## Abstract

Spatial data are often derived from multiple sources (e.g. satellites, in-situ sensors, survey samples) with different supports, but associated with the same properties of a spatial phenomenon of interest. It is common for predictors to also be measured on different spatial supports than the variables making up the response. Although there is no standard way to work with spatial data with different supports, a prevalent approach used by practitioners has been to use downscaling or interpolation to project all the variables of analysis towards a common support, and then using standard spatial models on this common support. The main disadvantage with this approach is that simple interpolation can introduce biases and, more importantly, the uncertainty associated with the change of support is not taken into account in the parameter estimation of the main model of interest. In this article, we propose a Bayesian spatial latent Gaussian model that can handle data with different rectilinear supports in the response variable and the predictors. Our approach allows us to handle changes of support more naturally according to the properties of the spatial stochastic process being used, and to take into account the uncertainty from the change of support in parameter estimation and prediction. We use spatial stochastic processes as linear combinations of basis functions where Gaussian Markov random fields define the weights. This process can be projected to different supports whilst maintaining the same parameters. Our hierarchical modelling approach can be described by the following steps: (i) define a latent model where response variables and predictors are considered as latent stochastic processes with continuous support, (ii) link the continuous-index set stochastic processes with its projection to the support of the observed data, (iii) link the projected process with the observed data. We show the applicability of our approach by simulation studies and modelling the land suitability of improved grassland in Rhondda Cynon Taf, a county borough in Wales.

**Keywords:** Data integration, Gaussian processes, geo-additive models, land suitability, model-based geostatistics, spatial misalignment.

## 1. Introduction

Many research questions in environmental science and public health necessitate the utilisation of heterogeneous spatial data encompassing different supports. The characteristics of the support, commonly referred to as spatial sampling units, can vary significantly across data sources, including variations in size, shape, spacing, and extent [\(Dungan et al., 2002\)](#page-20-0). In disease incidence and prevalence modelling, it is common to obtain case data at multiple levels of aggregation, such as at the individual level, census areas, counties, and districts, along with predictors observed at both individual and aggregated levels, including satellite pixels [\(Wang et al., 2018;](#page-22-0) [Alegana et al., 2016;](#page-20-1) [Lee and Anderson, 2022\)](#page-21-0). In environmental modelling, there is also a frequent need to combine information from data sources with different supports across both the response and predictor variables, with a particular emphasis on the use of satellite products and synthetic data derived from climate models [\(Brown et al.,](#page-20-2) [2022;](#page-20-2) [Pacifici et al., 2019;](#page-21-1) [Ma and Kang, 2020\)](#page-21-2). Integrating different data sources to address a research question offers the potential to enhance parameter estimation and improve prediction accuracy [\(Wang et al., 2018;](#page-22-0) [Pacifici et al., 2019;](#page-21-1) [Law et al., 2018;](#page-21-3) [Leopold et al., 2006\)](#page-21-4). However, to achieve reliable results, it is crucial to employ a data fusion framework that appropriately acknowledges the support of the data and incorporates reasonable assumptions to mitigate biases and accurately quantify uncertainty [\(Gotway and Young, 2002;](#page-21-5) [Pacifici](#page-21-1) [et al., 2019\)](#page-21-1).

The process of projecting observed data to a common support, known as *change of support* (COS) in spatial statistics, is essential when integrating heterogeneous data with different supports. This encompasses two key situations: the *change of support problem* (COSP), where the response variable is observed at different supports, and *spatial misalignment*, where the support of predictors and responses differ [\(Gelfand et al., 2001;](#page-21-6) [Gotway and](#page-21-5) [Young, 2002;](#page-21-5) [Zhu et al., 2003\)](#page-22-1). Both scenarios require addressing the challenge of effectively utilising the information from different sources and aligning the data appropriately. In this paper, we adopt the term change of support to encompass both situations, highlighting the importance of expressing the projection of spatial data to a specific support within a unified framework for data integration and handling spatial misalignment.

