ABSTRACT

A Möbius strip comprising of two antiferromagnetically coupled spin chains showcase exotic magnon excitations with non-trivial physical behavior, which is solely attributed to the real-space boundary condition even in the absence of local curvature effects. Counterintuitively, magnons on a Möbius strip feature linear polarization of the Néel vector devoid of chirality even when the spin Hamiltonian preserves local rotational symmetry around the anisotropic easy axis. These linearly-polarized magnons form two non-degenerate branches that can neither be smoothly connected to nor be decomposed by the circularly-polarized magnons of opposite chirality commonly found in antiferromagnets. Only one branch supports standing-wave formation on the Möbius strip while the other does not, owing to its spectral shift incurred by the boundary condition. By unraveling a hitherto unknown mechanism of *topology-induced symmetry breaking*, our findings highlight the profound impact of real-space topology on the physical nature of not only magnons but also other bosonic quasiparticles.

Introduction

Physical properties of quasiparticles have been largely pursued as direct manifestations of symmetry and interactions, whereas the subtle impact of real-space topology remains elusive. Here we explore a unique scenario where non-trivial effects of quasiparticles are solely attributed to the real-space topology while both local interactions and symmetry are kept trivial.

In prevailing studies, a solid-state system is often subject to periodic boundary conditions (PBCs) in the real space¹, for which it becomes topologically equivalent to a circle, a torus, or a 3D-torus depending on the dimensionality. However, there exist exotic structures such as Möbius strips and Klein bottles that do not conform with the PBCs adopted in most known systems. Concerning the physical behavior of quasiparticles on such an object, it is tempting to ask: what are the physical implications of the non-trivial boundary conditions?

By topological nature, a Möbius strip is non-orientable with a single surface and a single edge, hence precluding the application of any ordinary PBC. Recently, elementary excitations residing on Möbius strips have aroused increasing theoretical attentions²⁻⁹. Experimentally, Möbius strips have been realized in a wide range of systems such as molecules^{10,11}, single crystals¹², resonators¹³⁻¹⁵, and optical cavities^{16,17}, fertilizing a vibrant arena for exploring new physics emerging from the Möbius topology. However, most of these studies focused on the local curvature effects of the strip based on continuous geometry. It is far from clear if there are any residual consequences arising *only* from the Möbius boundary condition when spatial curvature is discarded.

Motivated by the above question, we investigate a specific physical context and demonstrate non-trivial behavior of quasiparticles that are solely attributed to the Möbius boundary condition and visible only in a discretized lattice description. As illustrated in Fig. 1(a), we consider a nano-ribbon composed of two ferromagnetic spin chains oppositely aligned, forming an effective antiferromagnetic (AFM) system involving two sub-lattices. The nano-ribbon can be wrapped into a Möbius strip using two distinct ways of twisting based on Fig. 1(b) and (c). To motivate the following discussions, we first make a critical observation: although the ground-state AFM spin configuration is compatible with the boundary condition, the magnons excitations (*i.e.*, quanta of spin waves) with circular polarizations are inherently irreconcilable with the Möbius topology. Specifically, when only the exchange interactions and the easy-axis anisotropy are considered, the system respects the $O(2)$ rotational symmetry in the spin space. Consequently, the magnon eigenmodes disregarding the boundary condition are circularly polarized, exhibiting either left-handed or right-handed chirality for both spin species¹⁸⁻²⁰. For example, in the left-handed mode, \mathcal{S}_A and \mathcal{S}_B both rotate clockwise, but \mathcal{S}_A has a larger oscillation amplitude, which is indicated by the black dashed arrows. As illustrated in Fig. 1(b) and (c), however, imposing the Möbius boundary condition by connecting the 1 and N sites with A and B swapped will inevitably disrupt both the chirality and the amplitude of the spin precessions.

