#### Abstract

Causal discovery in the presence of unobserved common causes from observational data only is a crucial but challenging problem. We categorize all possible causal relationships between two random variables into the following four categories and aim to identify one from observed data: two cases in which either of the direct causality exists, a case that variables are independent, and a case that variables are confounded by latent confounders. Although existing methods have been proposed to tackle this problem, they require unobserved variables to satisfy assumptions on the form of their equation models. In our previous study [10], the first causal discovery method without such assumptions is proposed for discrete data and named CLOUD. Using Normalized Maximum Likelihood (NML) Code, CLOUD selects a model that yields the minimum codelength of the observed data from a set of model candidates. This paper extends CLOUD to apply for various data types across discrete, mixed, and continuous. We not only performed theoretical analysis to show the consistency of CLOUD in terms of the model selection, but also demonstrated that CLOUD is more effective than existing methods in inferring causal relationships by extensive experiments on both synthetic and real-world data.

# 1 Introduction

Intelligent systems that utilize accurate prediction based on data has enjoyed remarkable success by the development of machine learning methodology. It is expected that an accurate predictor learned from data possesses a certain form of information on the data. This expectation motivates us to render information extracted from data by a learning algorithm into a form in which humans can understand. For this sake, it is considered that the study of causal inference, aiming at extracting the underlying causal mechanism, has gained prominence in the context of machine learning as well as other various fields [25, 31].

As it is impractical to perform randomized control trials in many cases, many studies have focus on inferring causal structures based soly on observational data [20]. In the context of classical causal discovery, the decision whether X is a direct cause of Y or Y is a direct cause of X is already a hard problem so that standard methods assume there is no unknown common cause (causal sufficiency). However, in practice, this assumption is often violated, which can results in the methods producing unreliable results. Therefore, causal discovery that allows for the presence of unobserved common causes becomes crucial.

We consider a new problem setting by revisiting Reichenbach's common cause principle quoted as follows [25, Principle 1.1]:

If two random variables X and Y are statistically dependent, then there exists a third variable C that causally influences both. (As a special case, C may coincide with either X or Y.) Furthermore, this variable C screens X and Y from each other in the sense that given C, they become independent.

As a logical conclusion of the statement above, we can always categorize the relationship between X and Y into 4 cases: 1) X causally influences (X and ) Y, 2) Y causally influences X (and Y), 3) there exists a third variable C that causally influences X and Y, and 4) X and Y are statistically independent. We call a problem to decide which among those cases from data *Reichenbach problem* and deal with it. The solution for this problem is advantageous over the traditional methods in the sense that it does not require the prior knowledge on the nonexistence of unobserved confounder and then it is widely applicable.

There has been many existing studies on the detection of unobserved common cause as well. As we discuss in later sections, those methods require a type of assumptions such that unobserved confounding variables and the observed variables can be described by a specific formulation. However, we consider that such assumptions on unobserved variables are hard to guarantee, even if the domain knowledge on the dataset is available. Therefore, we aim to deal with the Reichenbach problem without assuming such a specificity on the possible relations between unobserved confounder and observed variables.

In our previous study [10], we proposed CLOUD (CodeLength-based methOd for Unobserved common causes between Discrete data) to address the Reichenbach problem for discrete data. In this paper, we extend CLOUD to accomodate all types of data including discrete, mixed, and continuous. Unlike all existing methods, CLOUD does not specify a form of unobserved confounders. We take a strategy in which we select a causal model which yields the minimum codelength among all candidates, known as the minimum description length (MDL) principle [26]. The key for our method is to employ normalized maximum likelihood (NML) code to compute the codelength in models of different capacities. We show this method exhibits high performance both in theoretically and experimentally.

The rest of this paper is organized as follows. The next section introduces the MDL principle and Structural Causal Models (SCMs), and then defines the Reichenbach problem formally. In section 3, we review existing methods from the viewpoint of two approaches and then see how it is hard to deal with the Reichenbach problem without assumptions in both approaches. In section 4, we describe models for which we consider the NML code and proposed method. In section 5 and section 6, we conduct theoretical analysis and extensive experiments, respectively. Finally, the conclusion is given in section 7.

# 2 Preliminaries

We introduce three theoretical frameworks upon which we construct our method for causal discovery, namely the minimum description length (MDL) principle, Structural Causal Models (SCMs) and the Reichenbach problem.

### 2.1 The MDL principle and the NML Codelength

The Minimum Description Length (MDL) principle is a model selection principle grounded in the concept of data compression. It asserts that the optimal model is the one that most succinctly describes both the data  $x^n$  and the model M, where  $x^n = (x_i)_{i=1,...,n}$  is a data sequence of length n. In this principle, we compute the codelength of data with a universal code for each model, as an information criteria.

In this context, we introduce the Normalized Maximum Likelihood (NML) code as a universal code. The NML code is justified by the fact that, it is optimal in terms of the minimax regret criterion [29] and that it exhibits consistency in model selection [28]. The NML codelength, also known as stochastic complexity, is derived from the NML distribution. The NML distribution for statistical model M with respect to data  $x^n$  is defined as follows:

$$P_{\text{NML}}\left(x^{n};M\right) = \frac{P\left(x^{n};M,\hat{\boldsymbol{\theta}}(x^{n})\right)}{\sum_{X^{n}} P\left(X^{n};M,\hat{\boldsymbol{\theta}}(X^{n})\right)},\tag{1}$$

where  $\hat{\theta}(x^n)$  denotes the maximum likelihood estimator of the parameters of the model M given the data  $x^n$  and the summation  $\sum_{X^n}$  is taken over the space of all the possible values of the data  $X^n \in \mathcal{X}^n$ .

The stochastic complexity, or the NML codelength, of  $x^n$  is the negative logarithmic likelihood of the NML distribution:

$$\mathcal{SC}(x^n; M) \coloneqq -\log P_{\text{NML}}(x^n; M)$$

$$= -\log P\left(x^{n}; M, \hat{\boldsymbol{\theta}}\left(x^{n}\right)\right) + \log \sum_{X^{n}} P\left(X^{n}; M, \hat{\boldsymbol{\theta}}\left(X^{n}\right)\right)$$
(2)

The first term of Eq. (2) is the negative maximum log-likelihood, which is efficiently computable for many models. The second term, referred to as parametric complexity, is expressed as follows:

$$\log \mathcal{C}_n(M) \coloneqq \log \sum_{X^n} P\left(X^n; M, \hat{\boldsymbol{\theta}}\left(X^n\right)\right)$$
(3)

The parametric complexity is not always analytically tractable, and its computation is one of the major focuses of the NML-based model selection. Techniques for its computation include deriving asymptotically consistent approximations [29] and employing the g-function [5].

As we see in below, the parametric complexity of a categorical distribution model with K categories, denoted by  $\log C_{CAT}(K, n)$ , is represented by the following equation:

$$\mathcal{C}_{\mathsf{CAT}}(K,n) = \sum_{X^n \in \{1,\ldots,K\}^n} \prod_{k=1}^K \left(\frac{n(X=k)}{n}\right)^{n(X=k)}.$$

Here, n(X = k) is the frequency of occurrence of value k in the sequence  $x^n$ , defined as  $n(X = k) = \sum_{i=1}^{n} \mathbb{I}(x_i = k)$ , where I is the indicator function. Kontkanen and Myllymäki developed an efficient recurrence formula for this model with a linear time complexity of  $\mathcal{O}(n + K)$  [12]:

$$\begin{split} \mathcal{C}_{\mathsf{CAT}}(K=1,n) &= 1, \\ \mathcal{C}_{\mathsf{CAT}}(K=2,n) &= \sum_{h_1+h_2=n} \frac{n!}{h_1!h_2!} \left(\frac{h_1}{n}\right)^{h_1} \left(\frac{h_2}{n}\right)^{h_2}, \\ \mathcal{C}_{\mathsf{CAT}}(K+2,n) &= \mathcal{C}_{\mathsf{CAT}}(K+1,n) + \frac{n}{K} \mathcal{C}_{\mathsf{CAT}}(K,n). \end{split}$$

In dealing with continuous variables, the summation in Eq. (3) is replaced with an integral. Lastly, we illustrate how to compute the NML codelength for some statistical models. These examples cover data sequences of either discrete-type or continuous-type.

**Example 1** (The NML Codelength for a Discrete Data). We compute the NML codelength for a data sequence  $x^n$  under a categorical distribution model  $CAT^{m_X}$  with  $m_X$  categories:

$$\mathsf{CAT}^{m_X} = \left\{ P(X; \boldsymbol{\theta}) \mid \boldsymbol{\theta} = (\theta_0, \dots, \theta_{m_X-1}), \theta_k \ge 0, \sum_{k=0}^{m_X-1} \theta_k = 1 \right\}.$$

For given data  $x^n$ , the maximum likelihood estimator of parameter  $\hat{\boldsymbol{\theta}} = (\hat{\theta}_0, \dots, \hat{\theta}_{m_X-1})$ is  $\hat{\theta}_k(x^n) = \frac{n(X=k)}{n}$  for  $k = 0, \dots, m_X - 1$ . Consequently, the first term in Eq. (2) is

computed as

$$-\log P(x^{n}; \mathsf{CAT}^{m_{X}}, \hat{\theta}(x^{n})) = -\sum_{k=0}^{m_{X}-1} n(X=k) \log \frac{n(X=k)}{n}.$$

The second term in Eq. (2), the parametric complexity of  $CAT^{m_X}$ , is given by  $\log C_{CAT}(K = m_X, n)$ . Thus, the NML codelength for the discrete data  $x^n$  under the  $CAT^{m_X}$  is given by

$$\mathcal{SC}(x^{n}; \mathsf{CAT}^{m_{X}}) = -\sum_{k=0}^{m_{X}-1} n(X=k) \log \frac{n(X=k)}{n} + \log \mathcal{C}_{\mathsf{CAT}}(K=m_{X}, n).$$
(4)

**Example 2** (The NML codelength for a Continuous Data). Let the domain of continuous data sequence  $x^n$  is  $\mathcal{X} = [0, 1)$ . We divide  $\mathcal{X}$  into  $m_X$  cells  $\{I_k^X\}$  of equal length  $\frac{1}{m_X}$ :

$$\mathcal{X} = \bigcup_{k=0}^{m_X - 1} I_k^X, \ I_k^X = \left[\frac{k}{m_X}, \frac{k+1}{m_X}\right) (k = 0, \dots, m_X - 1)$$

We define the histogram density function model  $HIS^{m_X}$  as follows:

$$\mathsf{HIS}^{m_X} = \left\{ p(X; \boldsymbol{\theta}) = \sum_{k=0}^{m_X - 1} \theta_k \mathbb{I}[X \in I_k^X] \, \middle| \, \boldsymbol{\theta} = (\theta_0, \dots, \theta_{m_X - 1}), \theta_k \ge 0, \sum_{k=0}^{m_X - 1} \frac{\theta_k}{m_X} = 1 \right\}.$$

The maximum likelihood estimator for this model results in  $\hat{\theta}_k(x^n) = \frac{n(X \in I_k^X)}{n} m_X$ . Consequently, the maximum log-likelihood of data is calculated as:

$$\log p(x^{n}; \hat{\theta}(x^{n})) = \sum_{k=0}^{m_{X}-1} n(X \in I_{k}^{X}) \log \hat{\theta}_{k}$$
$$= \sum_{k=0}^{m_{X}-1} n(X \in I_{k}^{X}) \log \frac{n(X \in I_{k}^{X})}{n} + n \log m_{X}.$$

where  $n(X \in I_k^X)$  is the frequency of observations in interval  $I_k^X$  in the data sequence  $x^n$ , formally defined as  $n(X \in I_k^X) = \sum_{i=1}^n \mathbb{I}(x_i \in I_k^X)$ . Let  $\tilde{x}^n = (\tilde{x}_1, \dots, \tilde{x}_n) \in \{0, \dots, m_X - 1\}^n$  be a sequence of n bin labels and  $I_{\tilde{x}^n}^X \coloneqq I_{\tilde{x}_1}^X \times \dots \times I_{\tilde{x}_n}^X \subset [0, 1)^n$  be the n-dimensional hyper-bin associated with  $\tilde{x}^n$ . The parametric complexity of  $\mathsf{HIS}^{m_X}$  is then given by:

$$\log \mathcal{C}_n(\mathsf{HIS}^{m_X}) = \log \int_{[0,1)^n} p(x^n; \hat{\boldsymbol{\theta}}(x^n)) dx^n$$
$$= \log \sum_{\tilde{x}^n \in \{0,\dots,m_X-1\}^n} \int_{I_{\tilde{x}^n}} p(x^n; \hat{\boldsymbol{\theta}}(x^n)) dx^n$$

$$\begin{split} &= \log \sum_{\tilde{x}^n \in \{0, \dots, m_X - 1\}^n} \prod_{k=0}^{m_X - 1} \left( \frac{n(\tilde{X} = k)}{n} \right)^{n(\tilde{X} = k)} \\ &= \log \mathcal{C}_{\mathsf{CAT}}(K = m_X, n), \end{split}$$

which results in the same value as the parametric complexity of the  $m_X$ -valued categorical model  $CAT^{m_X}$ .

The NML codelength thus becomes

$$\mathcal{SC}(x^n; \mathsf{HIS}^{m_X}) = -\sum_{k=0}^{m_X-1} n(X \in I_k^X) \log \frac{n(X \in I_k^X)}{n} - n \log m_X + \log \mathcal{C}_{\mathsf{CAT}}(K = m_X, n), \quad (5)$$

for continuous data  $x^n$  based on  $HIS^{m_X}$ .