Numerous attempts have been made to address the change of support problem in order to integrate multiple spatial data sources. The first set of approaches focuses on geostatistical methods, including point-to-point, block-to-block, point-to-block, and block-to-point Kriging [\(Kyriakidis, 2004\)](#page-21-7). These methods involve computing the covariance matrix using Monte Carlo integration and parameter estimation through variogram fitting. When dealing with spatial misalignment, predictors are projected to the response support using one of the types of Kriging and incorporated into regression models [\(Young et al., 2009\)](#page-22-2).

The second set of approaches utilises Gaussian processes, a widely applied tool in spatial statistics, to tackle the change of support problem. Several strategies exist within this framework. One common approach is similar to Kriging, where the covariance matrix is computed using Monte Carlo integration [\(Gelfand et al., 2001\)](#page-21-6). Inference under the Gaussian process framework typically involves optimising the likelihood function or utilising Bayesian inference. Another strategy involves incorporating spatial point-level auxiliary variables, approximating the integral of the Gaussian process over a region by averaging the spatial

auxiliary variables within that region [\(Cowles et al., 2009\)](#page-20-3). The objective here is to obtain the posterior distribution of these auxiliary variables. Additionally, a multivariate approach can be employed, treating all variables as responses and defining a full covariance matrix between sources. This approach leverages separable covariances to reduce computational costs and approximates the covariance structure on aggregated supports using Monte Carlo integration [\(Finley et al., 2014\)](#page-21-8). Predictions can be made for all responses or specific ones. An alternative spectral approach, proposed by [Reich et al.](#page-21-9) [\(2014\)](#page-21-9), utilises the spectral representation of a Gaussian process. The model at aggregated support resembles a linear model with pseudo-predictors derived from spectral analysis. Finally, a computationally efficient approach involves utilising stochastic partial differential equations (SPDE) to approximate the aggregated Gaussian process [\(Moraga et al., 2017\)](#page-21-10). The representation of the aggregated GP using SPDE has a similar structure as the continuous GP with a custom linear transformation. With this approximation, the methods for spatial inference and prediction using SPDE can be applied.

The third set assumes that data arise from processes that are piecewise constant on a predefined grid. This allows for analytical simplification, where integrals become linear combinations of areas. The projection of piecewise processes to other supports is computed as weighted averages of the latent process values at cells intersecting the area of interest. These approaches often utilise grids based on the highest observed resolution or custom computational grids. The main objective is to obtain the posterior distribution of the piecewise constant process [\(Taylor et al., 2015,](#page-22-3) [2018;](#page-22-4) [Bradley et al., 2016\)](#page-20-4).

Although various approaches have been developed to address the change of support problem using Kriging, Gaussian processes, and piecewise processes, they are not without limitations. Many of these approaches rely on approximating covariance matrices on aggregated supports using Monte Carlo integration or by averaging spatial random variables. However, the accuracy of these approximations depends on the number of points used and the sampling algorithms employed, and the discussion of approximation errors is often neglected. Moreover, these approximations are necessary even in simpler domains like regular and rectilinear grids. Another limitation is the lack of a precise connection between the continuous and aggregated spatial processes in some approaches. Lastly, most existing approaches are tailored to specific types of models, which restricts their flexibility in handling more complex modelling scenarios within a unified framework.

In this article, we propose a Bayesian *latent Gaussian spatial model* that addresses the challenge of handling data with different supports in the response variable and predictors. Our approach offers a more natural and flexible way to handle the change of support problem, taking into account the properties of the underlying spatial stochastic process. We incorporate the uncertainty associated with the change of support into parameter estimation and prediction. Our proposed model utilises a spatial stochastic process expressed as a linear combination of basis functions, where the weights are determined by Gaussian Markov random fields. Notably, this process allows for accurate projection onto rectilinear supports while preserving the same set of parameters. The hierarchical nature of our model involves the following steps: (i) defining a latent model using latent stochastic processes with continuous support that are related to the response variables and predictors, (ii) establishing the connection between the continuous-index set stochastic processes and their projection onto the support of the observed data, and (iii) linking the observed data as noisy realisations of the projected processes. We demonstrate the practical application of our approach in modelling the land suitability of improved grassland in Rhondda Cynon Taf, a county borough in Wales. Our prediction of land suitability relies on various predictors, including elevation, growing degree days, and soil moisture surplus. Notably, these predictors are available at different resolutions than the land cover data  $(25m)$ .