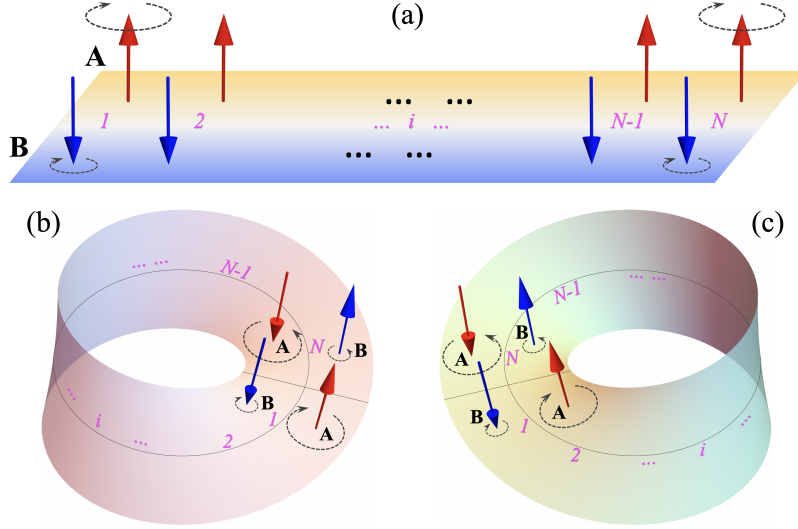

Figure 1. Schematic illustration of the system. (a) An AFM nano-ribbon consists of two ferromagnetic spin chains, where the red (blue) arrows signify the equilibrium spin orientation of the A (B) sub-lattice. The black dashed arrows indicate the manner of spin precessions associated with the left-handed magnon mode, where \mathcal{S}_A has a larger amplitude than \mathcal{S}_B . On the contrary, the right-handed mode is characterized by a larger precession of \mathcal{S}_B over \mathcal{S}_A (not shown). (b) and (c) depict the two distinct ways of connecting the ribbon into a Möbius strip. While the AFM ground state is compatible with the boundary condition, the excited states in the form of circularly-polarized magnons are radically disrupted.

Therefore, the magnon solutions that are commensurate with the Möbius topology must be fundamentally different from the circularly-polarized magnons widely known for collinear AFM materials. As will become clear later, the magnon excitations on a Möbius strip entail a hitherto unknown mechanism, which we call "topology-induced symmetry breaking", revealing the profound impact of real-space topology on the physical nature of bosonic quasiparticles applicable to not only magnons but also photons and phonons.

Model and Results

Let us start with the AFM spin configuration depicted in Fig. 1(a), where the red and blue arrows indicate the spins on the A and B sub-lattices for the ground state. A Möbius strip can then be constructed based on either Fig. 1(b) or Fig. 1(c), which are topologically distinct and entail different boundary conditions to be specified later. Excluding any geometric effects originating from the curvature of the strip^{21–26}, we consider a minimal Hamiltonian that preserves the local rotational symmetry about the local z axis:

$$H_0 = -J_F \sum_{\langle i,j \rangle} (\mathcal{S}_{Ai} \cdot \mathcal{S}_{Aj} + \mathcal{S}_{Bi} \cdot \mathcal{S}_{Bj}) + J_{AF} \sum_i \mathcal{S}_{Ai} \cdot \mathcal{S}_{Bi} - K \sum_i (\mathcal{S}_{Ai}^z + \mathcal{S}_{Bi}^z), \quad (1)$$

where i labels the lattice on the strip, J_F (J_{AF}) is the nearest-neighbor exchange interaction for (between) the same (different) spin species, and K is the perpendicular easy-axis anisotropy. In our convention, all these parameters are positive. Contrary to a single ferromagnet spin chain arranged on a Möbius strip^{23,27}, our system is free from geometrical frustration, thus no domain walls are present in the ground state.