## 2.2 Structural Causal Model

A Structural Causal Model (SCM) [20] represents the data-generating process through a set of structural assignments. In an SCM, variables are expressed as functions of their parent variables (direct causes) and exogenous variables. In particular, when we consider only two variables X and Y, which are both one-dimensional, with the causal graphs  $X \to Y$  or  $X \leftarrow Y$ , SCMs can be represented as follows:

$$M_{X \to Y} : \begin{cases} X = E_X \\ Y = f(X, E_Y) \end{cases} \qquad \qquad M_{X \leftarrow Y} : \begin{cases} X = g(Y, E_X) \\ Y = E_Y, \end{cases}$$

where f and g are functions, and  $E_X, E_Y$  are one-dimensional exogenous variables such that  $E_X \perp\!\!\!\perp E_Y$ . Here, the statistical models  $M_{X \to Y}, M_{X \leftarrow Y}$ , derived from each SCM, are referred to as causal models. In general, without constraints on the distributions of the exogenous variables and/or on the forms of functions f and g, it is not identifiable whether samples from the joint distribution P(X,Y) are induced by the causal relationship of  $M_{X \to Y}$  or  $M_{X \leftarrow Y}$  [25, Proposition 4.1]. In other words, causal discovery from observational data usually requires making specific assumptions on the functional forms and/or the distributions of exogenous variables, which limits the scope of the joint distributions led by SCMs. Some notable SCMs in the context of causal discovery are listed in below.

**Example 3** (Additive Noise Model (ANM)). ANM[6, 22, 24] assumes a data generating process as per the following equations where effects are the nonlinear functions of their causes with additive noise:

$$M_{X \to Y} : \begin{cases} X = E_X \\ Y = f(X) + E_Y, \end{cases} \qquad \qquad M_{X \leftarrow Y} : \begin{cases} X = g(Y) + E_X \\ Y = E_Y, \end{cases}$$

where additive noises  $E_X, E_Y$  satisfy  $E_X \perp \!\!\perp Y, E_Y \perp \!\!\perp X$ , respectively.

**Example 4** (Linear NonGaussian Acyclic Model (LiNGAM)). *LiNGAM*[32, 33], which is a special case of ANM, assumes that causal relationships are linear and that exogenous variables follow non-Gaussian distributions:

$$M_{X \to Y} : \begin{cases} X = E_X \\ Y = b_{X \to Y} X + E_Y, \end{cases} \qquad \qquad M_{X \leftarrow Y} : \begin{cases} X = b_{X \leftarrow Y} Y + E_X \\ Y = E_Y, \end{cases}$$

where  $b_{X \to Y}, b_{X \leftarrow Y} \in \mathbb{R}$  are the linear coefficients, and  $E_X, E_Y$  follow Non-Gaussian distributions.

**Example 5** (Linear Mixed causal model (LiM)). LiM [39] is an extension of LiNGAM to accommodate mixed data types, including both continuous and discrete variables. In the case of continuous variables, LiM assumes the same SCMs as LiNGAM. When X is a continuous variable and Y is a binary variable, LiM assumes the following SCM:

$$M_{X \to Y} : \begin{cases} X = E_X \\ Y = \begin{cases} 1 \ (b_{X \to Y}X + E_Y > 0), \\ 0 \ (otherwise), \end{cases}$$

where  $E_Y$  follows a Logistic distribution.

**Example 6** (LiNGAM with latent confounder (IvLiNGAM)). IvLiNGAM extends the basic LiNGAM model to incorporate hidden common causes [7]. Besides the linear and non-Gaussian assumptions of LiNGAM, IvLiNGAM explicitly models unobserved common causes C. For a one-dimensional C, the model can be represented with the following SCM:

$$M_{X \leftarrow C \to Y} : \begin{cases} X = \lambda_X C + E_X \\ Y = \lambda_Y C + E_Y, \end{cases}$$

where  $\lambda_X, \lambda_Y \in \mathbb{R}$  denote the direct causal effects from the unobserved common cause C to each observed variable to the observed variables X and Y, respectively. In this SCM, the latent variable C is assumed to be non-Gaussian and independent of  $E_X$  and  $E_Y$ , and it is assumed to have linear effects on the observed variables.

## 2.3 Reichenbach Problem

This section describes the Reichenbach problem formally, which is central to our study. Suppose we have i.i.d. observational data  $z^n = (x^n, y^n) \in \mathcal{X}^n \times \mathcal{Y}^n$  generated from joint distribution P(X, Y). Here, X and Y can be either discrete or continuous variables.

Based on Reichenbach's common cause principle, we can categorize the causal relationship between X and Y into four cases. The goal is to infer one of these causal models M that best explains the underlying causal relationship:

- $M_{X \perp \downarrow Y}$ : X and Y are independent, with no direct causal link.
- $M_{X \leftarrow C \rightarrow Y}$ : There exist common causes C that causally influence both X and Y.

- $M_{X \to Y}$ : X causes Y, but not vice versa.
- $M_{X \leftarrow Y}$ : Y causes X, but not vice versa.

In solving the Reichenbach problem, it is desirable to use methods that do not make any assumption about unobserved variables C. This is crucial because it is almost impossible to have prior knowledge of all potential unobserved variables. Therefore, we propose a method capable of detecting the presence of unobserved common causes, even in situations where the candidates for latent variables are unknown or when unexpected unobserved variables are present, without relying on assumptions about C.

To employ existing causal discovery methods that rely on modeling unobserved variables, one needs to know the nature of the unobserved causes beforehand. However, it is challenging to acquire complete knowledge about all possible unobserved variables solely from the domain knowledge of the observed variables. Thus, when applying these methods to real-world data, a heightened level of caution is required. Nevertheless, existing approaches to the Reichenbach problem typically depend on models that make assumptions about the relationships between unobserved variables C and the observed variables X, Y.

# 3 Existing Work

Existing causal discovery methods from a joint distribution of two variables can be categorized into two approaches: one employs the identifiability of the model and the other is based on the principle of algorithmic independence of conditionals. Furthermore, in the context of the Reichenbach problem, there are methods focused on solving the sub-problem of choosing between  $X \to Y$  and  $X \leftarrow Y$ , and those that attempt to solve the Reichenbach problem by making assumptions about unobserved common causes. In this section, we describe these approaches and discuss why it is difficult to detect unobserved common factors without making assumptions about these causes.

## 3.1 Identifiable models

In this approach, when we formulate causal relationships using SCMs, we restrict the functional forms and the distributions of the exogenous variables. The causal models induced by SCMs are said to be identifiable if different causal structures always lead to different joint distributions of the observed variables.

In order to infer a causal structure using identifiable models, we assume that the observed data have been generated by a distribution belonging to one of these models. Then, we infer X is the cause of Y when the corresponding model explains the data best of all models. This reasoning applies similarly to other causal relationships.

To determine the causal direction, various type of indentifiable models are studied in existing work so that various types of data can be applied. Shimizu et al. [32] showed that causal models become identifiable if function is linear and the distribution of exogenous variables is non-Gaussian as in Example 4 (LiNGAM). A general case of LiNGAM is Additive Noise Models (ANMs, [6]), as detailed in Example 3, where we assume that the noise is additive and independent of the cause. In general, ANM is identifiable if functional form is non-linear even without imposing any restrictions

on the noise distributions [6, 24]. [22] proposed DR, which is an extension of ANMs to discrete variables and showed that ANM is generally identifiable in discrete case. For mixed-type data, [39] formulated Linear Mixed causal model (LiM) as shown in Example 5, and Li et al. [14] proposed an algorithm, HCM, which formulates nonlinear causal relationships as mixed-SCMs.

In this approach, we can recover the true causal relationship based on observed data as long as there is no latent confounder, i.e., the true distribution belongs to one of the models we adopt. Therefore, this framework requires practitioners to make use of domain knowledge such that causal relationship, if any, can be formulated in a certain type of SCM. However, causal discovery methods under the assumption of causal sufficiency, which assume no unobserved common causes, can lead to incorrect conclusions when applied to data where unobserved common causes actually exist. To avoid such issues, it becomes crucial to consider unobserved common causes in causal discovery.

As for models that allow for the presence of unobserved common causes, Hoyer et al. proposed a model called IvLiNGAM [7], which extends LiNGAM to the models with latent counfounding variables by explicitly modeling them. IvLiNGAM, shown in Example 6, assumes that the latent confounder C follow non-Ganssian distributions and relationships between C and observed variables are linear. Parce LiNGAM (BUPL, [37]) and Repetitive Causal Discovery (RCD, [16]) make the same assumptions on SCMs. Maeda et al. extended IvLiNGAM to its non-linear variant, and proposed CAMUV algorithm [17].

For models to be identifiable including  $M_{X\leftarrow C\rightarrow Y}$ , one must make an assumption on the model of unobserved common causes. This means that one must have known the nature of the unobserved common causes beforehand to successfully perform causal discovery. Otherwise, conclusions led by this framework will be unreliable when unobserved common causes do not follow the assumptions. Even with domain knowledge of X and Y, it remains challenging to accurately determine the form of SCM for an unobserved common cause, which a practitioner is not certain if exists, will satisfy.

## 3.2 Algorithmic Independence of Conditionals

This section describes the approach based on the principle of algorithmic independence of conditionals, which is described as follows: if true causality is  $X \to Y$ , then mechanism  $P^*(Y|X)$  is independent of the cause  $P^*(X)$  [8], where  $P^*$  denotes true distributions we assume under the corresponding causal relationship. By denoting the Kolmogorov complexity as K, it leads to the following inequality:

$$K(P^*(X)) + K(P^*(Y|X)) < K(P^*(Y)) + K(P^*(X|Y)),$$

if true causality is  $X \to Y$  [35]. This inequality can not be evaluated due to the following two reasons: Kolmogorov complexity is not computable and true distribution is unknown. Therefore, Marx and Vreeken [18] has justified that this principle leads to the approximation build upon two-part MDL as follows:

$$\mathcal{L}(z^n; M_{X \to Y}) < \mathcal{L}(z^n; M_{X \leftarrow Y}),$$

where  $\mathcal{L}(z^n; M_{X \to Y})$  is the description length of data  $z^n$  under statistical model  $M_{X \to Y} = M_X \times M_{Y|X}$  in which we assume  $P^*(X) \in M_X$  and  $P^*(Y|X) \in M_{Y|X}$ , formally defined as follows:

$$\mathcal{L}(z^n; M_{X \to Y}) = L(x^n; M_X) + L(y^n; x^n, M_{Y|X}).$$

We define  $\mathcal{L}(z^n; M_{X \leftarrow Y})$  analogously. Methods such as Causal Inference by Stochastic Complexity (CISC, [2]), Accurate Causal Inference on Discrete data (ACID, [3]) and Distance Correlation (DC, [15]) model  $\mathcal{L}(z^n; M)$  using refined MDL, Shannon Entoropy and distance correlation, respectively.

If one considers including confounded model  $M_{X\leftarrow C\to Y}$  with unobserved common causes C, the description length under the joint distributions of that model,  $\mathcal{L}(z^n; M_{X\leftarrow C\to Y})$  which is an approximation of  $K(P^*(X, Y, C))$ , must be evaluated and compared with directed cases of  $M_{X\to Y}$  and  $M_{X\leftarrow Y}$ . A naive approximation approach based solely on likelihood invariably leads to the selection of the confounded model  $M_{X\leftarrow C\to Y}$ , due to its inherently minimized complexity. To address this issue, Confounded-or-Causal (COCA) method was developed [9]. COCA selects between  $X \to Y$  and  $X \leftarrow C \to Y$  under the assumption that not only the observed variables but also unobserved common causes C follow specific-dimensional Gaussian distributions. It employs Bayesian coding to approximate the description length of data, considering not only the likelihood but also the complexity of the model class, including C. This approach enables to comparison between different sizes of statistical models, specifically  $M_{X\to Y}$  and  $M_{X\leftarrow C\to Y}$ . However, it is important to note that this approach relies on certain assumptions about C.

In Summary, in challenging the Reichenbach problem, all existing methods face a common limitation: they require additional assumptions about unobserved common causes. Our previous work has already shown that CLOUD successfully overcomes this limitation in the context of discrete variables [10]. We claimed that this is achievable by comparing models with different capacities, as quantified using the NML codelength. In this paper, our objective is to expand the applicability of CLOUD to encompass continuous and mixed data types, thereby enhancing its effectiveness in solving the Reichenbach problem across a wider range of data types.

# 4 Proposed Method

In this section, we extend CLOUD to cover all data types, which was originally designed for the Reichenbach problem in discrete data. In CLOUD, we formulate causal models for four causal relationships in the Reichenbach problem (Section 4.1). Then, based on MDL principle, we calculate the codelength of the observed data  $z^n$  based on NML coding and select a causal model M which achieves the shortest codelength (Section 4.2).

We formulate confounded model  $M_{X\leftarrow C\to Y}$  to represent any joint distribution, thus avoiding assumptions about C. Since this model has the highest complexity compared to the other three, the NML-based codelength on this model is not necessarily the shortest although the negative loglikilhood is the smallest. Thus, by considering both

model complexity and data likelihood, we can select an appropriate causal model among models of different complexities.

#### 4.1 Model

In this section, we describe causal models for cases where both X and Y are discrete or continuous variables, represented as statistical models derived from the assumed Structural Causal Models (SCMs) for each causal relationship.

First, we formulate SCMs for each causal model M to describe the causal relationships between  $X \in \mathcal{X}$  and  $Y \in \mathcal{Y}$ :

$$M_{X \perp Y} : \begin{cases} X = E_X \\ Y = E_Y \end{cases} \qquad \qquad M_{X \leftarrow C \rightarrow Y} : \begin{cases} X = f(C, E_X) \\ Y = g(C, E_Y) \end{cases}$$
$$M_{X \rightarrow Y} : \begin{cases} X = E_X \\ Y = f(X) + E_Y \end{cases} \qquad \qquad M_{X \leftarrow Y} : \begin{cases} X = g(Y) + E_X \\ Y = E_Y \end{cases}$$

Here, the exogenous variables  $E_X \in \mathcal{X}, E_Y \in \mathcal{Y}$  are independent of each other. For  $M_{X \perp \perp Y}$ , we assume faithfullness [34] in the sense that we regard X and Y is causally independent when they are statistically independent.