The paper is structured as follows. In Section [2,](#page-3-0) we introduce spatial latent Gaussian models as a comprehensive framework encompassing common models used in spatial statistics. Section [3](#page-4-0) builds upon this foundation and extends the discussion to the properties of these processes when projected onto aggregated supports. We present our proposed Bayesian latent Gaussian spatial model with change of support in this section. To demonstrate the reliability and flexibility of our approach, we conduct simulation studies in Section [4.](#page-10-0) In Section [5,](#page-15-0) we model the land suitability of improved grassland in Rhondda Cynon Taf. Finally, in Section [6,](#page-18-0) we discuss the contributions, advantages, disadvantages, limitations, and potential future directions of our work.

## <span id="page-3-0"></span>2. Spatial latent Gaussian models

Spatial latent Gaussian models (SLGM) encompass commonly used models for analysing spatial point-level and area-level data. They can be tailored to specific classical generalised spatial models depending on the latent stochastic process used to capture spatial variation. We define a SLGM in Section [2.1](#page-3-1) and discuss the limitations concerning their ability to handle spatial data with different levels of support in Section [2.2.](#page-4-1)

## <span id="page-3-1"></span>2.1. Definition

A classical SLGM assumes that the conditional distribution  $\mathcal{F}(\cdot)$  of a random function  $Y(l)$ , for a location  $l \in D \subset R^2$ , given a p-dimensional set of covariates  $\boldsymbol{x}(l) = [x_1(l), \ldots, x_p(l)]^{\dagger}$ and the Gaussian random function  $W(l)$ , can be defined as follows

<span id="page-3-2"></span>
$$
Y(l) | \mathbf{x}(l), W(l) \sim \mathcal{F}(\theta(l), \tau^2),
$$
  
\n
$$
g(\theta(l)) = \eta(l) = \beta_0 + \mathbf{x}^{\mathsf{T}}(l)\boldsymbol{\beta} + W(l),
$$
\n(1)

where  $q(\cdot)$  is the link function between the conditional mean  $\theta(l)$  and the linear predictor  $\eta(l)$ , and  $\tau^2$  is an additional parameter. As usual,  $\beta_0$  and  $\boldsymbol{\beta}$  are the intercept and covariate effects, respectively. For a set of locations  $\mathcal{L} = \{s_1, \ldots, s_n\}$ , which can be points, lines or regions, this implies that the elements of a set of random variables  $\{Y(s_i): i = 1, 2, \ldots, n\}$ are conditionally independent given the covariates  $\{\boldsymbol{x}(s_i)\}\$  and the spatial stochastic process  $\{W(l): l \in D\}$ . This model assumes that the random vector  $W_l = [W(l_1), \ldots, W(l_n)]$ follows a multivariate Gaussian distribution.

The model defined by the Equation [\(1\)](#page-3-2) encompasses various classical spatial models based on the specific type of l (point or regions) and the properties of the spatial stochastic process  $\{W(l)\}\$ . There are three main cases: i) In the classical generalised geostatistical model, l represents a point, and  $\{W(l)\}\$ is defined as a Gaussian process with zero-mean and covariance function  $\kappa(l, l^*)$ ). ii) In the generalised conditional autoregressive (CAR) spatial model, l represents a region and  $\{W(l)\}\$ is defined as a Gaussian Markov random field (GMRF) with zero-mean and precision matrix  $Q$ . iii) In the geoadditive model, l represents a point, and  $\{W(l)\}\$ is defined using basis functions. Details of common stochastic processes can be found in Section [B.1](#page-26-0) of the Supplementary Material (SM).

## <span id="page-4-1"></span>2.2. Limitations

Although the framework defined by Equation [\(1\)](#page-3-2) is attractive and encompasses different types of spatial models, it has certain requirements. Firstly, it assumes that responses are observed at the same type of support, such as either point-level or aggregated-level data. Secondly, both responses and predictors need to be available at the same sampling units to make inferences. Lastly, predictors should be available for any location within the area of interest  $(s \in \mathcal{D})$  to enable spatial prediction at unobserved locations. However, these assumptions are often challenging to satisfy in real-world applications and are closely tied to the concept of change of support discussed earlier.