To derive the quantum magnon excitations, we apply the linearized Holstein–Primakoff transformations on the spin raising and lowering operators, $S^\pm = S_x \pm iS_y$, for each sublattice

$$S_{Ai}^+ \approx \sqrt{2S}a_i, \quad S_{Ai}^- \approx \sqrt{2S}a_i^\dagger, \quad S_{Ai}^z = S - a_i^\dagger a_i, \quad (2a)$$

$$S_{Bi}^+ \approx \sqrt{2S}b_i^\dagger, \quad S_{Bi}^- \approx \sqrt{2S}b_i, \quad S_{Bi}^z = b_i^\dagger b_i - S, \quad (2b)$$

where a_i (b_i) represents the annihilation of a magnon on site i and sublattice A (B), and S is the spin magnitude on each site. By neglecting the constant terms, we obtain the magnon Hamiltonian as

$$H = (2K + 2J_F + J_{AF})S \sum_i (a_i^\dagger a_i + b_i^\dagger b_i) - J_F S \sum_{\langle i,j \rangle} (a_i^\dagger a_j + a_j^\dagger a_i + b_i^\dagger b_j + b_j^\dagger b_i) + J_{AF} S \sum_i (a_i^\dagger b_i^\dagger + a_i b_i). \quad (3)$$

We cannot directly apply Fourier transformations to Eq. (3) because the PBCs, $a_{i+N} = a_i$ and $b_{i+N} = b_i$, are explicitly broken. Instead, we have

$$a_{i+N} = b_i, \quad b_{i+N} = a_i, \quad (4)$$

which means the definitions of A and B chains are interchanged after winding around the Möbius strip by 2π . Regarding Eq. (4), we recombine a_i and b_i to define the following operators:

$$\alpha_i = \frac{1}{\sqrt{2}}(a_i - b_i)e^{i\xi\frac{\pi x_i}{L}}, \quad \beta_i = \frac{1}{\sqrt{2}}(a_i + b_i), \quad (5)$$

where x_i specifies the position of site i from 1 to N along the strip [see Fig. 1], L is the total length of the nano-ribbon, and $\xi = \pm 1$ corresponds the two distinct ways of connection illustrated in Fig. 1(b) and 1(c). The new magnon operators α_i and β_i satisfy not only the bosonic commutation relations but also the PBCs: $\alpha_{i+N} = \alpha_i$ and $\beta_{i+N} = \beta_i$. Using this new set of basis, the magnon Hamiltonian Eq. (3) becomes

$$H = (2K + 2J_F + J_{AF})S \sum_i \left[\alpha_i^\dagger \alpha_i + \beta_i^\dagger \beta_i \right] - J_F S \sum_{\langle i,j \rangle} \left[e^{i\pi\xi(x_i - x_j)/L} \alpha_i^\dagger \alpha_j + \beta_i^\dagger \beta_j + h.c. \right] - \frac{J_{AF}S}{2} \sum_i \left[e^{i2\pi\xi x_i/L} \alpha_i^\dagger \alpha_i^\dagger - \beta_i^\dagger \beta_i^\dagger + h.c. \right], \quad (6)$$

where $h.c.$ denotes hermitian conjugate. Equation (6) is naturally decomposed into $H = H_\alpha + H_\beta$ for the α_i and β_i sectors. Applying the Fourier transformations

$$\alpha_k = \frac{1}{\sqrt{2N}} \sum_i e^{-i(k - \xi\pi/L)x_i} (a_i - b_i), \quad \beta_k = \frac{1}{\sqrt{2N}} \sum_i e^{-ikx_i} (a_i + b_i), \quad (7)$$

we can derive the momentum-space Hamiltonian. To this end, we adopt the Bogoliubov-de-Gennes (BdG) basis

$$\Psi_\alpha = (\alpha_k, \alpha_{-k+2\pi\xi/L}^\dagger)^\top, \quad \Psi_\beta = (\beta_k, \beta_{-k}^\dagger)^\top \quad (8)$$

with $l = L/N$ being the lattice constant, $H_\alpha = \Psi_\alpha^\dagger \mathcal{H}_\alpha \Psi_\alpha$ and $H_\beta = \Psi_\beta^\dagger \mathcal{H}_\beta \Psi_\beta$. Here, the BdG Hamiltonian reads

$$\mathcal{H}_{\alpha(\beta)} = S \begin{pmatrix} Q_{\alpha(\beta)} & -J_{AF}/2 \\ -J_{AF}/2 & Q_{\alpha(\beta)} \end{pmatrix}, \quad (9)$$

where $Q_\alpha = K + J_{AF}/2 + J_F[1 - \cos(k - \xi\pi/L)l]$ and $Q_\beta = K + J_{AF}/2 + J_F[1 - \cos(kl)]$. It should be noted that in the α sector, magnons of momentum k couple those of momentum $-k + 2\pi\xi/L$; whereas in the β sector, k pairs with $-k$ without a shift.