For  $M_{X \leftarrow C \to Y}$ , any probability density functions on  $(\mathbb{Z}/m_X\mathbb{Z}) \times (\mathbb{Z}/m_Y\mathbb{Z})$  and probability density functions on  $(\mathbb{R}/\mathbb{Z})^2$  belong to the  $M_{X\leftarrow C\to Y}$  by considering appropriate choice of f, g and C. In this sense, we do not impose assumptions on the unobserved common cause C for confounded case.

For  $M_{X \to Y}$  and  $M_{X \leftarrow Y}$ , we assume additive noise models (ANMs) [22], which employs functions from the function sets  $\mathcal{F} = \{f : \mathcal{X} \to \mathcal{Y} \mid f \text{ is not constant}\}$  and  $\mathcal{G} = \{g : \mathcal{Y} \to \mathcal{X} \mid g \text{ is not constant}\}$ . In case X is discrete, we set  $\mathcal{X} = \{0, 1, \dots, m_X - 1\}$  and addition is taken over  $\mathbb{Z}/m_X\mathbb{Z}$  as in [23, 25]. In case X is continuous, we set  $\mathcal{X} = [0, 1)$  and addition is taken over  $\mathbb{R}/\mathbb{Z}$ . The same goes for cases Y is either discrete or continuous. In continuous cases, the addition can be regarded as addition over  $\mathbb{R}$ for data scaled with a sufficiently small constant  $\epsilon$ . This implies that, in practical applications, models with periodic boundary conditions can be considered as including non-periodic ANMs.

Second, we identify the causal models  $M_{X \perp \!\!\!\perp Y}$ ,  $M_{X \leftarrow C \rightarrow Y}$ ,  $M_{X \rightarrow Y}$  and  $M_{X \leftarrow Y}$  with a set of joint probability distributions on (X, Y) that models imply. It can be justified in case in which only observations from the joint distribution are available.

#### Discrete Case:

If both X and Y are discrete, then  $\mathcal{X} = \mathbb{Z}/m_X\mathbb{Z}$  and  $\mathcal{Y} = \mathbb{Z}/m_Y\mathbb{Z}$ . Any discrete probability distribution on (X, Y) can be identified with a parameter  $\boldsymbol{\theta} \in \boldsymbol{\Theta}$  by the following relation:

$$P(X,Y;\boldsymbol{\theta}) = \prod_{k,k'} \theta_{k,k'}^{\mathbb{I}[X=k,Y=k']},$$

where we define  $\Theta = \{ \theta = (\theta_{k,k'})_{k,k'} \in \mathbb{R}^{m_X \times m_Y} | \theta_{k,k'} \ge 0, \sum \theta_{k,k'} = 1 \}$ . Based on this parametrization, we represent causal models by characterizing the respective subset of the parameter space as follows:

$$M_{X \perp Y} = \left\{ P\left(X, Y; \boldsymbol{\theta}\right) = \prod_{k,k'} \theta_{k,k'}^{\mathbb{I}[X=k,Y=k']} \middle| \boldsymbol{\theta} \in \boldsymbol{\Theta}_{X \perp Y} \right\},$$
$$M_{X \leftarrow C \rightarrow Y} = \left\{ P\left(X, Y; \boldsymbol{\theta}\right) = \prod_{k,k'} \theta_{k,k'}^{\mathbb{I}[X=k,Y=k']} \middle| \boldsymbol{\theta} \in \boldsymbol{\Theta}_{X \leftarrow C \rightarrow Y} \right\},$$
$$M_{X \rightarrow Y} = \left\{ P\left(X, Y; \boldsymbol{\theta}\right) = \prod_{k,k'} \theta_{k,k'}^{\mathbb{I}[X=k,Y=k']} \middle| \boldsymbol{\theta} \in \boldsymbol{\Theta}_{X \rightarrow Y} \right\},$$
$$M_{X \leftarrow Y} = \left\{ P\left(X, Y; \boldsymbol{\theta}\right) = \prod_{k,k'} \theta_{k,k'}^{\mathbb{I}[X=k,Y=k']} \middle| \boldsymbol{\theta} \in \boldsymbol{\Theta}_{X \rightarrow Y} \right\},$$

where

$$\boldsymbol{\Theta}_{X \perp Y} = \left\{ (\theta_k^X \, \theta_{k'}^Y)_{k,k'} \in \boldsymbol{\Theta} \, \middle| \, \sum_k \theta_k^X = 1, \theta_k^X \ge 0, \sum_{k'} \theta_{k'}^Y = 1, \theta_{k'}^Y \ge 0 \right\}, \tag{6a}$$

$$\Theta_{X \leftarrow C \to Y} = \Theta, \tag{6b}$$

$$\boldsymbol{\Theta}_{X \to Y} = \left\{ (\theta_k^X \, \theta_{f(k)+k'}^Y)_{k,k'} \in \boldsymbol{\Theta} \, \middle| \, \sum_k \theta_k^X = 1, \theta_k^X \ge 0, \sum_{k'} \theta_{k'}^Y = 1, \theta_{k'}^Y \ge 0, f \in \mathcal{F} \right\},$$
(6c)

$$\boldsymbol{\Theta}_{X\leftarrow Y} = \left\{ (\theta_{g(k')+k}^X \, \theta_{k'}^Y)_{k,k'} \in \boldsymbol{\Theta} \, \middle| \, \sum_k \theta_k^X = 1, \theta_k^X \ge 0, \sum_{k'} \theta_{k'}^Y = 1, \theta_{k'}^Y \ge 0, g \in \mathcal{G} \right\}. \tag{6d}$$

Note that the addition in subscripts is taken over each respective finite space. For discrete case, we encode the data  $z^n$  based on these discrete causal models.

#### Continuous Case:

In case the domains of X and Y are both continuous, we represent their joint density function by the infinite union of histogram densities.

Firstly, we consider partitioning  $\mathcal{X}$  into  $m_X$  equally-sized cells  $\{I_k^X\}$   $(k = 0, \ldots, m_X - 1)$  and  $\mathcal{Y}$  into  $m_Y$  equally-sized cells  $\{I_{k'}^Y\}$   $(k' = 0, \ldots, m_Y - 1)$ . We then define the two-dimensional density function model  $\mathsf{HIS}^{m_X, m_Y}$  as follows:

$$\mathsf{HIS}^{m_X,m_Y} = \left\{ p(X,Y;\boldsymbol{\theta}) = \sum_{k=0}^{m_X-1} \sum_{k'=0}^{m_Y-1} \theta_{k,k'} \mathbb{I}[X \in I_k^X, Y \in I_{k'}^Y] \, \middle| \, \boldsymbol{\theta} \in \boldsymbol{\Theta}^{m_X,m_Y} \right\}$$

where

$$\mathbf{\Theta}^{m_X,m_Y} = \left\{ \boldsymbol{\theta} = (\theta_{k,k'})_{k,k'} \in \mathbb{R}^{m_X \times m_Y} \, \middle| \, \theta_{k,k'} \ge 0, \sum_{k=0}^{m_X-1} \sum_{k'=0}^{m_Y-1} \frac{\theta_{k,k'}}{m_X m_Y} = 1 \right\}.$$

Then, the infinite union  $\bigcup_{m_X,m_Y} \text{HIS}^{m_X,m_Y}$  can represent any joint density function n an arbitrary precision level. Due to the universality of  $M_{X \leftarrow C \rightarrow Y}$ , we represent

$$M_{X \leftarrow C \rightarrow Y} = \bigcup_{m_X, m_Y} M_{X \leftarrow C \rightarrow Y}^{m_X, m_Y}, \quad M_{X \leftarrow C \rightarrow Y}^{m_X, m_Y} = \mathsf{HIS}^{m_X, m_Y}.$$

It means that we can identify any joint distribution on (X, Y) by an element of  $M_{X \leftarrow C \rightarrow Y}$ , in the sense that it gives the same distribution of codelength for a given code when the approximation level is fixed.

$$\begin{split} M_{X\perp\!\!\!\perp Y} &= \bigcup_{m_X,m_Y} M_{X\perp\!\!\!\perp Y}^{m_X,m_Y}, \quad M_{X\perp\!\!\!\perp Y}^{m_X,m_Y} = \{ p(X,Y;\boldsymbol{\theta}) \mid \boldsymbol{\theta} \in \boldsymbol{\Theta}_{X\perp\!\!\!\perp Y}^{m_X,m_Y} \} \\ M_{X\rightarrow\!Y} &= \bigcup_{m_X,m_Y} M_{X\rightarrow\!Y}^{m_X,m_Y}, \quad M_{X\rightarrow\!Y}^{m_X,m_Y} = \{ p(X,Y;\boldsymbol{\theta}) \mid \boldsymbol{\theta} \in \boldsymbol{\Theta}_{X\rightarrow\!Y}^{m_X,m_Y} \} \\ M_{X\leftarrow\!Y} &= \bigcup_{m_X,m_Y} M_{X\leftarrow\!Y}^{m_X,m_Y}, \quad M_{X\leftarrow\!Y}^{m_X,m_Y} = \{ p(X,Y;\boldsymbol{\theta}) \mid \boldsymbol{\theta} \in \boldsymbol{\Theta}_{X\leftarrow\!Y}^{m_X,m_Y} \} . \end{split}$$

We can regard  $M_{X\perp \downarrow Y}$  as a set of any density function that is decomposable as p(X,Y) = p(X)p(Y). As for  $M_{X\rightarrow Y}$ , we can see it as a special form of decomposition of the density function such as p(X,Y) = p(X)p(Y - f(X)) using a function f.

#### 4.2 Algorithm

We regard the Reichenbach problem as a problem of model selection and conduct a selection under the MDL criterion. That is, among the causal models defined in Section 4.1, we infer the underlying causal relationship of the data  $z^n$  is such a causal model M that yields the shortest description length of the data.

Discrete Case:

 Algorithm 1 Main function in Discrete Case

 Input: Data  $z^n$ , A set of model candidates  $\mathcal{M}$  

 Output: Best model  $\hat{M}$  

 1: for M in  $\mathcal{M}$  do

 2:  $\begin{bmatrix} Compute \mathcal{L}^d(z^n; M) & using (9) \\ 3: & \hat{M} = argmin_{M \in \mathcal{M}} \mathcal{L}^d(z^n; M) \\ 4: return & \hat{M} \end{bmatrix}$ 

We infer a causal relationship by selecting a discrete causal model according to the following equation:

$$\hat{M}(z^n) = \operatorname*{argmin}_{M \in \mathcal{M}} \mathcal{L}^d(z^n; M), \tag{7}$$

where  $\mathcal{L}^d(z^n; M)$  is a universal codelength of the discrete data  $z^n$  for the discrete causal model M, and we employ NML code to compute the codelength.  $\mathcal{M}$  is a set of model candidates,  $\mathcal{M} = \{M_{X \to Y}, M_{X \leftarrow Y}, M_{X \perp Y}, M_{X \leftarrow C \to Y}\}$ . We can also set  $\mathcal{M}$  to be its subset, such as  $\{M_{X \to Y}, M_{X \leftarrow Y}\}$ , based on the prior knowledge. The algorithm for discrete case is shown in Algorithm 1.

We calculate  $\mathcal{L}^d(z^n; M)$  for  $M_{X \perp \!\!\!\perp Y}$  and  $M_{X \leftarrow C \rightarrow Y}$  using exact NML codes. For  $M_{X \rightarrow Y}$  and  $M_{X \leftarrow Y}$ , we employ two-stage coding based on the NML code since it is hard to exactly calculate the codelength of the NML code because functions f and g are not fixed. For  $M_{X \rightarrow Y}$ , we compute the codelength based on two-stage coding with respect to function f as follows:

$$\mathcal{L}^d(z^n; M_{X \to Y}) = L(f; M_{X \to Y}) + L(z^n; M_{X \to Y}, f), \tag{8}$$

The first term on the right-hand side is a codelength required to encode a function f, and the second term represents the NML codelength for the model  $M_{X\to Y}$  with function f fixed. The same applies to  $M_{X\leftarrow Y}$ . The forms of each codelength are provided in Proposition 1. We provide its proof in Appendix B.

**Proposition 1** (NML-based codelength for discrete data). For a given discrete data  $z^n$  and the discrete causal models  $M \in \{M_{X \perp \perp Y}, M_{X \rightarrow Y}, M_{X \leftarrow Y}, M_{X \leftarrow C \rightarrow Y}\}$ , the codelengths defined as above have the following expressions:

where

$$\ell_X = -\sum_{k=0}^{m_X - 1} n(X = k) \log \frac{n(X = k)}{n},$$
  
$$\ell_{Y|X}(f) = -\sum_{k'=0}^{m_Y - 1} n(Y = f(X) + k') \log \frac{n(Y = f(X) + k')}{n},$$

$$\ell_{X,Y} = -\sum_{k=0}^{m_X-1} \sum_{k'=0}^{m_Y-1} n \left( X = k, Y = k' \right) \log \frac{n \left( X = k, Y = k' \right)}{n},$$

and similarity for  $\ell_Y$  and  $\ell_{X|Y}$ . Here,  $\hat{f}$  and  $\hat{g}$  are functions derived through maximum likelihood estimation.

Proposition 1 shows that while  $M_{X\leftarrow C\rightarrow Y}$  is the most expressive model and the negative log-likelihood of the data is always minimized in  $M_{X\leftarrow C\rightarrow Y}$ , its parametric complexity is the largest among all models. Therefore, by employing NML-based codelength as shown in Eq. (9), we can compare between models with varies capacities as per Eq. (7) under the trade-off between data likelihood and model complexity.

The algorithm for estimation of function  $\hat{f}$  or  $\hat{g}$  is shown in Algorithm 4 in Appendix A.