In practice, it is common for practitioners to perform pre-processing steps when using the models defined in Equation [1.](#page-3-2) This is because the three assumptions mentioned earlier are often not met, and existing approaches for dealing with change of support are often inflexible. These approaches typically involve approximating covariance matrices on aggregated supports using Monte Carlo integration or by averaging spatial random variables. A common practice is to interpolate the spatial data to a consistent support, which enables the application of models like [\(1\)](#page-3-2). However, it can introduce biases in mean predictions and also affect the accuracy of uncertainty quantification.

Our research on this topic proposes models for continuous spatial variation able to (i) include data at different support types for the response variable, (ii) include predictors observed at different spatial sampling units, (iii) perform spatial prediction of the response variable  $Y(\mathbf{s})$  even in cases where the covariates  $x(\mathbf{s})$  are not available for all  $\mathbf{s} \in D$ .

## <span id="page-4-0"></span>3. Spatial latent Gaussian model with change of support

We present a hierarchical SLGM that addresses the challenge of handling spatial data with different supports in the response variable and predictors. We introduce the concept of change of support in spatial stochastic processes and discuss the properties of Gaussian processes (GPs) and linear combinations of basis functions when the support is altered (Section [3.1\)](#page-4-2). Subsequently, in Section [3.2,](#page-6-0) we propose a hierarchical SLGM that effectively handles the change of support by utilising latent spatial processes. Bayesian inference and spatial prediction of our approach are explained in sections [C.2](#page-29-0) and [C.3](#page-32-0) of the SM.

## <span id="page-4-2"></span>3.1. Change of Support on Stochastic Processes

Let  $\{W(\mathbf{s}) : \mathbf{s} \in \mathcal{D}\}\)$  represent a spatial stochastic process with a continuous index set  $\mathcal{D}$ and continuous state space  $\mathbb{R}$ . When the support is changed, the process is defined over a different index set, resulting in another process  $\{W(c): c \subset \mathcal{D}\}\$ , where c represents any geometry included in  $\mathcal{D}$ . Specifically, we focus on the case where c represents a region, and  $W(c)$  is defined as a integral over that region:

<span id="page-4-3"></span>
$$
W(c) = \int_{c} W(\mathbf{s})h(\mathbf{s})d\mathbf{s}.\tag{2}
$$

In this equation, the function  $h(s)$  serves as a weighting function that determines the importance of each location  $s$  within the region  $c$ . In practical applications, this function can take into account factors such as the sampling effort at a specific location. Alternatively,  $h(\boldsymbol{s})$  can be defined as  $|c|^{-1}$  to obtain an average over c, or as 1 for a total.

To effectively integrate datasets with different spatial supports through the change of support, it is necessary to use stochastic processes  $\{W(\mathbf{s})\}$  that allow for efficient and ac-curate computation of Equation [\(2\)](#page-4-3). Specifically, when considering a set of points  $S =$  $\{\mathbf s_i : i = 1, \ldots, n_{\mathbf s}\}\$ and regions  $\mathcal C = \{c_i : i = 1, \ldots, n_c\}$ , we need the capability to obtain the joint density of the associated random vectors  $W_{s} = [W(s_1), W(s_2), \ldots, W(s_m)]^{\top}$  and  $W_c = [W(c_1), W(c_2), \ldots, W(c_m)]^{\top}$ . Furthermore, we should be able to establish the connection or association between these random vectors  $W_s$  and  $W_c$ . In the following section, we discuss the properties with respect to the change of support for Gaussian processes and linear combinations of basis functions.

