. Then we can list the irreducible representation (IR) of each matrix in Supplementary Sec. I. Based on that, the effective Hamiltonian is described by

$$\mathcal{H} = \mathcal{H}_{\text{NM}} + \mathcal{H}_{ex} = \begin{pmatrix} \mathcal{H}_A & \mathcal{H}_{AB} \\ \mathcal{H}_{AB}^\dagger & \mathcal{H}_B \end{pmatrix} + \begin{pmatrix} \mathcal{H}_{M,A} & \mathcal{H}_{M,AB} \\ \mathcal{H}_{M,AB}^\dagger & \mathcal{H}_{M,B} \end{pmatrix} \quad (4)$$

$$\begin{aligned} \mathcal{H}_{A/B} = & (\pm A_1 k_x + A_2 k_y)\sigma_1\tau_1 + (B_1 k_x \pm B_2 k_y)\sigma_2\tau_1 \pm C_1 k_z\sigma_3\tau_1 \\ & + D_1 k_z\sigma_0\tau_2 + E_{01}\sigma_0\tau_0 + (F_{01} + F_1 k_x^2 + F_2 k_y^2 + F_3 k_z^2 \pm F_4 k_x k_y)\sigma_0\tau_3, \end{aligned} \quad (5)$$

$$\begin{aligned} \mathcal{H}_{AB} = & A_3 k_y\sigma_1\tau_1 + B_3 k_x\sigma_2\tau_1 + D_2 k_z\sigma_0\tau_2 + E_{02}\sigma_0\tau_0 + F_{02}\sigma_0\tau_3 \\ & - iG_0\sigma_3\tau_0 - iL_0\sigma_3\tau_3 - iM_1 k_x\sigma_1\tau_2 - iN_1 k_y\sigma_2\tau_2 - iO_1 k_x\sigma_3\tau_2, \end{aligned} \quad (6)$$

where F_{01} controls the bandgap so it can be approx-

imately treated as the inverse of the effective SOC

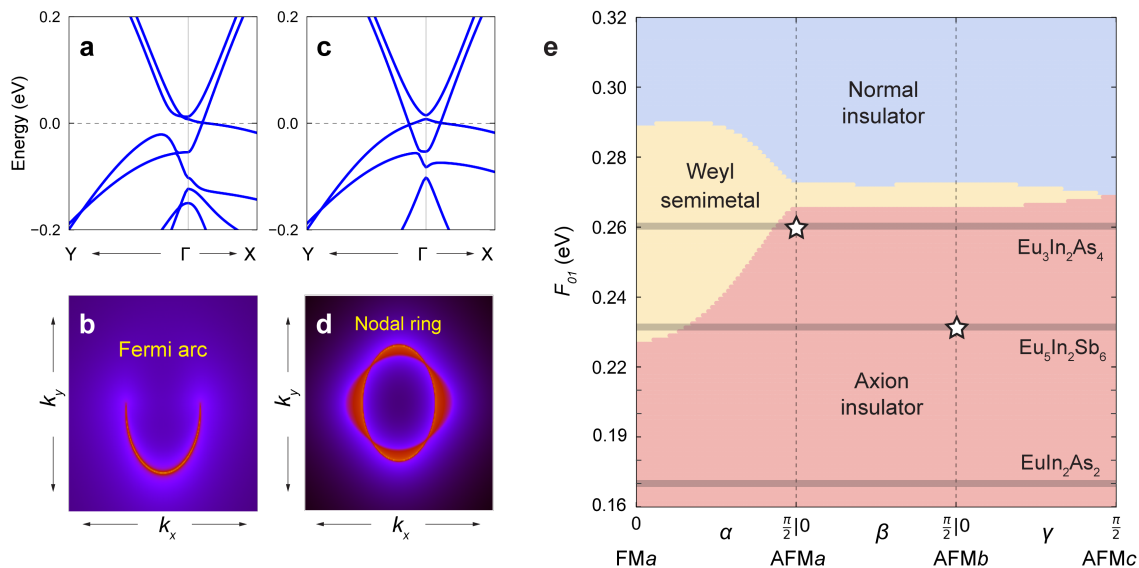

FIG. 4. Multiple magnetic topological phases in Zintl compounds. **a,c** Band structure near Γ point of the FMa and FMc phases. **b,d** Projected (001) Fermi surface. The Fermi arc connects two Weyl points in **b**. Symmetry M_z protects a Weyl nodal ring in **c**. **e** Topological phase diagram in terms of SOC strength F_{01} and magnetic orders. strength. Experimentally, F_{01} is tuned by pnictide doping or pressure [64]. The other material-dependent parameters are chosen to make dispersion close to Γ qualitatively or semi-quantitatively consistent with Fig. 2b.