#### Continuous Case:

Algori	thm 2 Main function in Continuous Case
Input:	Data $z^n$ , a set of model candidates $\mathcal{M}$ , and candidates $\mathcal{P}$ for bin numbers $m_{\mathcal{P}}$
	and $m_Y$
Outpu	<b>t:</b> Best model $\hat{M}$
1: <b>for</b>	$(m_X, m_Y)$ in $\mathcal{P}$ do
2:	for $M$ in $\mathcal{M}$ do
3:	Compute $\mathcal{L}^{c}(z^{n}, m_{X}, m_{Y}; M)$ using (13)
4: <b>ret</b>	<b>urn</b> $\hat{M} = \operatorname{argmin}_{M \in \mathcal{M}} \min_{(m_X, m_Y) \in \mathcal{P}} \mathcal{L}^c(z^n, m_X, m_Y; M)$

We infer a causal relationship by selecting a continuous causal model M according to the following equation:

$$\hat{M}(z^n) = \underset{M \in \mathcal{M}}{\operatorname{argmin}} \min_{(m_X, m_Y) \in \mathcal{P}} \mathcal{L}^c(z^n, m_X, m_Y; M).$$
(10)

Here,  $\mathcal{L}^{c}(z^{n}, m_{X}, m_{Y}; M)$  is a codelength of data  $z^{n}$  required to encode  $z^{n}$  up to an arbitrarily precision  $\delta > 0$ . In order to construct a universal code of  $z^{n}$  under causal model M, we employ two-stage coding for  $m_{X}, m_{Y}$  as follows:

$$\mathcal{L}^{c}(z^{n}, m_{X}, m_{Y}; M) = L(m_{X}, m_{Y}; M) + L(z^{n}; M, m_{X}, m_{Y}),$$
(11)

where  $L(m_X, m_Y; M)$  is the codelength required to encode the numbers of bins  $m_X$  and  $m_Y$ . The second term,  $L(z^n; M, m_X, m_Y)$ , represents codelengths for encoding  $z^n$  based on continuous models of corresponding bin sizes,  $M_{X \perp \perp Y}^{m_X, m_Y}, M_{X \leftarrow C \rightarrow Y}^{m_X, m_Y}, \text{ or } M_{X \leftarrow Y}^{m_X, m_Y}$ . In order to encode  $z^n = (x^n, y^n)$  with the precision  $\delta$ , we again employ two-

In order to encode  $z^n = (x^n, y^n)$  with the precision  $\delta$ , we again employ twopart coding through  $\operatorname{disc}(x^n; m_X)$  and  $\operatorname{disc}(y^n; m_Y)$ . Here, we define  $\operatorname{disc} : \mathcal{X}^n \to \{0, \ldots, m_X - 1\}^n$  as a function that discretizes continuous data  $x^n \in \mathcal{X}$  into  $m_X$ equal categories. Note that the discretized data is encoded by the strategy mentioned

above as in discrete case. After the discretized data is encoded, additional codelength are required to attain the prespecified precision level. This additional codelength is denoted by  $L(x^n; \operatorname{disc}(x^n; m_X))$  or  $L(y^n; \operatorname{disc}(y^n; m_Y))$ . Thus, the second term in Eq. (11) has the following expression.

$$L(z^{n}; M, m_{X}, m_{Y}) = \mathcal{L}^{d}(\operatorname{disc}(x^{n}; m_{X}), \operatorname{disc}(y^{n}; m_{Y}); \operatorname{DISC}(M; m_{X}, m_{Y})) + L(x^{n}; \operatorname{disc}(x^{n}; m_{X})) + L(y^{n}; \operatorname{disc}(y^{n}; m_{Y})),$$
(12)

where  $\text{DISC}(M; m_X, m_Y)$  denotes the discrete causal model of causality  $M \in \mathcal{M}$  with the category numbers  $m_X$  and  $m_Y$ . Consequently, the form of each codelength have an expression as provided in Proposition 2. We provide its proof in Appendix C. **Proposition 2** (Codelength in Continuous Case). The codelength of data  $z^n$  required to encode  $z^n$  as described above has the following expression:

$$\mathcal{L}^{c}(z^{n}; M) = \mathcal{L}^{d}(\operatorname{disc}(x^{n}; m_{X}), \operatorname{disc}(y^{n}; m_{Y}); \operatorname{DISC}(M; m_{X}, m_{Y}))$$
(13)  
+  $L^{c \to d}(m_{X}, n) + L^{c \to d}(m_{Y}, n) + \operatorname{const.},$ 

where the first term on the right-hand side in Eq. (13) can be calculated using Eq. (9) in Proposition 1 and  $L^{c \to d}(m, n)$  for  $m \in \mathbb{N}^+$  is defined as:

$$L^{c \to d}(m, n) = -n \log m + \log^* m, \tag{14}$$

where  $\log^* m$  is given by Rissanen's universal integer coding [27]

$$\log^* m = \log c + \log m + \log \log m + \dots \quad (c \approx 2.865), \tag{15}$$

where the summation is only taken over nonnegative terms. The constant term only depends on the precision level  $\delta$ .

The algorithm for the continuous case is presented in Algorithm 2. For computational efficiency, a practical algorithm can limit search range for  $m_X$  and  $m_Y$  to a subset  $\mathcal{P} \subset (\mathbb{N}^+)^2$ .

#### Mixed Case:

We can consider the both of mixed cases as a special case of the continuous case. If X is a continuous variable and Y is a discrete variable, we regard  $y^n = (y_i)_i$  as continuous values by mapping  $y^n$  to  $\operatorname{cont}(y^n; m_Y) = (y_i/m_Y)_i$  and calculate the description length using continuous causal models by  $\mathcal{L}^c(x^n, \operatorname{cont}(y^n), m_X, m_Y; M)$ . The causal discovery algorithm for the mixed case is presented in Algorithm 3.

# 5 Theoretical analysis of the statistical consistency

In this section, we provide the theoretical analysis on the consistency of our method. By consistency, we mean that the probability that our method select the true model converges to 1 at the limit of large n. Noting the inclusion relation in our

Algorithm 3 Main function in Mixed Case in which X is continuous

Input: Data  $z^n = (x^n, y^n)$ , a set of model candidates  $\mathcal{M}$ , search range  $\mathcal{P} \subset \mathbb{N}^+$  for  $m_X$ , and the number of categories  $m_Y$ Output: Best model  $\hat{M}$ 

1: for  $m_X$  in  $\mathcal{P}$  do

2: for M in  $\mathcal{M}$  do

3: Compute  $\mathcal{L}^{c}(x^{n}, \operatorname{cont}(y^{n}; m_{Y}), m_{X}, m_{Y}; M)$  using (13)

4: return  $\hat{M} = \operatorname{argmin}_{M \in \mathcal{M}} \min_{m_X \in \mathcal{P}} \mathcal{L}^c(x^n, \operatorname{cont}(y^n; m_Y), m_X, m_Y; M)$ 

case,  $M_{X \perp \!\!\!\perp Y}, M_{X \to Y}, M_{X \leftarrow Y} \subset M_{X \leftarrow C \to Y}$ , we consider the true model for a given probability distribution is the minimal model that contains it.

## 5.1 Discrete Case

**Theorem 1.** Define true model  $M^*(P^*)$  given as follows:

$$M^*(P^*) = \begin{cases} M_{X \perp Y} & P^* \in M_{X \perp Y} \\ M_{X \to Y} & P^* \in M_{X \to Y} \\ M_{X \leftarrow Y} & P^* \in M_{X \leftarrow Y} \\ M_{X \leftarrow C \to Y} & P^* \in M_{X \leftarrow C \to Y} \setminus (M_{X \perp Y} \cup M_{X \leftarrow Y} \cup M_{X \leftarrow Y}). \end{cases}$$

Then, the probability that CLOUD outputs  $M^*(P^*)$  given n i.i.d. samples from  $P^*$ , converges to 1 in the limit of  $n \to \infty$ , provided that the maximum likelihood estimation of  $\hat{f}$  and  $\hat{g}$  is successful.

Proof. In case of  $P^* \in M_{X \perp\!\!\perp Y}$ :

The asymptotic expansion of log-likelihood [1] implies

$$-\log P\left(z^{n}; M, \hat{\boldsymbol{\theta}}\left(z^{n}\right)\right) = nH(P^{*}) + n\mathrm{KL}(P^{*}||P) + O_{P}\left(1\right), \tag{16}$$

for all  $M \in \mathcal{M}_{all}$ . Here, H(P) denotes the entropy of P defined as

$$H(P) = -\sum_{k,k'} P(X = k, Y = k') \log P(X = k, Y = k'),$$

 $\mathrm{KL}(P^*||P)$  denotes the KL-divergence defined as

$$K(P^*||P) = \sum_{k,k'} P^*(X = k, Y = k') \frac{\log P^*(X = k, Y = k')}{\log P(X = k, Y = k')},$$

and  $O_P(\cdot)$  denotes the asymptotic order with respect to n in probability. Specifically, in case of  $M \in \{M_{X \perp \perp Y}, M_{X \leftarrow C \rightarrow Y}\}$ , the asymptotic expansion of Eq. (16) becomes

$$-\log P\left(z^{n}; M, \hat{\boldsymbol{\theta}}\left(z^{n}\right)\right) = nH(P^{*}) + O_{P}\left(1\right), \qquad (17)$$

since  $P^*$  belongs to both  $M_{X \perp Y}$  and  $M_{X \leftarrow C \rightarrow Y}$ . We see  $\log C_n(M_{X \perp Y}) < \log C_n(M_{X \leftarrow C \rightarrow Y})$ , which leads to

$$\mathcal{L}^{d}(z^{n}; M_{X \leftarrow C \to Y}) - \mathcal{L}^{d}(z^{n}; M_{X \perp Y}) = \log \mathcal{C}_{n}(M_{X \leftarrow C \to Y}) - \log \mathcal{C}_{n}(M_{X \perp Y}) + O_{P}(1)$$
$$= \Omega(\log n) + O_{P}(1).$$

Thus, the probability that  $M_{X\leftarrow C\to Y}$  achieves the smallest codelength converges to 0. As for  $M \in \{M_{X\to Y}, M_{X\leftarrow Y}\}$ , the negative log-likelihood function in the first term in Eq. (2) divided by n converges to

$$-\frac{1}{n}\log P(z^{n};\boldsymbol{\theta}) = -\sum_{k,k'} \frac{n(X=k,Y=k')}{n}\log P(X=k,Y=k';\boldsymbol{\theta})$$
$$= -\sum_{k,k'} \theta^{*}_{k,k'}\log P(X=k,Y=k';\boldsymbol{\theta}) + o_{P}(1)$$
(18)

# In case of $P^* \in M_{X \to Y}$ or $P^* \in M_{X \leftarrow Y}$ :

By the symmetry, we restrict ourselves to the case of  $P^* \in M_{X \to Y}$  without loss of generality. Let  $\theta^*$  be a parameter such that  $P^*(X,Y) = P(X,Y;\theta^*)$ . The first term of Eq. (2) for both  $M_{X \to Y}$  and  $M_{X \leftarrow C \to Y}$  converges to  $-\log P(z^n;\theta^*) + O_P(1)$ . As for the second term, we see  $\log C_n(M_{X \to Y}) < \log C_n(M_{X \leftarrow C \to Y})$ , which leads to

$$\mathcal{L}^{d}(z^{n}; M_{X \leftarrow C \to Y}) - \mathcal{L}^{d}(z^{n}; M_{X \to Y}) = \log \mathcal{C}_{n}(M_{X \leftarrow C \to Y}) - \log \mathcal{C}_{n}(M_{X \to Y}) + O_{P}(1)$$
$$= \Omega(\log n) + O_{P}(1).$$

Therefore, the probability that  $M_{X\leftarrow C\to Y}$  achieves the smallest codelength converges to 0. As discussed in the case above, the negative log-likelihood function in the first term in Eq. (2) divided by *n* converges to strictly larger value than  $H(P^*)$  if  $M \in \{M_{X\perp LY}, M_{X\leftarrow Y}\}$ . The difference between the first terms gets dominant as mentioned above. Hence, the probability that  $\mathcal{L}^d(z^n; M_{X\to Y})$  is shortest converges to 1.

In case of  $P^* \in M_{X \leftarrow C \rightarrow Y} \setminus (M_{X \leftarrow Y} \cup M_{X \leftarrow Y} \cup \cup M_{X \perp Y})$ :

As discussed in the case above, the negative log-likelihood function in the first term in Eq. (2) divided by n converges to strictly larger value than  $H(P^*)$  if  $M \neq M_{X \leftarrow C \rightarrow Y}$ . Since the first term is dominant as mentioned in above, the probability that  $M_{X \leftarrow C \rightarrow Y}$  will be selected converges to 1 as  $n \rightarrow \infty$ .

#### 5.2 Continuous Case

**Theorem 2.** Let  $\mathcal{P}$  be a finite set so that  $\cup_{(m_X, m_Y) \in \mathcal{P}} \mathsf{HIS}^{m_X, m_Y} = \mathsf{HIS}^{\bar{m}_X, \bar{m}_Y}$  holds for some  $(\bar{m}_X, \bar{m}_Y) \in \mathcal{P}$ . For true distribution  $p^*$ , we define  $p^*_{m_X, m_Y} \in \mathsf{HIS}^{m_X, m_Y}$  as follows:

$$p_{m_X,m_Y}^*(x,y) = \frac{\iint_{(x',y')\in I(x,y)} p^*(x',y')dx'dy'}{m_X m_Y},$$

where  $I(x, y) = I_k^X \times I_{k'}^Y$  such that  $x \in I_k^X$  and  $y \in I_{k'}^Y$  holds. Then we define true model  $M^*(p^*)$  as follows:

$$M^{*}(p^{*}) = \begin{cases} M_{X \perp Y} & p_{\bar{m}_{X}, \bar{m}_{Y}}^{*} \in M_{X \perp Y} \\ M_{X \rightarrow Y} & p_{\bar{m}_{X}, \bar{m}_{Y}}^{*} \in M_{X \rightarrow Y} \\ M_{X \leftarrow Y} & p_{\bar{m}_{X}, \bar{m}_{Y}}^{*} \in M_{X \leftarrow Y} \\ M_{X \leftarrow C \rightarrow Y} & p_{\bar{m}_{X}, \bar{m}_{Y}}^{*} \in M_{X \leftarrow C \rightarrow Y} \setminus (M_{X \perp Y} \cup M_{X \leftarrow Y} \cup M_{X \leftarrow Y}). \end{cases}$$

Then, the probability that CLOUD outputs  $M^*(p^*)$  using  $\mathcal{P}$  and n i.i.d. samples from  $p^*$  converges to 1 in the limit of  $n \to \infty$ , provided that the maximum likelihood estimation of  $\hat{f}$  and  $\hat{g}$  is successful.