#### Gaussian Processes

The main property for a  $\text{GP}(\mu(\mathbf{s}), \kappa(\mathbf{s}, \mathbf{s}^*))$  is that the random vector  $W_{\mathbf{s}}$  for any finite set of points  $S = \{s_i : i = 1, \ldots, n_s\}$  follows a multivariate normal distribution with vector mean  $\mu_{\mathbf{s}} = [\mu(\mathbf{s}_1), \dots, \mu(\mathbf{s}_{n_{\mathbf{s}}})]$  and covariance matrix  $\Sigma_{\mathbf{s}}$  with elements  $(\Sigma_{\mathbf{s}})_{ij} = \kappa(\mathbf{s}_i, \mathbf{s}_j)$ . When the support is changed, as presented in Equation [\(2\)](#page-4-3), the random vector  $W_c$  for any finite set of regions  $\mathcal{C} = \{c_i : i = 1, \ldots, n_c\}$  follows also a multivariate normal distribution with mean  $\mu_c = \left[\int_{c_1} \mu(s) ds, \ldots, \int_{c_n} \mu(s) ds\right]$  and covariance matrix  $\Sigma_c$  [\(Gelfand et al., 2001\)](#page-21-6). The elements of the covariance matrix are defined by  $(\mathbf{\Sigma}_c)_{ij} = \frac{1}{|c_i||}$  $\frac{1}{|c_i||c_j|}\int_{\mathbf{s}\in c_i}\int_{\mathbf{s}^*\in c_j} \kappa(\mathbf{s}-\mathbf{s}^*)d\mathbf{s}d\mathbf{s}^*,$ where  $|\cdot|$  is the area operator.

More generally, considering the set of points and regions  $A = \{s_1, \ldots, s_{n_s}, c_1, \ldots, c_{n_c}\},\$ the associated random vector  $W_a$  also follows a multivariate normal distribution with  $\mu_a =$  $[\mu_{\rm s}^{\rm r}]$  $_{\rm s}^{\rm T}, \boldsymbol \mu_c^{\rm T}$ <sup>r</sup><sub>c</sub></sub> and covariance matrix  $\Sigma_a$  =  $\left\lceil \ \sum_{\mathbf{s}} \right\rceil \sum_{\mathbf{s}c}$  $\overline{\Sigma^\intercal_{\mathrm{sc}}\big|~\Sigma_c}$ 1 , where  $(\mathbf{\Sigma}_{\mathbf{s}c})_{ij} = \frac{1}{|c|}$  $\frac{1}{|c_j|}\int_{s\in c_j}\kappa(\mathbf{s}_i-\mathbf{s})d\mathbf{s}.$ Hence, it is possible to derive the joint density function for any set of points and/or regions, which can be utilised for statistical inference and spatial prediction. However, both depends of the elements of the covariate matrix, which are commonly approximated using Monte Carlo integration (see Section [C.1.1](#page-28-0) of the SM).

#### <span id="page-5-1"></span>Linear Combinations of Spatial Basis Functions

The evaluation of the linear combination of spatial basis functions over any n-dimensional set of points S can be expressed as  $W_s = B_s \delta$  where  $\delta$  is a n-dimensional GMRF and the row *i* of  $B_s$  is the evaluation of the basis function at point  $s_i$ . Under a change of support, the continuous process is projected to

<span id="page-5-0"></span>
$$
W(c) = \sum_{j=1}^{q_1} \sum_{l=1}^{q_2} \delta_{jl} \left( \int_{\mathbf{s} \in c} b_{jl}(\mathbf{s}) d\mathbf{s} \right) = \boldsymbol{b}^\mathsf{T}(c) \boldsymbol{\delta},\tag{3}
$$

where  $\delta$  is the q-dimensional GMRF and  $\boldsymbol{b}(c)$  is a vector containing the integral of the twodimensional basis functions  $b_{il}(\cdot)$  over c. Hence, any random vector associated with a set of regions C can be expressed as  $W_c = B_c \delta$  where the *i*th row of  $B_c$  is the evaluation of the basis functions at region  $c_i$ .

Notice that, under change of support, our process remains similar and we only need to update the basis functions as integrals over the region of interest while the main latent process  $\delta$  does not need any transformation. This provides a close connection between a subset of the process over any finite set of points  $\mathcal S$  and a set of regions  $\mathcal C$ . Both are simply a linear transformation of the latent GMRF  $\delta$  with different and known design matrices  $B_s$ and  $B_c$  respectively.