Owing to the bosonic commutation relations of the BdG basis, we need to diagonalize $\sigma_z \mathcal{H}_{\alpha(\beta)}$ rather than $\mathcal{H}_{\alpha(\beta)}$ for the magnon solutions²⁸. In this regard, we obtain the eigen-frequencies (we set $\hbar = 1$)

$$\omega_{\alpha(\beta)}^\pm = \pm S \sqrt{q_{\alpha(\beta)}^1 q_{\alpha(\beta)}^2} \quad (10)$$

with the corresponding eigenvectors

$$v_{\alpha(\beta)}^+ = \left(\sqrt{q_{\alpha(\beta)}^1} + \sqrt{q_{\alpha(\beta)}^2}, \sqrt{q_{\alpha(\beta)}^1} - \sqrt{q_{\alpha(\beta)}^2} \right)^\top \quad (11a)$$

$$v_{\alpha(\beta)}^- = \left(\sqrt{q_{\alpha(\beta)}^1} - \sqrt{q_{\alpha(\beta)}^2}, \sqrt{q_{\alpha(\beta)}^1} + \sqrt{q_{\alpha(\beta)}^2} \right)^\top \quad (11b)$$

where $q_{\alpha(\beta)}^1 = Q_{\alpha(\beta)} + J_{AF}/2$ and $q_{\alpha(\beta)}^2 = Q_{\alpha(\beta)} - J_{AF}/2$ are both positive. The negative frequency branches and their associated eigenvectors are redundant solutions, which can be interpreted as a *hole* representation. For instance, $v_{\beta}^-(k)$ describes a hole at k that corresponds to a real β -magnon at $-k$. A similar picture is applicable to the α branch so long as the $2\pi\xi/L$ momentum shift appearing in Eq. (8) is taken into account. Consequently, $v_{\alpha(\beta)}^+$ and $v_{\alpha(\beta)}^-$ are linearly dependent, representing one unique physical solution.

Let us concentrate on the positive frequency branches and consider the $\xi = 1$ connection [*i.e.*, Fig. 1(b)]. For simplicity, we also omit the super-index $+$. With a proper normalization of Eq. (11)(a), the magnon eigenmodes associated with $\omega_{\alpha(\beta)}$ are described by

$$\tilde{\alpha}_k = \frac{\sqrt{q_\alpha^1} + \sqrt{q_\alpha^2}}{2\sqrt{Q_\alpha}} \alpha_k + \frac{\sqrt{q_\alpha^1} - \sqrt{q_\alpha^2}}{2\sqrt{Q_\alpha}} \alpha_{-k+2\pi/L} \quad (12a)$$

$$\tilde{\beta}_k = \frac{\sqrt{q_\beta^1} + \sqrt{q_\beta^2}}{2\sqrt{Q_\beta}} \beta_k + \frac{\sqrt{q_\beta^1} - \sqrt{q_\beta^2}}{2\sqrt{Q_\beta}} \beta_{-k} \quad (12b)$$

and their $\tilde{\alpha}_k^\dagger, \tilde{\beta}_k^\dagger$ counterparts. Figure 2(a) and (b) plot the discretized dispersion relations for $N = 10$ (only the lowest few states on each branch are shown), along with illustrations of the magnon eigenmodes at $k = 0$. While the β modes distribute symmetrically $\omega_\beta(-k) = \omega_\beta(k)$, the α branch shifts rightward by $\delta k = \pi/L$ such that $\omega_\alpha(-k) = \omega_\alpha(k + 2\delta k)$. The skewed $\omega_\alpha(k)$ is intimately related to the asymmetric pairing of Ψ_α in Eq. (8), which originates from the non-trivial topology of the Möbius strip. It is easy to verify that setting $\xi = -1$ [*i.e.*, using the connection of Fig. 1(c)] leads to a leftward shift of $\omega_\alpha(k)$, or $\delta k = -\pi/L$. Interestingly, if we reversely count the sites on the strip, the spectral shift δk also flips sign, but in this case the eigenvectors are different from what one would obtain for $\xi = -1$.