We next consider the exchange coupling terms \mathcal{H}_{ex} , namely \mathcal{T} -odd terms when introducing spin orders. Note that the AFMa phase shares the same IR with FMb (also for AFMb and FMa), so both the on-site terms $\sigma_1\tau_0\zeta_3$ and $\sigma_2\tau_0\zeta_0$ will couple with IR Γ_4^+ . Generally, $\mathbf{m} \cdot \boldsymbol{\sigma}$ could be taken to characterize the magnetization of one sublattice and thus to distinguish them. Take the AFMa phase as an example, we have

$$\mathcal{H}_{AFMa,A/B} = \pm \Delta_{x1}\sigma_1\tau_0 \pm \Delta_{x2}\sigma_1\tau_3, \quad (7)$$

$$\mathcal{H}_{AFMa,AB} = \Delta_3\sigma_2\tau_0 + \Delta_4\sigma_2\tau_3. \quad (8)$$

Similarly, the exchange terms for the FMa, AFMb, and AFMc phases can be obtained, respectively. Additionally, the intermediate phases between them can be expressed as a linear combination.

By numerically solving the model, we construct a \mathcal{T} -broken phase diagram (Fig. 5) as functions of F_{01} and α, β, γ . We find $\text{Eu}_3\text{In}_2\text{As}_4$ can be very well mapped onto the grey horizontal line with $F_{01} = 0.26$ eV. As an intermediate region between two insulating phases, the chance of being a Weyl semimetal is intimately related to the magnetic configuration. Within the FM order, the Zeeman effect results in a large semimetallic region. Then it shrinks to a fairly narrow range in the AFMa/b or tilted phase, and eventually vanishes in the AFMc

phase. The axion insulator phase is quite robust against the perturbation on orientations of the AFM order in $\text{Eu}_3\text{In}_2\text{As}_4$. The model parameters and verification are provided in the Supplementary Sec. III.

DISCUSSION

Materials. We emphasize the results above also apply to EuIn_2As_2 and $\text{Eu}_5\text{In}_2\text{Sb}_6$, which are fitted in the phase diagram by only considering the anticrossing energy. To observe hinge states, EuIn_2As_2 is a bit special for the presence of both $C_{2z}\mathcal{T}$ and $C_{2x}\mathcal{T}$ symmetries by the ‘broken helix order’ [43]. When the sample is in the orthorhombic geometry (Fig. 1a), the system presents a first-order topology with the only gapped (001) surface. In the hexagonal geometry (Fig. 1b), $C_{2x}\mathcal{T}$ axis passing through the center of two hinges reverts the gap masses of neighboring facets so that the hinge current can appear along the c direction (\hat{y}). $\text{Eu}_5\text{In}_2\text{Sb}_6$ exhibits the same boundary states as $\text{Eu}_3\text{In}_2\text{As}_4$ because spin moments are aligned in a collinear or coplanar way to present only $C_{2z}\mathcal{T}$ [49].

The hybrid-order topology could also emerge in systems summarized in Table I and hatches different surface-dependent quantum geometry. Besides χ^{QMD} , the second-order Hall conductivity also includes contributions from the Drude weight χ^{D} (nongeometric) and Berry curvature dipole χ^{BCD} (imaginary part of the quantum geometry) [39]. On the $C_2\mathcal{T}$ -preserved surfaces, the surface quantum geometry only contains χ^{QMD} . In other systems, the surface NLAHE tensors

TABLE I. Emergence of a hybrid-order topology classified from symmetries. The details are explained in Supplementary Sec. IV. Here, the mirror plane (M) must go through both the crystal surface and hinges (*e.g.* SnTe). The glide symmetry (G) is restricted to exist only on one set of surfaces [*e.g.* (100) surface of the canted AFM MnBi_2Te_4 [14]]. When more than one following symmetries exist, the hybrid-order topology may be quenched to the first-order.