*Proof.* From the definition of  $\mathcal{L}^{c}(z^{n}, m_{X}, m_{Y}; M)$  in Eq. (13), we see

$$\mathcal{L}^{c}(z^{n}, m_{X}, m_{Y}; M)$$

$$= \mathcal{L}^{d}(\operatorname{disc}(x^{n}; m_{X}), \operatorname{disc}(y^{n}; m_{Y}); \operatorname{DISC}(M; m_{X}, m_{Y})) - n \log m_{X} m_{Y} + \operatorname{const.}$$

$$= \min_{P \in \operatorname{DISC}(M; m_{X}, m_{Y})} - \log P(\operatorname{disc}(x^{n}; m_{X}), \operatorname{disc}(y^{n}; m_{Y})) + \mathcal{C}_{n}(\operatorname{DISC}(M; m_{X}, m_{Y}))$$

$$- n \log m_{X} m_{Y} + \operatorname{const.}$$
(19)

For fixed  $\hat{P} \in \text{DISC}(M, m_X, m_Y)$ , there is a corresponding density function  $\hat{p} \in M^{m_X, m_Y} \subset \text{HIS}^{m_X, m_Y}$  such that  $m_X m_Y \hat{P}(\text{disc}(x^n; m_X), \text{disc}(y^n; m_Y)) = \hat{p}(x^n, y^n)$  for all  $x^n$  and  $y^n$ . Using this correspondence, we see the following expansion in probability:

$$-\log \hat{P}(\operatorname{disc}(x^{n}; m_{X}), \operatorname{disc}(y^{n}; m_{Y})) - n\log m_{X}m_{Y} = -\log \hat{p}(z^{n})$$
  
=  $nH(p^{*}) + n\operatorname{KL}(p^{*} || \hat{p}) + O_{P}(1),$   
(20)

where  $H(p)=\iint p(x,y)\log\frac{1}{p(x,y)}dxdy$  and  $\mathrm{KL}(p||p')=\iint p(x,y)(\log p(x,y)-\log p'(x,y))dxdy.$  We thus obtain

$$\mathcal{L}^{c}(z^{n}, m_{X}, m_{Y}; M) = nH(p^{*}) + n \min_{\hat{p} \in M^{m_{X}, m_{Y}}} \operatorname{KL}(p^{*} \| \hat{p}) + \mathcal{C}_{n}(\operatorname{DISC}(M; m_{X}, m_{Y})) + O_{P}(1).$$

From the assumption on  $\mathcal{P}$ , we further obtain

$$\min_{\substack{(m_X,m_Y)\in\mathcal{P}}} \mathcal{L}^c(z^n, m_X, m_Y; M) 
= nH(p^*) + n \min_{\substack{(m_X,m_Y)\in\mathcal{P}\ \hat{p}\in M^{m_X,m_Y}}} \operatorname{KL}(p^* \| \, \hat{p}) + \mathcal{C}_n(\operatorname{DISC}(M; m_X, m_Y)) + O_P(1) 
= nH(p^*) + n \min_{\hat{p}\in M^{\bar{m}_X,\bar{m}_Y}} \operatorname{KL}(p^* \| \, \hat{p}) + \mathcal{C}_n(\operatorname{DISC}(M; \bar{m}_X, \bar{m}_Y)) + O_P(1).$$

For any  $\hat{p} \in \mathsf{HIS}^{m_X, m_Y}$ , we see

$$\begin{split} \operatorname{KL}(p^* \parallel \hat{p}) \\ &= \sum_{k,k'} \iint_{(x,y) \in I_k^X \times I_{k'}^Y} p^*(x,y) \left( \log \frac{p^*(x,y)}{p_{m_X,m_Y}^*(x,y)} + \log \frac{p_{m_X,m_Y}^*(x,y)}{\hat{p}(x,y)} \right) dxdy \\ &= \operatorname{KL}(p^* \parallel p_{m_X,m_Y}^*) + \sum_{k,k'} \iint_{(x,y) \in I_k^X \times I_{k'}^Y} p^*(x,y) \left( \log \frac{p_{m_X,m_Y}^*(x,y)}{\hat{p}(x,y)} \right) dxdy \\ &= \operatorname{KL}(p^* \parallel p_{m_X,m_Y}^*) + \sum_{k,k'} \iint_{(x,y) \in I_k^X \times I_{k'}^Y} p_{m_X,m_Y}^*(x,y) \left( \log \frac{p_{m_X,m_Y}^*(x,y)}{\hat{p}(x,y)} \right) dxdy \\ &= \operatorname{KL}(p^* \parallel p_{m_X,m_Y}^*) + \sum_{k,k'} \iint_{(x,y) \in I_k^X \times I_{k'}^Y} p_{m_X,m_Y}^*(x,y) \left( \log \frac{p_{m_X,m_Y}^*(x,y)}{\hat{p}(x,y)} \right) dxdy \\ &= \operatorname{KL}(p^* \parallel p_{m_X,m_Y}^*) + \operatorname{KL}(p_{m_X,m_Y}^* \parallel \hat{p}). \end{split}$$

The third equality holds since  $\left(\log p_{m_X,m_Y}^*(x,y) - \log \hat{p}(x,y)\right)$  is constant for all  $(x,y) \in I_k^X \times I_{k'}^Y$  and  $\iint_{(x,y)\in I_k^X \times I_{k'}^Y} p^*(x,y) dx dy = \iint_{(x,y)\in I_k^X \times I_{k'}^Y} p_{m_X,m_Y}^*(x,y) dx dy$ . Therefore,  $\hat{p}_{m_X,m_Y}^*$  is a unique minimizer of  $\operatorname{KL}(p^* \parallel \hat{p})$ , which implies that

$$\min_{(m_X, m_Y)\in\mathcal{P}} \mathcal{L}^c(z^n, m_X, m_Y; M) = nH(p^*) + n\mathrm{KL}(p^* \parallel p^*_{\bar{m}_X, \bar{m}_Y}) + \mathcal{C}_n(\mathrm{DISC}(M; \bar{m}_X, \bar{m}_Y)) + O_P(1).$$

for M such that  $p^*_{\bar{m}_X,\bar{m}_Y}\in M.$  If  $p^*_{\bar{m}_X,\bar{m}_Y}\notin M$  otherwise, we see

$$\min_{(m_X,m_Y)\in\mathcal{P}} \mathcal{L}^c(z^n, m_X, m_Y; M) - \min_{(m_X,m_Y)\in\mathcal{P}} \mathcal{L}^c(z^n, m_X, m_Y; M_{X\leftarrow C\to Y}) 
= \min_{(m_X,m_Y)\in\mathcal{P}} \mathcal{L}^c(z^n, m_X, m_Y; M) - nH(p^*) - n\text{KL}(p^* || p^*_{\bar{m}_X, \bar{m}_Y}) + o_P(n) 
= \min_{\hat{p}\in M^{\bar{m}_X, \bar{m}_Y}} n\text{KL}(p^*_{\bar{m}_X, \bar{m}_Y} || \hat{p}) + o_P(n),$$

since it always holds  $p_{\bar{m}_X,\bar{m}_Y}^* \in M_{X\leftarrow C\to Y}$ . This implies that the probability that M is chosen converges to 0. The consistency among models in which  $p_{\bar{m}_X,\bar{m}_Y}^* \in M$  follows similarly as that of CLOUD in the discrete case.

# 6 Experiment

In this section, we demonstrate that 1) our proposed method CLOUD can solve the Reichenbach problem in situations where it is difficult to make assumptions about unobserved common causes, and 2) CLOUD shows higher inference accuracy in identifying causal relationships compared to existing methods, even when the true data-generating mechanism violates the assumptions of our method.

In the first experiment, we designed the Reichenbach problem scenarios with all set of synthetic data types — discrete, mixed, and continuous, and verified that our proposed method exhibits high accuracy and consistency in solving the problem. In particular, it effectively detects the presence of unobserved common causes C even in situations where the observed variables X, Y are generated from complex mechanisms f(X, C), g(Y, C).

In the second experiment, we compared the performance of our proposed method against existing methods in identifying causal relationships in synthetic data generated from either  $M_{X\to Y}$  or  $M_{X\leftarrow C\to Y}$ , and demonstrated its effectiveness.

The third experiment tested the ability of our proposed method to determine the directions of causality and detect unobserved common causes in real-world data generated from unknown and complex data-generating process.

We implemented CLOUD in Python and provide the source code at https://github.com/Matsushima-lab/CLOUD.

## 6.1 Consistency of **CLOUD** on the Reichenbach problem

In the first experiment, we verified the performance of CLOUD on the Reichenbach problem with synthetic data and confirmed its consistency in model selection. We randomly selected each SCM corresponding to the four causal relationships, and then generated data  $z^n$  with sample size  $n = 10^2, 10^3, 10^4$ . The data-generating processes for each combination were defined as follows:

#### Discrete Case:

#### • $M_{X \perp \!\!\!\perp Y}$ :

X and Y were independently generated from categorical distributions.

•  $M_{X \leftarrow C \rightarrow Y}$ :

 $C \in \{0, 1, \ldots, 99\}$  was independently generated from a categorical distribution, and X and Y were set to the quotient and remainder of C divided by 10, respectively.

•  $M_{X \to Y}$ :

X and  $E_Y$  were independently generated from categorical distributions, f was generated uniformly randomly from all non-constant functions, and subsequently Y was set to  $Y = f(X) + E_Y \pmod{10}$ . The same applied to the case of  $M_{X \leftarrow Y}$ .

#### Mixed Case (X is continuous and Y is discrete):

•  $M_{X \perp \!\!\!\perp Y}$ :

X was independently generated from a Gaussian distribution, and Y from a categorical distribution.

•  $M_{X \leftarrow C \rightarrow Y}$ :

 $C \in \{0, 1, \ldots, 99\}$  was independently generated from a categorical distribution. X and Y were then generated as follows:  $X = b \sin C + E_X, Y = \lfloor \frac{C}{10} \rfloor$ , where b was sampled from a uniform distribution  $\mathcal{U}(2, 4)$  and  $E_X$  follows a Gaussian distribution  $\mathcal{N}(0, 0.1^2)$ .

•  $M_{X \to Y}$ :

 $\boldsymbol{X}$  was generated from a mixture of Gaussian distributions with three clusters as:

$$p(X) = 0.6 \cdot \mathcal{N}(X; -5, 2^2) + 0.2 \cdot \mathcal{N}(X; 0, 1^2) + 0.2 \cdot \mathcal{N}(X; 5, 2^2).$$

Then, X was divided into  $m_X \sim \text{Uniform}\{2,3,4\}$  equal intervals, with  $f(X) \sim \text{Uniform}\{0,1,\ldots,10\}$  assigned to each interval. Additive noise  $E_Y \sim \text{Uniform}\{-1,0,1\}$  was added to generate Y, with addition over  $\mathbb{R}/10\mathbb{Z}$ . The correlation coefficient was ensured to be greater than 0.2.

•  $M_{X \leftarrow Y}$ :

Y was generated from an  $m_Y$ -valued categorical distribution, and then X was set to  $X = 2Y + 3 \sin Y + E_Y$ , where  $m_Y$  was generated from uniform distribution Uniform  $\{2, 3, \ldots, 8\}$  and  $E_Y \sim \mathcal{N}(0, 1)$ , with addition taken over  $\mathbb{R}/20\mathbb{Z}$ .

#### Continuous Case:

•  $M_{X \perp \!\! \perp Y}$ :

X and Y were independently generated from Gaussian distributions.

•  $M_{X \leftarrow C \rightarrow Y}$ :

X and Y were generated based on an ellipse equation with eccentricity e and semi-major axis a:  $r = \frac{a(1-e^2)}{1+e\cos(\phi)}$  with  $0 \le \phi < 2\pi$  In this process, we sampled e from  $\mathcal{U}(0.5, 0.9)$  and a from Uniform $\{1, 2, 3\}$ . X and Y were then set to  $X = r\cos(\phi + \eta) + E_X, Y = r\sin(\phi + \eta) + E_Y(0 \le \phi \le 2\pi)$ , where  $\eta$  were sampled from  $\mathcal{U}(\pi/4, \pi/3)$ , and  $E_X$  and  $E_Y$  follow  $\mathcal{N}(0, (0.1a)^2)$ .

•  $M_{X \to Y}$ :

X was generated from a probability density function of a mixture Gaussian distribution with three clusters. Then Y was set to  $Y = a*disc(X, m_X)+b+E_Y$ , where  $m_X \sim \text{Uniform}\{2,3,4\}, a \sim \mathcal{U}(4,7), b \sim \mathcal{U}(1,5), E_Y \sim \mathcal{N}(0,1)$ , with addition taken over  $\mathbb{R}/20\mathbb{Z}$ . The procedure for the  $M_{X\leftarrow Y}$  was analogous.

Table 1 shows the transition of accuracy as a fraction of correct inference with sample size n. Figures 1, 2, and 3 visualize the inference results of CLOUD as confusion matrices for each data type. These indicate that accuracy improves as n increases. In all cases, the accuracy reaches ~100% at n = 10000. We thus empirically observed the consistency of CLOUD.