To better understand the magnon eigenmodes, we now express Eq. (12) in terms of the original spin variables. Using $S^\pm = S^x \pm iS^y$ and Eqs. (2) and (7), we obtain

$$\tilde{\alpha}_k^\dagger = \sum_i \frac{e^{i(k-\delta k)x_i}}{2\sqrt{NSQ_\alpha}} \left[\sqrt{q_\alpha^1} S_{Ai}^x - i\sqrt{q_\alpha^2} S_{Ai}^y - \sqrt{q_\alpha^1} S_{Bi}^x - i\sqrt{q_\alpha^2} S_{Bi}^y \right], \quad (13a)$$

$$\tilde{\beta}_k^\dagger = \sum_i \frac{e^{ikx_i}}{2\sqrt{NSQ_\beta}} \left[\sqrt{q_\beta^1} S_{Ai}^x - i\sqrt{q_\beta^2} S_{Ai}^y + \sqrt{q_\beta^1} S_{Bi}^x + i\sqrt{q_\beta^2} S_{Bi}^y \right], \quad (13b)$$

where it is important to note that $q_{\alpha(\beta)}^1 > q_{\alpha(\beta)}^2 > 0$. In the classical limit, both the α and β branches feature a right-handed (left-handed) elliptical precession of \mathbf{S}_A (\mathbf{S}_B) with the major axes lying in the x direction; \mathbf{S}_A and \mathbf{S}_B always precess about the easy-axis with the same amplitude and opposite chirality. The distinctions between the two branches manifest in two aspects, as schematically demonstrated in Fig. 2(a)–(c). First, from a local bird-eye view, \mathbf{S}_A and \mathbf{S}_B in the α -mode at $k = 0$ overlap with each other when passing the minor axes of their elliptical trajectories while becoming back-to-back when passing the major axes. On the contrary, \mathbf{S}_A and \mathbf{S}_B in the β -mode at $k = 0$ are back-to-back on the minor axes while overlapping each other on the major axes. Second, due to the momentum shift $\delta k = \pi/L$ in the α branch, the spin precessions on site $i = N$ differ from those on site $i = 1$ by a π phase even for $k = 0$, which exactly compensates the impact of the Möbius boundary condition that connects sites 1 and N with a flip. In contrast, the β mode at $k = 0$ does not exhibit a phase difference between $i = 1$ and $i = N$, which, in combination with the first distinction above, is just commensurate with the Möbius boundary condition.

Discussion

The unique characteristics of the magnon eigenmodes entail profound implications. We draw a 3D perspective in Fig. 2(c) where \mathbf{S}_A and \mathbf{S}_B share the same origin such that their precessional trajectories are concentric about the local z axis. It is easy to deduce that the Néel vector $\mathbf{n} = (\mathbf{S}_A - \mathbf{S}_B)/2S$ undergoes a pendulum-like oscillation restricted to the plane containing the major (minor) axes of the two elliptical trajectories in an α mode (β mode). Comparatively, the total spin vector $\mathbf{S} = (\mathbf{S}_A + \mathbf{S}_B)/2S$ oscillates linearly on a plane orthogonal to that of the Néel vector. That is to say, by the standard of spin wave polarization^{19,20}, both the α and β modes are linearly polarized, thus being devoid of chirality.