Integrating basis functions: An important aspect in Equation [\(3\)](#page-5-0) is that we should be able to integrate the basis functions over any arbitrary region c. Given that we define two dimensional basis functions as the product of uni-dimensional basis functions, then the integral is  $\int_{s\in c} b_{jl}(s)ds = \int_{(s_1,s_2)\in c} b_j^1(s_1)b_l^2(s_2)ds_1ds_2$ . This expression can be reduced for rectangular regions such as  $s_1 \in [L_1, U_1]$  and  $s_2 \in [L_2, U_2]$ ,  $\int_{\mathbf{s}\in c} b_{jl}(\mathbf{s})d\mathbf{s} = \int_{L_1}^{U_1} b_j^1(s_1)ds_1 \times$  $\int_{L_2}^{U_2} b_l^2(s_2)ds_2$ , as it is only required to compute the integral of the univariate basis functions. We use basis functions because the integral can be computed efficiently due to:

- 1. The j-th basis spline  $B_{jk}(x)$  of order k is non-zero from knot  $t_j$  to  $t_{j+k}$ .
- 2. The integral from knot  $t_j$  to an arbitrary value x is

$$
\int_{t_j}^{x} B_{j,k}(t)dt = \begin{cases} \frac{t_{j+k} - t_j}{k} \sum_{i=j}^{s-1} B_{i,k+1}(x), & t_j < x \le t_{j+k} \\ \frac{t_{j+k} - t_j}{k} \sum_{i=j}^{j+k-1} B_{i,k+1}(x), & t_{j+k} < x \end{cases}
$$

for s such that  $t_{s-1} < x \leq t_s$ .

3. The integral can be evaluated from  $t_i$  to x such that  $i \geq j$  and  $t_i < x \leq t_{j+k}$ ,

$$
\int_{t_i}^{x} B_{j,k}(t)dt = \begin{cases} \frac{t_{j+k} - t_j}{k} \left( \sum_{r=0}^{s-1} B_{j+r,k+1}(x) - \sum_{r=0}^{i-j-1} B_{j+r,k+1}(t_i) \right), & t_j < x \le t_{j+k} \\ \frac{t_{j+k} - t_j}{k} \left( \sum_{r=0}^{j+k-1} B_{j+r,k+1}(x) - \sum_{r=0}^{i-j-1} B_{j+r,k+1}(t_i) \right), & t_{j+k} < x \end{cases}
$$

for s such that  $t_{s-1} < x \leq t_s$ .

These results led to efficient computation of the integral by: i) evaluating it only when required, according to the local definition of basis splines, and ii) computing the integral depending only on few basis splines at order  $k + 1$ . The proofs of these results are provided in Section [A](#page-23-0) of SM. Hence, using linear combinations of basis functions we can integrate the process efficiently and exactly in rectangular geometries. Details of inference and prediction can be found in Section [C.1.2](#page-29-1) of SM.

## <span id="page-6-0"></span>3.2. Spatial Latent Gaussian Model with Change of Support

We propose a model-based approach to integrate spatial data by extending the spatial latent Gaussian models (SLGM) discussed in Section [2](#page-3-0) and leveraging the principles of change of support as outlined in Section [3.1.](#page-4-2) We begin by presenting a general framework for SLGM with change of support. Later, we provide specific models for the Gaussian and Bernoulli cases and describe key details of Bayesian inference for these models.

#### General framework

Our approach is founded on the existence of latent continuous processes that underlie the fundamental mechanisms of the studied phenomena. It acknowledges that change of support could also be required under transformations of the latent processes and considers that measurement error is shaped by the characteristics of the observations, independent of the latent process. With these fundamental principles in mind, our approach comprises three key components: the latent Gaussian model, the change of support model, and the observation model. A directed graph representing our model across the three layers is presented in Figure [1.](#page-8-0)

The *latent Gaussian model* closely resembles a linear geostatistical model, where a latent response process  $\{\eta(s)\}\$ is expressed as a function of zero-mean latent predictors  $\{V_i(s)\}\$ for  $j = 1, \ldots, p$  and a zero-mean latent spatial process  $\{W(\mathbf{s})\}\)$ , capturing additional spatial variation. This relationship is defined by the equation:

<span id="page-7-0"></span>
$$
\eta(\mathbf{s}) = \beta_0 + \mathbf{V}(\mathbf{s})^{\mathsf{T}} \boldsymbol{\beta} + W(\mathbf{s}), \quad \text{for } \mathbf{s} \in \mathcal{S}, \tag{4}
$$

In this model,  $\beta_0$  serves as an intercept parameter,  $\mathbb{E}[\eta(s)] = \beta_0$ , while  $\beta$  represents a vector of regression coefficients associated with the latent predictors  $V(s)$ . The latent processes  $\{\eta(s)\}\$  and  $\{V(s)\}\$ are linked to the responses and predictors, respectively, which can be observed at either point or aggregated levels.