Hinge states	\mathcal{T}	Symmetries on the surface	Surface QAHE and Surface NLAHE
Helical	\checkmark	C_2, C_4, C_6 M [6], G [9]	– χ^{BCD}
Chiral	\times	$C_4\mathcal{T}$ $C_2\mathcal{T}, C_6\mathcal{T}$ M, G [14]	$\bar{\mathcal{C}}$ $\bar{\mathcal{C}}, \chi^{\text{D}}, \chi^{\text{QMD}}$ $\bar{\mathcal{C}}, \chi^{\text{D}}, \chi^{\text{BCD}}, \chi^{\text{QMD}}$

allowed are elaborated below and in Supplementary Sec. IV. First, in \mathcal{T} -preserved TCIs, $C_{2,4,6}$ symmetry eliminates all the surface $\chi^{ii;j}$ tensors while mirror/glide planes only permits χ^{BCD} . Second, in \mathcal{T} -broken TCIs, the mirror/glide symmetry accommodates both χ^{BCD} and χ^{QMD} . However, it is fragile against magnetic perturbation and thus hard to protect surface/hinge states. Overall, the surface NLAHE is driven by surface states rather than hinge states.

Topological superconductivity. $\text{Eu}_3\text{In}_2\text{As}_4$ nanowires were recently grown from InAs nanowires by a toptaxial mutual-exchange method [50] and can inherit good interface quality to the ordinary superconductor (*e.g.*, Al) [57]. Because of the intrinsic magnetism, strong SOC effect, and topological surface states, $\text{Eu}_3\text{In}_2\text{As}_4$ paves an appealing avenue to explore Majorana physics, as illustrated in Fig. 5. The intrinsic magnetism and SOC together lift the spin degeneracy and an odd number of Fermi surfaces can be realized at an accessible chemical potential, which is the precondition to design structure with Majorana [65, 66]. (i) In a nanowire configuration [67, 68], the finite size effect gaps the hinge and surface states, leading to nondegenerate topology-driven nanowire bands. In proximity to an *s*-wave superconductor, localized zero-energy Majorana modes will arise at two ends. Compared to earlier proposals [69, 70], we do not require an external magnetic field to break time-reversal symmetry here. (ii) On the gapped surface (*e.g.*, *ac/bc* facet), one can deposit a superconductor island and expect chiral Majorana edge states around the island, if the superconductor's gap Δ overcomes the magnetization-induced surface gap h . Using Fu and Kane's proposal [3, 65], we expect a stable nontrivial pairing by covering a superconductor on *ac* or *bc* surfaces (criterion $|h| < \Delta$ when the Fermi energy lies inside the gap). In this case, 1D chiral Majorana modes

FIG. 5. Schematics of the axion insulator $\text{Eu}_3\text{In}_2\text{As}_4$ (cyan-blue) in proximity to an *s*-wave superconductor (SC) (grey). (a) The nanowire configuration. (b) The SC proximity to the gapped surface, *e.g.*, the *ac/bc* surfaces in AFMa phase. (c) The SC proximity to the gapless surface, *e.g.*, the *ab* surface in AFMa phase. One chiral hinge state (pink lines) splits into two chiral Majorana edge modes, providing an interferometer configuration. Yellow lines (dots) represent the chiral Majorana modes (Majorana end modes). The red arrows represent spin moments in the axion insulator.

appear at the interface between the axion insulator's surface and a superconductor region [71]. If the Fermi energy crosses an odd number of Dirac bands (metallic regime), similar chiral Majorana modes also appear in this case. (iii) On the gapless surface (*e.g.*, *ab* facet in AFMa), covering a superconductor on the whole surface may lead to co-propagating 1D chiral Majorana edge modes. Two Majorana modes merge into one chiral electronic state at the hinge [72]. As illustrated by Fig. 5c, two chiral Majorana modes and two chiral hinge states naturally form a Mach-Zehnder interferometer, in which the conductance between two chiral hinge modes depends on the parity of the number of enclosed vortices in the superconductor region [71, 73].