The above intuitive picture can be corroborated by a straightforward algebra. According to Eqs. (12) and (13), the real-time evolution of the classical spin vectors is

$$\mathbf{S}_{A/B}^\alpha \sim \text{Re} \left[\left(\pm \sqrt{q_\alpha^1} \hat{x} + i\sqrt{q_\alpha^2} \hat{y} \right) e^{i\omega_\alpha t - i(k-\delta k)x} \right], \quad (14a)$$

$$\mathbf{S}_{A/B}^\beta \sim \text{Re} \left[\left(\sqrt{q_\beta^1} \hat{x} \pm i\sqrt{q_\beta^2} \hat{y} \right) e^{i(\omega_\beta t - kx)} \right], \quad (14b)$$

for the α - and β -branch, respectively, where the $+$ ($-$) sign corresponds to the A (B) sublattice. From Eq. (14), we can read off

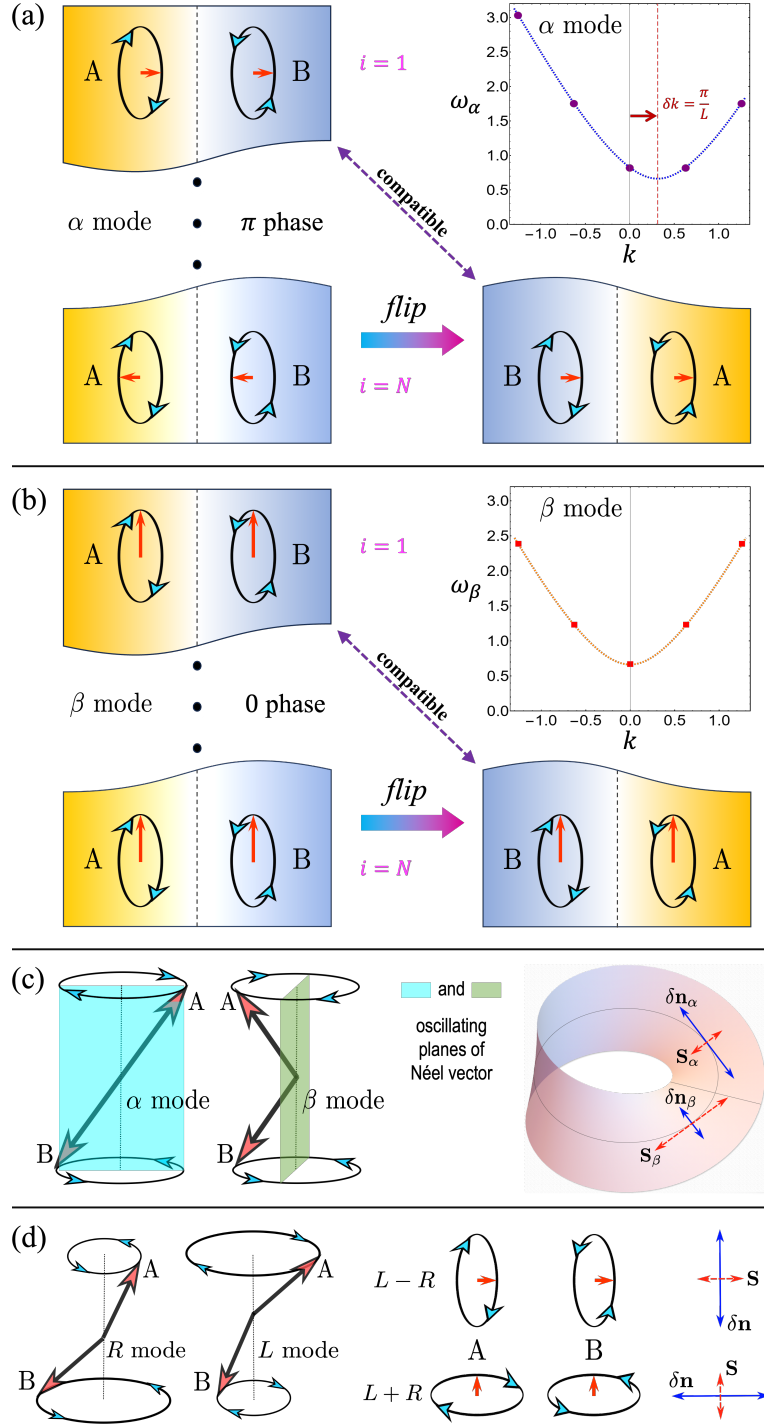

Figure 2. (a, b) Illustrations of the α and β modes at $k = 0$, and the plots of the lowest few modes on each branch for $\xi = 1$, $N = 10$, $l = 1$, $S = 2$, $J_F = J_{AF} = 1$, and $K = 0.1$. While $\omega_\beta(-k) = \omega_\beta(k)$ is symmetric, $\omega_\alpha(-k) = \omega_\alpha(k + 2\delta k)$ is skewed by $\delta k = \pi/L$. The spectral shift of the α branch is accompanied by an intrinsic π phase difference in the spin precessions between sites $i = 1$ and $i = N$, reflecting the impact of the Möbius boundary condition. (c) Left: a 3D illustration of the spin precessions in the α and β modes, where \mathbf{S}_A and \mathbf{S}_B rotate elliptically with an equal amplitude and opposite chirality, rendering the Néel vector linearly-polarized, as indicated by the color-shaded planes. Right: an illustration of the oscillating Néel vector (solid blue) and the oscillating spin vector (dashed red) for the α and β modes based on Eq. (15). That $\delta \mathbf{n}_\alpha \perp \delta \mathbf{n}_\beta$ should not be confused by their being shown in different locations. (d) Ordinary right-circular (R) and left-circular (L) magnon modes, and their superposition $L - R$ and $L + R$ characterized by a linearly-polarized Néel vector (solid blue) orthogonal to the oscillating spin vector (dashed red).