CLOUD calculates the codelength of the observed data for each causal model and selects the one that achieves the shortest codelength. Therefore, we can expect that our method is more confident in its inference when the difference in the codelengths

Table 1Results on experiment 1

Fig. 2 Confusion matrices in the Mixed Case of Experiment 1

between the shortest one and the rest is larger. The next experiment examined whether the difference in the codelengths per sample size of the shortest and the second shortest model, denoted as  $\Delta$ , can be interpreted as the confidence of CLOUD. We generated 1000 synthetic datasets from discrete causal models and calculated the accuracy at each decision rate d. The accuracy at decision rate d is defined as the accuracy at the upper d% of datasets when datasets are sorted in descending order of  $\Delta$ . The result

Fig. 3 Confusion matrices in the Continuous Case of Experiment 1  $\,$ 

is shown in Fig 4. For each model, the accuracy is higher when the decision rate is smaller, i.e.,  $\Delta s$  are larger. We thus conclude that  $\Delta$  is interpreted as the confidence of the inference in CLOUD.

Fig. 4 Accuracy vs. decision rate of CLOUD on synthetic data

# 6.2 Comparison to existing methods in case of $X \to Y$ and $X \leftarrow C \to Y$

In the second experiment, we compared the accuracy of out proposed method CLOUD with existing methods in two scenarios where the ground truth of the causal relationship is either  $X \to Y$  or  $X \leftarrow C \to Y$ . This comparison aimed to evaluate CLOUD's performance in identifying the direction of causality and in detecting unobserved common causes. We set the sample size at n = 500. For each SCM, synthetic datasets  $z^{n=500} = x^{n=500} \times y^{n=500}$  were generated 100 times. The accuracy was determined by calculating the proportion of correctly identified causal relationships across these iterations.

To verify the cases where the true data-generating process violates the assumptions of our models, for  $M_{X \to Y}$ , we employ a non-cyclic ANM in which addition is taken without modulo operation:

• Discrete Case

X and  $E_Y$  were randomly and independently generated from categorical distributions, and Y was set to  $Y = f(X) + E_Y$  with a mapping function f that was also randomly set.

• Mixed Case [X is continuous and Y is discrete]

X was generated from  $\mathcal{N}(0, 10^2)$ , and then X was divided into  $m_X \sim$ Uniform $\{2, 3, 4\}$  equal intervals. For each interval, a value  $f(X) \sim$ Uniform $\{1, 2, \ldots, 24\}$  was randomly assigned, and additive noise  $E_Y \sim$ Uniform $\{-1, 0, 1\}$  was added to generate Y.

• Continuous Case

X was generated from a three-class mixture Gaussian distribution as in Experiment 1, and Y was generated from  $Y = af(X) + b\sin 2\pi X + E_Y$ , where  $a, b \sim \mathcal{U}([-2, -0.5] \cup [0.5, 2])$ , and  $E_Y \sim \mathcal{N}(0, 1)$ . For the function f(X), we considered two cases: one linear and the other a cubic function  $x^3$ .

In the case where  $M_{X \leftarrow C \rightarrow Y}$  is the ground truth, the same process used in Experiment 1 was used.

For existing methods, we employed ECI [11], DR [23], CISC [2], ACID [3], LiM [39], HCM [14], LiNGAM [33], ANM [24], RCD [16], CAMUV [17], BUPL [37], and COCA [9]. These methods are categorized into those that can detect  $M_{X\leftarrow C\to Y}$  and those that cannot. While ECI, DR, CISC, ACID, LiM, HCM, LiNGAM, and ANM distinguish between  $M_{X\to Y}$  and  $M_{X\leftarrow Y}$ , RCD, CAMUV, and BUPL infer a causal model from a set of model candidates including  $M_{X\leftarrow C\to Y}$ . Moreover, COCA selects a model only from  $\mathcal{M} = \{M_{X\to Y}, M_{X\leftarrow C\to Y}\}$ . We note that our proposed method CLOUD as well as LiM and HCM can accept all type of data, wheres others specialize for either discrete or continuous data.

We utilized the implementations of HCM by Li et al. (2022), COCA by Kaltenpoth et al. (2019), and others by Ikeuchi et al. (2023). Default hyper parameter values were used.

Results are shown in Table 2. Unlike existing methods, CLOUD is applicable to all experimental conditions. In particular, CLOUD is the first method capable of detecting unobserved common causes in discrete and mixed cases. As Table 2 demonstrates, CLOUD showed consistently high inference accuracy across all cases, regardless of the data type, even though the number of model candidates of CLOUD is as many as 4 models. Especially, CLOUD outperformed previous methods in the discrete case.

#### 6.3 Real World Data

#### 6.3.1 Direct case: Tübingen Benchmark Pairs

In this section, we examined the effectiveness of CLOUD of inferring direct causality in data generated from complex causal mechanisms by real-world datasets.

We employed datasets in various application fields from the Tübingen Cause-Effect Pairs Database [19], which provides a collection of datasets for testing causal discovery

Table 2	Results	on	experiment	2

Performance comparison of CLOUD against existing methods w.r.t. accuracy in the discrete case (disc.), mixed case (mix.) and continuous case (cont.) based on synthetic data generated either from direct case or confounded case.  $|\mathcal{M}|$  column denotes the number of model candidates each method considers, and C one represents whether each method allows for the existence of unobserved common causes or not (\*: Yes, -: No)

methods. The database contains datasets with known ground truth to distinguish between cause and effect variables. We note that the ground truth does not mean there are no unobserved counfounders in general, except for dataset No.101 which was explicitly generated in an unconfounded experimental environment. The statistical information of the datasets used in the experiments is shown in Table 3, and scatter plots for each data pair are presented in Figure 5. Descriptions for each data pair are given in Appendix D.

We determined the data type for each data pair based on the information of the variables and run applicable causal discovery methods. Results are shown in Table 4. CLOUD demonstrated an excellent ability to determine the causal directions across various data types. Notable, it correctly identified the causal directions in every case both in mixed and continuous cases. While LiM and HCM are applicable across all cases, CLOUD achieved the highest number of correct answers.

In discrete case, CLOUD showed performance comparable to CISC, a state-of-theart causal discovery method for discrete data. CLOUD also correctly inferred the right directions with high confidence (large  $\Delta$ ) for cases No.47 and No.68, where LiM and HCM were incorrect. Notably, in case No.107, CLOUD detected the presence of a confounding factor (indicated as 'conf') rather than a clear causal direction. This is a crucial feature in real-world data analysis involving potential confounding variables.

Table 3 Characteristics of Tübingen Cause-Effect-Pairs

Dataset	Data-type	n	Ground Truth	X	Y
No. 47	disc.	254	$X \leftarrow Y$	number of cars	working days or not
No. 68	disc.	498	$X \leftarrow Y$	bytes sent at minute	open http connections
No. 107	disc.	240	$X \to Y$	contrast	answer correct or not
No. 85	mix.	994	$X \to Y$	day	protein content of the milk
No. 95	mix.	9504	$X \to Y$	hour of the day	total electricity consumption
No. 99	mix.	2287	$X \leftarrow Y$	language test score	social-economic status
No. 23	cont.	452	$X \to Y$	age	weight
No. 77	cont.	8401	$X \leftarrow Y$	daily average temperature	solar radiation
No. 101	cont.	300	$X \to Y$	grey value of a pixel	light intensity

In continuous case, CLOUD successfully identified the causal directions across all pairs, despite having four model candidates. In contrast, RCD, CAMUV, and BUPL, which also have  $|\mathcal{M}| = 4$ , frequently resulted in the 'conf' (confounded) classification. This tendency suggests a bias in these methods towards indicating confounded-ness rather than directly identifying causality. Particularly, it would be incorrect to conclude the presence of confounders in dataset No.101 mentioned above.

Overall, the results from the Tübingen Benchmark Pairs suggests that CLOUD is a reliable causal discovery method to identify the true causal direction, particularly in the situations involving complex data-generating process across all data types.

#### 6.3.2 Confounded case: SOS DNA Repair Network Dataset

Finally, we tested CLOUD's ability of detecting latent confounding variables in complex causal relationships using SOS DNA repair network in E.coli [30]. This dataset describes the causal relationships at the protein level between genes, consisting of measurements for eight different genes under four distinct ultraviolet radiation conditions, with a total sample size of n = 200. A ground truth network, as established by [21], is depicted in Fig. 6. The gene lexA has causal influence on all other genes, creating a situation where at least lexA is an unobserved common cause among variables downstream (children) of lexA. Therefore, we randomly selected pairs of child nodes of lexA and conducted experiments to detect the presence of an unobserved common cause (lexA) between each pair. We also note that while the experimental setup correctly represent confounded case, the correct directed cases could not be extracted, such as the arrow from lexA to umuDC. This is because there might be common causes between the two.

For comparison, we employed RCD, CAMUV, BUPL, and COCA, which are capable of inferring  $M_{X\leftarrow C\to Y}$ . Since COCA considers asymmetry between X and Y, we conducted experiments in two settings: one with  $\mathcal{M} = \{M_{X\to Y}, M_{X\leftarrow C\to Y}\}$  (referred to as  $COCA(X \to Y)$ ) and another with  $\mathcal{M} = \{M_{X\leftarrow Y}, M_{X\leftarrow C\to Y}\}$  (referred to as  $COCA(X \leftarrow Y)$ ).

Fig. 5 Scatter plots of the Tübingen Cause-Effect Pairs. The horizontal axis represents X, while the vertical axis represents Y. Each plot corresponds to a dataset pair.

The results are shown in Table 5. For the pairs (polB, umuDC) and (uvrD, uvrA), the methods CLOUD, RCD, and CAMUV successfully identified the presence of unobserved common causes. However, for the pair (uvrY, ruvA), only COCA detected the unobserved common cause. We observed that CLOUD inferred causal independence for this pair, likely due to ruvA exhibiting zero-inflation and the statistical independence of the pair.

CLOUD demonstrated performance comparable to existing state-of-the-art methods that allow for unobserved common causes.

Given the prevalence of unobserved confounders in real-world applications, which can lead to incorrect causal conclusions if not properly addressed, we can conclude that CLOUD is equipped with a crucial feature for handling such scenarios. Moreover, considering the results from the Tübingen Benchmark Pairs as well, as presented in Table 4, we further affirm that CLOUD is a reliable method for real-world data analysis.

 $\checkmark$  indicates that a method inferred  $M_{X\leftarrow C\rightarrow Y},$  while  $\times$  indicates that a method did not.

# 7 Conclusion

This paper proposed CLOUD, a novel causal discovery method for causal relationships between two variables with unobserved common causes across discrete, mixed, and continuous data types.

Based on the Reichenbach's common cause principle, we defined the Reichenbach problem as a problem to statistically infer the causal relationships among four models: one independent model, one with unobserved common cause, and two models with direct causality.

Fig. 6 Ground truth graph of SOS DNA repair network

Fig. 7 Scatter plots of variable pairs from the SOS DNA repair network dataset

By employing the NML code, CLOUD offers a model selection approach to solve the Reichenbach problem without relying on assumptions about unobserved common causes. CLOUD formulates four models for each causal relationship and data-type. In particular, CLOUD expresses all joint distributions of X and Y under  $M_{X\leftarrow C\rightarrow Y}$ , which enables us to avoid explicitly modeling C. CLOUD calculates the NML-based codelength of the observational data under those four models and then infers a causal relationship by selecting the corresponding causal model that achieves the shortest codelength. We successfully extended the CLOUD from discrete to continuous data, through discretization. CLOUD has a consistency with respect to selected models and it is theoretically proven.

Through both synthetic and real-world data experiments, CLOUD has proven its effectiveness in solving the Reichenbach problem with high accuracy and consistency. It stands out in its ability to identify causal directions with greater precision than existing methods, across a variety of data types and under complex data-generating

conditions. Additionally, CLOUD has demonstrated a strong performance in detecting latent variables, showcasing its robustness and reliability in causal discovery.

However, challenges remain, as evidenced by its performance on zero-inflated data in our final experiment where CLOUD mistakenly determined they are causally independent. This implies the applicable range of CLOUD is still restricted, despite its ability to detect unobserved common causes without additional assumptions on it. Moreover, Additive Noise Model which we assume has known to be vulnerable in handling data with heteroscedastic noise, i.e noise variances are dependent of observed variables unlike ANM's assumption. Recent research is actively addressing these challenges [4, 36, 38].

Future work aims to broaden CLOUD's scope, addressing its current SCM assumptions to enhance robustness and applicability across diverse data scenarios.

# Appendix AOptimization of f and g through<br/>Likelihood Maximization

The algorithm for estimating the function  $\hat{f}$  is shown in the Algorithm 4. In order to compute both terms in Eq. (8), we must estimate  $\hat{f}: \mathcal{X} \to \mathcal{Y}$  that achieves a higher likelihood to calculate a shorter codelength of data under  $M_{X \to Y}$ . First, we initialize the function  $\hat{f}$  that returns the most frequent y for each  $x \in \mathcal{X}$  (lines 1-3). Subsequently, we iteratively update the function value for  $x \in \mathcal{X}$ . At j-th step, we update the function value f(x) while fixing all other mapping f(x') for  $x' \neq x$  and check if the likelihood increases. If it increases, we change the value f(x) to new y. This update is done for all  $x \in \mathcal{X}$  and repeated until the likelihood no longer increases or for at most J times. Similarly, the function  $g: \mathcal{Y} \to \mathcal{X}$  can be estimated by replacing X and Y in algorithm 4.

# Appendix B Proof of Proposition 1

In this section, we provide the proof for Proposition 1.