In summary, through first-principle calculations and k - p model, we reveal the coexistence of the unpinned Dirac surface and chiral hinge states in $\text{Eu}_{2n+1}\text{In}_2(\text{As,Sb})_{2n+2}$. Established by $C_2\mathcal{T}$ symmetry, such a hybrid-order topology also leads to a surface-dependent quantum geometry. Our findings on the nonlinear transport suggest new fingerprint evidence of magnetic axion insulators and other \mathcal{T} -preserved TCIs. Since the single crystals and nanowires of $\text{Eu}_3\text{In}_2\text{As}_4$ are readily synthesized, angle-resolved photoemission spectroscopy (ARPES), scanning tunneling spectroscopy (STS) and other techniques are called to detect these topological surface states, hinge states, and Weyl points/Fermi arcs and explore their coupling to magnetism and superconductivity.

Note added. After we posted the manuscript, an experiment work was posted to report a pair of Weyl nodes in the ferromagnetic phase under an external magnetic field [51], consistent with our theory.

METHODS

Density-functional theory. Density-functional theory (DFT) calculations are performed with the Vienna Ab initio Simulation Package (VASP) using the projector-augmented wave method [74–76]. The Exchange-correlation functional based on generalized gradient approximation (GGA) parameterized by Perdew-Burke-Ernzerhof (PBE) is adopted [77]. The kinetic energy cutoff of the plane-wave basis is set to 400 eV. The Brillouin zone integration is performed by using $8 \times 5 \times 10$ Γ -centered \mathbf{k} point mesh. To treat the correlation effect of localized $4f$ electrons of Eu, the DFT+ U method by Dudarev et al. is employed [78]. The details about the DFT functional choice, Hubbard U , and the Green’s function can be found in Supplementary Sec. II.

Calculations of the layer-resolved Hall conductivity. We construct the maximally localized Wannier functions of In- $5s$ orbital and As- $4p$ orbitals by using WANNIER90 package [79]. The local Chern number (geometric part of the local AHC) is calculated by using a 121×121 k -mesh [31]. The nonlinear surface Hall conductivity is performed on the $k \cdot p$ Hamiltonian using an 800×800 k -mesh. The complete formula of the second-order nonlinear conductivity reads as

$$\begin{aligned} \sigma_{ij;k} &= \chi_{ij;k}^{\text{D}} + \chi_{ij;k}^{\text{BCD}} + \chi_{ij;k}^{\text{QMD}} \\ &= -\frac{e^3 \tau^2}{\hbar^3} \sum_n \int_{\mathbf{k}} f_n \partial_{k_i} \partial_{k_j} \partial_{k_k} \varepsilon_n \\ &\quad - \frac{e^3 \tau}{\hbar^2} \sum_n \int_{\mathbf{k}} f_n (\partial_{k_i} \Omega_n^{jk} + \partial_{k_j} \Omega_n^{ik}) \\ &\quad - \frac{e^3}{\hbar} \sum_n \int_{\mathbf{k}} f_n \left(2\partial_{k_k} \mathcal{G}_{\mathbf{k}}^{ij} - \frac{1}{2} (\partial_{k_i} \mathcal{G}_n^{jk} + \partial_{k_j} \mathcal{G}_n^{ik}) \right), \end{aligned} \quad (9)$$

where $\Omega_n = \sum_{m \neq n} \Omega_{nm}$ is the Berry curvature, and $\mathcal{G}_n = \sum_{m \neq n} 2g_{nm}/(\varepsilon_n - \varepsilon_m)$ is the band-normalized quantum metric.

DATA AVAILABILITY

All the data that support the findings of this study are available within the paper and Supplementary Information. Additional data are available from the corresponding authors upon reasonable request.

ACKNOWLEDGMENTS

We are inspired by a recent experiment work by Haim Beidenkopf and Hadas Shtrikman. We thank helpful discussions with Xi Dai, Mingqiang Gu, Hengxin Tan and Zhiqiang Mao. C.-X. L. acknowledges the support of NSF Grant No. (DMR-2241327). B.Y. acknowledges the financial support by the European Research Council (ERC Consolidator Grant “NonlinearTopo”, No. 815869) and the ISF - Personal Research Grant (No. 2932/21).

AUTHOR CONTRIBUTIONS

B.Y. conceived and supervised the project. Y.Z., and H.B. performed DFT calculations. Y.Z., Y.J., K.D. carried out the surface quantum geometry analysis. Y.Z. and C.-X. L. carried out the model Hamiltonian. The paper was written by Y.Z. and B.Y. All authors contributed to the discussion.