the oscillating components of the Néel vector and the total spin vector as

$$\delta \mathbf{n}_\alpha(k) \sim \hat{x} \sqrt{q_\alpha^1} \cos[\omega_\alpha(k)t - (k - \delta k)x], \quad (15a)$$

$$\mathbf{S}_\alpha(k) \sim \hat{y} \sqrt{q_\alpha^2} \sin[\omega_\alpha(k)t - (k - \delta k)x], \quad (15b)$$

$$\delta \mathbf{n}_\beta(k) \sim \hat{y} \sqrt{q_\beta^2} \sin[\omega_\beta(k)t - kx], \quad (15c)$$

$$\mathbf{S}_\beta(k) \sim \hat{x} \sqrt{q_\beta^1} \cos[\omega_\beta(k)t - kx], \quad (15d)$$

all of which are indeed linearly polarized bearing null chirality, confirming the picture inferred in Fig. 2(c). As $q_{\alpha(\beta)}^1 > q_{\alpha(\beta)}^2 > 0$, the oscillation amplitude of the Néel vector is larger (smaller) than that of the total spin in an α (β) mode, namely, $|\delta \mathbf{n}_\alpha| > |\mathbf{S}_\alpha|$ and $|\delta \mathbf{n}_\beta| < |\mathbf{S}_\beta|$. The geometry embedded in Eq. (15) is illustrated by the right panel of Fig. 2(c).

Since the total number of sites $N = L/l$ is finite, the magnon eigenmodes must be discrete, taking place only at $k = 0, \pm 2\pi/L, \pm 4\pi/L \dots$ as plotted in Fig. 2. Because the spectrum $\omega_\alpha(k) \neq \omega_\alpha(-k)$ is skewed by $\delta k = \pi/L$ while $\omega_\beta(k) = \omega_\beta(-k)$ is symmetric, only the β modes can form standing waves on the Möbius strip, whereas the α modes cannot. Consider the Néel vector for example, $\delta \mathbf{n}_\beta(k) + \delta \mathbf{n}_\beta(-k) \sim \hat{y} \sin \omega_\beta t \cos kx$, where t and x are separated, hence representing a standing wave. For the α branch, $\omega_\alpha(-k) = \omega_\alpha(k + 2\delta k)$, thus time and space do not separate in $\delta \mathbf{n}_\alpha(k) + \delta \mathbf{n}_\alpha(-k)$, prohibiting the formation of standing waves. The disparity between the α and β branches is an intrinsic topological property of the AFM magnons on a Möbius strip.