# B.1 Independent Case

We exactly calculate the stochastic complexity defined in Eq. (2) for causal models  $M_{X \perp \perp Y}$ :

$$\mathcal{L}^{d}(z^{n}; M_{X \perp \!\!\!\!\perp Y})$$
  
=  $\mathcal{SC}(z^{n}; M_{X \perp \!\!\!\perp Y})$   
=  $-\log P(z^{n}; M_{X \perp \!\!\!\!\perp Y}, \hat{\boldsymbol{\theta}}_{X \perp \!\!\!\perp Y}(z^{n})) + \log \mathcal{C}_{n}(M_{X \perp \!\!\!\!\perp Y})$ 

Using the result of likelihood estimation  $P(X = k, Y = k'; M_{X \perp \!\!\!\perp Y}, \hat{\boldsymbol{\theta}}_{X \perp \!\!\!\perp Y}(z^n)) = \frac{n(X=k)}{n} \frac{n(Y=k')}{n}$ , the maximum likelihood which the first term on the right-hand side is represented as:

$$\log P(z^n; M_{X \perp Y}, \hat{\boldsymbol{\theta}}_{X \perp Y}) = \sum_{k=0}^{m_X - 1} n(X = k) \log \frac{n(X = k)}{n} + \sum_{k'=0}^{m_Y - 1} n(Y = k') \log \frac{n(Y = k')}{n},$$

where  $\hat{\boldsymbol{\theta}}_{X \perp \perp Y} = (\hat{\theta}_{k,k'})$  is the maximum likelihood estimator in  $\boldsymbol{\Theta}_{X \perp \perp Y}$ . The parametric complexity for  $M_{X \perp \perp Y}$  as the second term is calculated as

$$\begin{split} &\log \mathcal{C}_{n}(M_{X \perp \perp Y}) \\ &= \log \sum_{Z^{n} \in \mathcal{X}^{n} \times \mathcal{Y}^{n}} \max_{\boldsymbol{\theta} \in \boldsymbol{\Theta}_{X \perp Y}} P(Z^{n}; M_{X \perp Y}, \boldsymbol{\theta}) \\ &= \log \left\{ \sum_{Z^{n}} \prod_{k=0}^{m_{X}-1} \left( \frac{n(X=k)}{n} \right)^{n(X=k)} \prod_{k'=0}^{m_{Y}-1} \left( \frac{n(Y=k')}{n} \right)^{n(Y=k')} \right\} \\ &= \log \left\{ \sum_{X^{n}} \prod_{k=0}^{m_{X}-1} \left( \frac{n(X=k)}{n} \right)^{n(X=k)} \sum_{Y^{n}} \prod_{k'=0}^{m_{Y}-1} \left( \frac{n(Y=k')}{n} \right)^{n(Y=k')} \right\} \\ &= \log \mathcal{C}_{\mathsf{CAT}}(K=m_{X}, n) + \log \mathcal{C}_{\mathsf{CAT}}(K=m_{Y}, n). \end{split}$$

Therefore, the NML codelength of the data  $z^n$  for  $M_{X \perp \downarrow Y}$  is calculated as:

$$\mathcal{L}^{d}(z^{n}; M_{X \perp \!\!\!\!\perp Y}) = \sum_{k=0}^{m_{X}-1} n(X=k) \log \frac{n(X=k)}{n} + \log \mathcal{C}_{\mathsf{CAT}}(K=m_{X}, n) + \sum_{k'=0}^{m_{Y}-1} n(Y=k') \log \frac{n(Y=k')}{n} + \log \mathcal{C}_{\mathsf{CAT}}(K=m_{Y}, n),$$

which is equal to  $\mathcal{SC}(z^n; CAT^{m_X})$ .

## B.2 Confounded Case

We exactly calculate the stochastic complexity defined in Eq. (2) for causal model  $M_{X\leftarrow C\rightarrow Y}$ :

$$\mathcal{L}^{d}(z^{n}; M_{X \leftarrow C \to Y})$$
  
=  $\mathcal{SC}(z^{n}; M_{X \leftarrow C \to Y})$   
=  $-\log P(z^{n}; M_{X \leftarrow C \to Y}, \hat{\theta}_{X \leftarrow C \to Y}) + \log \mathcal{C}_{n}(M_{X \leftarrow C \to Y}),$ 

where  $\hat{\theta}_{X \leftarrow C \to Y} = (\hat{\theta}_{k,k'})$  is the maximum likelihood estimator in  $\Theta_{X \leftarrow C \to Y}$ . Each element is  $\hat{\theta}_{k,k'} = \frac{n(X=k,Y=k')}{n}$ , where n(X=k,Y=k') counts the frequency of data satisfying X = k and Y = k' in  $z^n$ . Subsequently, the maximum likelihood as the first term on the right-hand side is represented as

$$\log P(z^n; M_{X \leftarrow C \to Y}, \hat{\theta}_{X \leftarrow C \to Y}) = \sum_{k=0}^{m_X - 1} \sum_{k'=0}^{m_Y - 1} n(X = k, Y = k') \log \frac{n(X = k, Y = k')}{n}.$$

Since the causal model of  $M_{X \leftarrow C \rightarrow Y}$  is the model of  $(m_X m_Y)$ -categorical distributions, the parametric complexity as the second term is calculated as

$$\log \mathcal{C}_n(M_{X \leftarrow C \to Y}) = \log \mathcal{C}_{\mathsf{CAT}}(m_X m_Y, n).$$

Thus, the NML codelength of the data  $z^n$  for  $M_{X \leftarrow C \rightarrow Y}$  is calculated as:

$$\mathcal{L}^{d}(z^{n}; M_{X \leftarrow C \to Y}) = -\sum_{k=0}^{m_{X}-1} \sum_{k'=0}^{m_{Y}-1} n \left(X = k, Y = k'\right) \log \frac{n \left(X = k, Y = k'\right)}{n} + \log \mathcal{C}_{\mathsf{CAT}}(m_{X}m_{Y}, n),$$

which is equal to  $\mathcal{SC}(z^n; CAT^{m_X m_Y}) = \mathcal{SC}(z^n; HIS^{m_X, m_Y}).$ 

#### B.3 Direct Case

First, we consider the first term on the right-hand side of Eq. (8). The first term,  $L(f; M_{X \to Y})$ , represents the codelength required to select one function from a finite set of possible functions  $f \in \mathcal{F}$ , and the following holds true:

**Theorem 1.** Let  $\mathcal{F}$  be a set of non-constant functions from  $\mathcal{X}$  to  $\mathcal{Y}$ . Then, we see

$$L(f; M_{X \to Y}) = \log |\mathcal{F}| = \log(m_Y^{m_X - 1} - 1)$$
(B1)

*Proof.* Naively, the number of the possible functions f amounts to  $m_Y^{m_X}$ , but one can remove redundant functions to shorten the resulting codelength.

First, one can remove constant functions since they are associated with the independence model  $M_{X\perp \downarrow Y}$  and not  $M_{X\rightarrow Y}$ .  $m_Y$  such functions exist in total.

Next, distinct functions are associated with the same NML codelength. For a function  $f_1$ , consider  $f_2$  given by a constant shift,

$$f_2(x) = f_1(x) + k' \pmod{m_Y},$$

where  $k' \in \{1, \dots, m_Y - 1\}$  and  $x \in \mathcal{X}$ . Now, for all k', the NML codelength with  $f_1$  is the same as that with  $f_2$ . Since  $m_Y$  such different but equivalent functions exist for any  $f_1$  including itself, one can further reduce the number of functions by a factor of  $m_Y$ .

Summing up, there remain  $|\mathcal{F}| = (m_Y^{m_X} - m_Y)/m_Y = m_Y^{m_X-1} - 1$  functions to encode.

As for the second term in Eq. (8),  $L(z^n; M_{X \to Y}, f)$ , the following statement holds: **Theorem 2.** We define n(Y = f(X) + k') as the frequency of data in  $z^n$  that satisfies Y = f(X) + k'. Then, for any f, it holds that

$$\begin{split} & L(z^n; M_{X \to Y}, f) \\ & = -\sum_{k=0}^{m_X - 1} n(X = k) \log \frac{n(X = k)}{n} - \sum_{k' = 0}^{m_Y - 1} n(Y = f(X) + k') \log \frac{n(Y = f(X) + k')}{n} \\ & + \log \mathcal{C}_{\mathsf{CAT}}(K = m_X, n) + \log \mathcal{C}_{\mathsf{CAT}}(K = m_Y, n). \end{split}$$

*Proof.* Let us denote the probability mass functions of  $E_X$  and  $E_Y$  by  $P(E_X; \pi_X)$  and  $P(E_Y; \pi_Y)$ , respectively, where  $\pi_X, \pi_Y$  are the corresponding parameters.

Now, the observable pair (X, Y) is one-to-one with the exogenous variable pair  $(E_X, E_Y)$  when the function f is fixed. Thus, under an appropriate transformation of data, the joint probability mass function of (X, Y) is equivalent to that of  $(E_X, E_Y)$ ,

$$P(X = x, Y = y; M_{X \to Y}, f, \pi_X, \pi_Y) = P(E_X = x, E_Y = y - f(x); M_{X \to Y}, f, \pi_X, \pi_Y) = P(E_X = x'; \pi_X) P(E_Y = y'; \pi_Y),$$

which implies the equivalence of  $M_{X \to Y}$  with fixed f and  $M_{X \perp \downarrow Y}$ 

$$P(X = x, Y = y; M_{X \to Y}, f, \boldsymbol{\pi}_X, \boldsymbol{\pi}_Y)$$
  
=  $P(X = x', Y = y'; M_{X \perp \downarrow Y}, \boldsymbol{\pi}_X, \boldsymbol{\pi}_Y)$ 

where z' = (x', y') = (x, y - f(x)) is the transformation of a datum z = (x, y) with fixed f.

The equivalence in terms of the probability mass functions immediately extends to the equivalence in terms of the NML codelengths. Particularly, the NML codelength of  $M_{X\to Y}$  with fixed f is the same as that of  $M_{X\perp Y}$  with the appropriate transformation,

$$L(z^n; M_{X \to Y}, f) = \mathcal{L}^d(z'^n; M_{X \perp\!\!\!\perp Y}),$$

where  $z'^n = (z'_1, ..., z'_n)$  and  $z'_i = (x_i, y_i - f(x_i))$  for all  $1 \le i \le n$ . This completes the proof.

Therefore, the codelength of  $z^n \in \mathcal{X}^n \times \mathcal{Y}^n = \{0, 1, \cdots, m_X - 1\}^n \times \{0, 1, \cdots, m_Y - 1\}^n$  for the causal model  $M_{X \to Y}$  is calculated as:

$$\begin{split} \mathcal{L}^{d}(z^{n}; M_{X \to Y}) \\ &= L(z^{n}; M_{X \to Y}, \hat{f}) + L(\hat{f}; M_{X \to Y}) \\ &= -\sum_{k=0}^{m_{X}-1} n(X=k) \log \frac{n(X=k)}{n} - \sum_{k'=0}^{m_{Y}-1} n(Y=\hat{f}(X)+k') \log \frac{n(Y=\hat{f}(X)+k')}{n} \\ &+ \log \mathcal{C}_{\mathsf{CAT}}(K=m_{X}, n) + \log \mathcal{C}_{\mathsf{CAT}}(K=m_{Y}, n) + \log(m_{Y}^{m_{X}-1}-1), \end{split}$$

which is equal to  $\mathcal{SC}(x^n; CAT^{m_X}) + \mathcal{SC}((y - \hat{f}(x))^n; CAT^{m_Y}) + L(\hat{f}; M_{X \to Y})$ . The subtraction is taken over  $\mathbb{Z}/m_Y\mathbb{Z}$ .

# Appendix C Proof of Proposition 2

In this section, we provide the proof for Proposition 2.

We first derive the first term on the right-hand side of Eq. (11),  $L(m_X, m_Y; M)$ , which is the codelength required to encode  $(m_X, m_Y)$  under causal model M. By the Rissanen's integer coding (Eq. (15)) we have:

$$L(m_X, m_Y; M) = \log^* m_X + \log^* m_Y.$$
 (C2)

For the second term on the right-hand side of Eq. (11),  $L(z^n; M, m_X, m_Y)$ , we calculate it under each causal model in the following sections, and we complete the proof of (13) in Proposition 2 for each causal relationship:

# C.1 Independent Case

For given data  $z^n = (x^n, y^n)$ , codelength  $L(z^n; M_{X \perp \!\!\!\perp Y}, m_X, m_Y)$  is calculated by two NML codes with respect to the histogram models  $\mathsf{HIS}^{m_X}$  and  $\mathsf{HIS}^{m_Y}$  for  $x^n$  and  $y^n$ , respectively. That is, we have:

$$L(z^n; M_{X \perp \!\!\!\perp Y}, m_X, m_Y) = \mathcal{SC}(x^n; \mathsf{HIS}^{m_X}) + \mathcal{SC}(y^n; \mathsf{HIS}^{m_X}).$$

Then, the total codelength  $\mathcal{L}^{c}(z^{n}, m_{X}, m_{Y}; M_{X \perp \!\!\!\perp Y})$  is expressed as follows:

$$\mathcal{L}^{c}(z^{n}, m_{X}, m_{Y}; M_{X \perp \!\!\!\!\perp Y}) = L(m_{X}, m_{Y}; M_{X \perp \!\!\!\perp Y}) + L(z^{n}; M_{X \perp \!\!\!\perp Y}, m_{X}, m_{Y})$$
  
= log\* m<sub>X</sub> + log\* m<sub>Y</sub> +  $\mathcal{SC}(x^{n}; \mathsf{HIS}^{m_{X}}) + \mathcal{SC}(y^{n}; \mathsf{HIS}^{m_{X}}).$ 

By the results of Example 1 and 2, the above is written as follows:

 $\mathcal{L}^{c}(z^{n}, m_{X}, m_{Y}; M_{X \perp \!\!\!\perp Y})$ 

$$\begin{split} &= \log^{*} m_{X} + \log^{*} m_{Y} + \mathcal{SC}(x^{n}; \mathsf{HIS}^{m_{X}}) + \mathcal{SC}(y^{n}; \mathsf{HIS}^{m_{X}}) \\ &= -\sum_{k=0}^{m_{X}-1} n(X \in I_{k}^{X}) \log \frac{n(X \in I_{k}^{X})}{n} + \log \mathcal{C}_{\mathsf{CAT}}(K = m_{X}, n) - n \log m_{X} + \log^{*} m_{X} \\ &- \sum_{k'=0}^{m_{Y}-1} n(Y \in I_{k'}^{Y}) \log \frac{n(Y \in I_{k'}^{Y})}{n} + \log \mathcal{C}_{\mathsf{CAT}}(K = m_{Y}, n) - n \log m_{Y} + \log^{*} m_{Y} \\ &= -\sum_{k=0}^{m_{X}-1} n(\operatorname{disc}(X; m_{X}) = k) \log \frac{n(\operatorname{disc}(X; m_{X}) = k)}{n} + \log \mathcal{C}_{\mathsf{CAT}}(K = m_{X}, n) + L^{c \to d}(m_{X}, n) \\ &- \sum_{k'=0}^{m_{Y}-1} n(\operatorname{disc}(Y; m_{Y}) = k') \log \frac{n(\operatorname{disc}(Y; m_{Y}) = k')}{n} + \log \mathcal{C}_{\mathsf{CAT}}(K = m_{Y}, n) + L^{c \to d}(m_{Y}, n) \\ &= \mathcal{L}^{d}(\operatorname{disc}(x^{n}; m_{X}), \operatorname{disc}(y^{n}; m_{Y}); \operatorname{DISC}(M_{X \perp LY}; m_{X}, m_{Y})) + L^{c \to d}(m_{X}, n) + L^{c \to d}(m_{Y}, n). \end{split}$$

Thus, our claim holds in case  $M = M_{X \perp \!\!\!\perp Y}$ .