At this point, it is instructive to compare the unique magnon eigenmodes on a Möbius strip with what would become the eigenmodes if the nano-ribbon in Fig. 1(a) is wrapped into a topologically trivial band without twisting (which imposes an ordinary PBC). The latter case only admits the well-known eigenmodes in collinear AFM materials²⁹ because we have excluded the local curvature effect in our model. To this end, Fig. 2(d) illustrates the right-circular (R) and left-circular (L) eigenmodes, as well as their coherent superposition $L - R$ and $L + R$ featuring elliptical precessions of \mathbf{S}_A and \mathbf{S}_B with opposite chirality, which leads to a linearly-polarized oscillation of the Néel vector \mathbf{n} without chirality (so does the total spin vector \mathbf{S}). While $L - R$ is locally identical to the α mode shown in Fig. 2(a), it is not accompanied by a built-in π phase shift at $k = 0$, let alone a spectral shift. The β modes are not even locally similar to $L - R$ or $L + R$, which are emergent eigenmodes enabled by the Möbius topology. Unlike $L - R$ and $L + R$, neither α nor β can be expressed as linear superposition of R and L . This is because a Möbius strip is a non-orientable manifold on which the chirality of spin precessions becomes ambiguous globally, given that $+z$ and $-z$ are indistinguishable. In other words, the eigenspace spanned by α and β is not smoothly connected to that spanned by R and L ; they belong to distinct topological classes.

It is established that in easy-axis AFM materials such as MnF_2 ^{19,30}, R and L are degenerate in energy in the absence of magnetic fields. In easy-plane AFM materials such as NiO , the existence of hard-axis anisotropy breaks the rotational symmetry and lifts the degeneracy, rendering $L - R$ and $L + R$ the magnon eigenmodes^{20,29}. That is to say, symmetry dictates the nature of eigenmodes. The spin Hamiltonian we adopted in this Letter, however, preserves the local rotational symmetry (with respect to the local easy axis). Therefore, the suppression of the circularly-polarized modes, hence the absence of chirality in the Néel vector dynamics, is solely attributed to the Möbius topology. This introduces an intriguing but hitherto unknown mechanism: Non-trivial topology in the real space alone can lead to spontaneous symmetry breaking in the eigenspace of elementary excitations without the aid of symmetry-breaking interactions. The physical consequence manifests as a lifted degeneracy of the eigenmodes which possess a lower symmetry than the Hamiltonian. Because a quantum of angular momentum associated with the R -(L -)circular mode is $+\hbar$ ($-\hbar$), the topology-induced symmetry breaking we found here is followed by the suppression of longitudinal magnon spin currents on a Möbius strip.

Outlook

Even though we have demonstrated the topology-induced symmetry breaking in the context of AFM magnons on a Möbius strip, the mechanism itself is general and can manifest in other quasiparticles but with different forms. For example, we anticipate that the eigenmodes of phonon excitations on a Möbius strip to be linearly polarized while the circularly-polarized chiral phonons are suppressed by the Möbius topology. For photons that are governed by Maxwell's equations, the axis of circular polarization must be parallel to the momentum \mathbf{k} , which is distinct from our case, calling for a separate investigation. For tight-binding electrons on a Möbius strip, even though the Hamiltonian is very similar to ours, the fermionic statistics brings a fundamental distinction in the diagonalization [which does not involve σ_z as that in Eq. (10)]. Therefore, our findings could greatly inspire a broader research endeavor in the near future highlighting the profound impact of real-space topology on the physical nature of elementary excitations.

To close our discussion, we mention that the lowest β mode ($k = 0$) is in principle observable via the AFM resonance driven by a microwave, while the α modes are difficult to probe as they are at odds with standing waves. Nonetheless, our findings are

amenable to meta-materials such as magnonic crystals, wherein an α -mode locally excited by an oscillating magnetic field will propagate in opposite directions but can never form standing waves, leaving a non-reciprocal circulation of energy along the strip which is detectable by optical methods.