# C.2 Confounded Case

The codelength  $L(z^n; M_{X \leftarrow C \rightarrow Y}, m_X, m_Y)$  is calculated by NML code with respect to the histogram model  $\mathsf{HIS}^{m_X, m_Y}$  for  $z^n$ . That is, we have:

$$\begin{split} L(z^n; M_{X \leftarrow C \to Y}, m_X, m_Y) &= \mathcal{SC}(z^n; \mathsf{HIS}^{m_X, m_Y}) \\ &= -\max_{p \in \mathsf{HIS}^{m_X, m_Y}} \log p(z^n; \hat{\boldsymbol{\theta}}(z^n)) + \log \mathcal{C}_n(\mathsf{HIS}^{m_X, m_Y}) \end{split}$$

The maximum likelihood estimator for  $\mathsf{HIS}^{m_X,m_Y}$  results in  $\hat{\theta}_{k,k'}(z^n) = \frac{n(X \in I_k^X, Y \in I_{k'}^Y)}{n} m_X m_Y$ . Thus, the maximum log-likelihood of data is calculated as

$$\begin{split} & \max_{p \in \mathsf{HIS}^{m_X, m_Y}} \log p(z^n; \hat{\boldsymbol{\theta}}(z^n)) \\ &= \sum_{k=0}^{m_X - 1} \sum_{k'=0}^{m_Y - 1} n(X \in I_k^X, Y \in I_{k'}^Y) \log \hat{\theta}_{k,k'}(z^n) \\ &= \sum_{k=0}^{m_X - 1} \sum_{k'=0}^{m_Y - 1} n(X \in I_k^X, Y \in I_{k'}^Y) \log \frac{n(X \in I_k^X, Y \in I_{k'}^Y)}{n} + n \log(m_X m_Y). \end{split}$$

The parametric complexity of  $\mathsf{HIS}^{m_X,m_Y}$  is given by

$$\log \mathcal{C}_n(\mathsf{HIS}^{m_X,m_Y}) = \log \int p(z^n; \hat{\boldsymbol{\theta}}(z^n)) dz^n$$
$$= \log \sum_{Z^n \in \{0,\dots,m_X-1\}^n \times \{0,\dots,m_Y-1\}^n} \int_{\Delta(Z^n)} p(z^n; \hat{\boldsymbol{\theta}}(z^n)) dz^n$$

$$= \log \sum_{\substack{Z^n \in \{0, \dots, m_X - 1\}^n \times \{0, \dots, m_Y - 1\}^n \\ = \log \mathcal{C}_{\mathsf{CAT}}(K = m_X m_Y, n)} \left( \frac{n(X \in I_k^X, Y \in I_{k'}^Y)}{n} \right)^n$$

Consequently, the NML codelength of  $z^n$  for  $HIS^{m_X, m_Y}$  becomes

$$\mathcal{SC}(z^{n}; \mathsf{HIS}^{m_{X}, m_{Y}}) = -\sum_{k=0}^{m_{X}-1} \sum_{k'=0}^{m_{Y}-1} n(X \in I_{k}^{X}, Y \in I_{k'}^{Y}) \log \frac{n(X \in I_{k}^{X}, Y \in I_{k'}^{Y})}{n} - n\log(m_{X}m_{Y}) + \log \mathcal{C}_{\mathsf{CAT}}(K = m_{X}m_{Y}, n).$$
(C3)

By comparing the result with Example 1, the total codelength  $\mathcal{L}^{c}(z^{n}, m_{X}, m_{Y}; M_{X \leftarrow C \rightarrow Y})$  obtains the following representation:

$$\begin{split} \mathcal{L}^{c}(z^{n}, m_{X}, m_{Y}, M_{X \leftarrow C \to Y}) \\ &= \log^{*} m_{X} + \log^{*} m_{Y} + \mathcal{SC}(z^{n}; \mathsf{HIS}^{m_{X}, m_{Y}}) \\ &= -\sum_{k=0}^{m_{X}-1} \sum_{k'=0}^{m_{Y}-1} n(X \in I_{k}^{X}, Y \in I_{k'}^{Y}) \log \frac{n(X \in I_{k}^{X}, Y \in I_{k'}^{Y})}{n} - n \log(m_{X}m_{Y}) \\ &+ \log \mathcal{C}_{\mathsf{CAT}}(K = m_{X}m_{Y}, n) + \log^{*} m_{X} + \log^{*} m_{Y} \\ &= -\sum_{k=0}^{m_{X}-1} \sum_{k'=0}^{m_{Y}-1} n(\operatorname{disc}(X; m_{X}) = k, \operatorname{disc}(Y; m_{Y}) = k') \log \frac{n(\operatorname{disc}(X; m_{X}) = k, \operatorname{disc}(Y; m_{Y}) = k')}{n} \\ &+ \log \mathcal{C}_{\mathsf{CAT}}(K = m_{X}m_{Y}, n) + L^{c \to d}(m_{X}) + L^{c \to d}(m_{Y}) \\ &= \mathcal{L}^{d}(\operatorname{disc}(x^{n}; m_{X}), \operatorname{disc}(y^{n}; m_{Y}); \operatorname{DISC}(M_{X \leftarrow C \to Y}^{m_{X}, m_{Y}})) + L^{c \to d}(m_{X}, n) + L^{c \to d}(m_{Y}, n). \end{split}$$

This completes the proof in case  $M = M_{X \leftarrow C \rightarrow Y}$ .

## C.3 Direct Case

In this case, we also employ two-stage coding for  $L(z^n; M_{X \to Y}, m_X, m_Y)$  with respect to function f. That is, for a given  $(m_X, m_Y)$ , we first estimate the optimal function  $\hat{f}$  using maximum likelihood estimation (Algorithm 4), and then encode the data  $z^n$ based on the histogram model  $\mathsf{HIS}_{X \to Y}^{m_X, m_Y}$  with  $\hat{f}$  fixed:

$$L(z^{n}; M_{X \to Y}, m_{X}, m_{Y}) = L(\hat{f}; M_{X \to Y}, m_{X}, m_{Y}) + L(z^{n}; M_{X \to Y}, m_{X}, m_{Y}, \hat{f}),$$

where the first term on the right-hand side is given by Eq. (B1) and the second one is calculated by encoding  $x^n$  and  $(y - \hat{f}(x))^n$  based on  $\mathsf{HIS}^{m_X}$  and  $\mathsf{HIS}^{m_Y}$ , respectively.

Therefore, the codelength is formulated as follows:

 $\mathcal{L}^c(z^n; m_X, m_Y; M_{X \to Y})$ 

$$= L(m_X, m_Y; M_{X \to Y}) + L(\hat{f}; M_{X \to Y}, m_X, m_Y) + L(z^n; M_{X \to Y}, m_X, m_Y, \hat{f}) = \log^* m_X + \log^* m_Y + \log m_Y^{m_X - 1} + \mathcal{SC}(x^n; \mathsf{HIS}^{m_X}) + \mathcal{SC}(y^n - \hat{f}(x^n); \mathsf{HIS}^{m_Y}),$$

By the results of Example 1 and Example 2, the total codelength in the above is expressed as follows:

$$\begin{split} \mathcal{L}^{c}(z^{n};m_{X},m_{Y};M_{X\to Y}) \\ &= \log^{*}m_{X} + \log^{*}m_{Y} + \log m_{Y}^{m_{X}-1} \\ &- \sum_{k=0}^{m_{X}-1} n(X \in I_{k}^{X}) \log \frac{n(X \in I_{k}^{X})}{n} + \log \mathcal{C}_{\mathsf{CAT}}(K = m_{X},n) - n \log m_{X} \\ &- \sum_{k'=0}^{m_{Y}-1} n(Y - f(X) \in I_{k'}^{Y}) \log \frac{n(Y - f(X) \in I_{k'}^{Y})}{n} + \log \mathcal{C}_{\mathsf{CAT}}(K = m_{Y},n) - n \log m_{Y} \\ &= - \sum_{k=0}^{m_{X}-1} n(\operatorname{disc}(X;m_{X}) = k) \log \frac{n(\operatorname{disc}(X;m_{X}) = k)}{n} + \log \mathcal{C}_{\mathsf{CAT}}(K = m_{X},n) \\ &- \sum_{k'=0}^{m_{Y}-1} n(\operatorname{disc}(Y - \hat{f}(X);m_{Y}) = k') \log \frac{n(\operatorname{disc}(Y - \hat{f}(X);m_{Y}) = k')}{n} + \log \mathcal{C}_{\mathsf{CAT}}(K = m_{Y},n) \\ &+ \log m_{Y}^{m_{X}-1} + L^{c \to d}(m_{X},n) + L^{c \to d}(m_{Y},n) \\ &= \mathcal{L}^{d}(\operatorname{disc}(x^{n};m_{X}), \operatorname{disc}(y^{n};m_{Y}); \operatorname{DISC}(M_{X \to Y};m_{X},m_{Y})) + L^{c \to d}(m_{X},n) + L^{c \to d}(m_{Y},n). \end{split}$$

This completes the proof in case  $M = M_{X \to Y}$ . The same argument holds for  $M = M_{X \leftarrow Y}$ 

# Appendix D Description of Tübingen Benchmark Pairs

We provide the detailed descriptions of every dataset [19] we employed in Section 6.3.1.

#### **Discrete Case:**

**Traffic Dataset (No. 47)**: This dataset focused on the relationship between the type of day and traffic volume. X represents the number of cars counted per 24 hours at various stations in Oberschwaben, Germany. Y is categorical, distinguishing between Sundays plus holidays (labelled as '1') and working days (labelled as '2'). The ground truth is  $X \leftarrow Y$ , suggesting that the type of day influences the traffic volume.

Internet Connections and Traffic Dataset (No. 68): This dataset comes from a time series study focusing on internet connections and traffic at the MPI for Intelligent Systems. It features X which represents the bytes sent at minute and Y which denotes the number of open HTTP connections during that same minute. Measurements were taken every 20 minutes. The established ground truth is Y(open HTTP connections) causes X(bytes sent).

**Direction of Gabor Patches Dataset (No. 107)**: This dataset originated from a psychophysics experiment involving human subjects and their perception of Gabor patches (stripe patterns used in psychological experiments) displayed on a screen. The Gabor patches were tilted either to the left or right, with varying contrast levels. X represents the contrast values, ranging from 0.0150 to 0.0500, in increments of 0.0025, and Y is binary, indicating whether the direction of the tilt was correctly identified or not. X is regarded as the cause of Y.

#### Mixed Case:

Milk Protein Dataset (No. 85): The pair0085 dataset used in our experiments is a subset of the milk protein trial dataset by Verbyla and Cullis in 1990. The dataset contains weekly measurements of the assayed protein content of milk samples taken from 71 cows over a 14-week period. The cows were randomly allocated to one of three diets: barley, mixed barley-lupins, and lupins. The variables in the dataset are X, representing the time at which the weekly measurement was taken (ranging from 1 to 14), and Y, representing the protein content of the milk produced by each cow at time X. The ground truth for our experiments was set as  $X \to Y$ . Note that the dataset does not consider the effect of the diets on the protein content.

Electricity Consumption Dataset (No. 95): This comprises 9,504 hourly measurements of total electricity consumption in MWh, denoted as Y, in a region of Turkey. The variable X represents the hour of the day during which these measurements were taken. The ground truth for this dataset is set as  $X \to Y$ , suggesting that the hour of the day is the driving factor for electricity consumption.

**NLSchools Dataset (No. 99)**: This dataset contains the information of 2287 Dutch eighth graders (about 11 years old) with features X(language test score) and Y(social-economic status of pupil's family).  $X \to Y$  is regarded as the ground truth.

#### **Continuous Case:**

Cardiac Arrhythmia Database (No. 23): The data, contributed in January 1998, includes 452 instances with two attributes: age and weight. Age was hypothesized to influence weight.

Solar Radiation and Air Temperature Dataset (No. 77): This contains daily measurements of solar radiation in  $W/m^2$  and the daily average temperature of the air in Furtwangen, Black Forest, Germany. The dataset covers a time period from January 1, 1985, to December 31, 2008, with a sample size of 8,401. Solar radiation is denoted by the variable Y, while the air temperature is denoted by the variable X. The ground truth for this dataset was set as  $X \leftarrow Y$ , indicating that solar radiation is the cause of air temperature.

Brightness of screen Dataset (No. 101): This is from an experiment that was performed to generate samples that were clearly unconfounded. X is grey value of a pixel randomly chosen from a fixed image. The grey value was displayed by the color of a square on a computer screen. Y is light intensity seen by a photo diode placed several centimeters away from the screen. X was the cause of Y.