The *change of support model* elucidates how processes within the latent Gaussian model can be projected onto different supports. This projection is not always required for the processes themselves but may be necessary for transformations. We define the change of support for the processes  $\{W(\mathbf{s})\}, \{V_j(\mathbf{s})\}$  and  $\{\eta(\mathbf{s})\}$  under transformations  $h_w(\cdot), h_{v_j}(\cdot)$ and  $h_n(\cdot)$  over the geometry  $c \subset \mathcal{S}$  as:

$$
W(c, h_w) = \frac{\int_{\mathbf{s}\in c} h_w(W(\mathbf{s}))d\mathbf{s}}{|c|}, \quad V_j(c, h_{v_j}) = \frac{\int_{\mathbf{s}\in c} h_{v_j}(V_j(\mathbf{s}))d\mathbf{s}}{|c|}, \quad \eta(c, h_\eta) = \frac{\int_{\mathbf{s}\in c} h_\eta(\eta(\mathbf{s}))d\mathbf{s}}{|c|}.
$$

This notation emphasises that the change of support under a transformation is distinct from the transformation of the change of support, i.e.,  $W(c, h_w) \neq h_w(W(c))$ . The choice of the transformation  $h(\cdot)$  depends on the relationship between the models proposed at the point and aggregated levels.

The *observation model* defines the distribution or data generation mechanism for observable variables (responses or predictors) at any location (point or geometry). This model incorporates the change of support processes and additional parameters. Specifically, let  $y_{ki}$ represent the observed response value at location  $l_{ki}^{[y]}$  for the *i*-th sampling unit of the *k*-th source of information, where  $k = 1, ..., K$  and  $i = 1, ..., n_k$ . The associated random variable follows:  $Y_k(l_{ki}^{[y]}) \sim \mathcal{F}(\eta(l_{ki}^{[y]}, h_\eta), \alpha_k)$ , where  $\alpha_k$  denotes additional parameters specific to the source of information k, required to define the data generation mechanism  $F(\cdot, \cdot)$ . These parameters can account for measurement errors or mean biases across different data sources. Notice that when observations are at point level, then  $\eta(l_{ki}^{[y]}, h_{\eta}) = h_{\eta}(\eta(l_{ki}^{[y]})).$ 

In a similar fashion, for observed predictor values at location  $l_{ji}^{[x]}$  for the *i*-th sampling unit of the *j*-th predictor, with  $j = 1, \ldots, p$  and  $i = 1, \ldots, m_j$ , the random variable associated with these observed predictors follows:  $X_j(l_{ji}^{[x]}) \sim \mathcal{F}(\eta(l_{ji}^{[x]}, h_{\eta}), \nu_j)$ , where  $\nu_j$  also represent additional parameters, primarily aimed at defining the variability of the measurement error in the predictors.

<span id="page-8-0"></span>Figure 1: A spatial latent Gaussian model with a change of support, involving three observed predictors  $(x_i)$  and two response datasets  $(y_i)$ .  $\{\eta(s)\}\$ represents the latent dependent stochastic process, while  ${V_i(\mathbf{s})}$  are latent predictors, and  ${W(\mathbf{s})}$  is a latent process accounting for unexplained spatial variability.  ${V_i(l_i^{[x]})}$  $\{a_i^{[x]}\}\}$  depicts the latent predictors projected to the supports of the observed predictors, while  $\{\eta(l_i^{[y]})\}$  $\{y_j^{[y]}\}\}$  shows the projection of the latent dependent process to the supports of the observed responses.

We have refrained from imposing specific distributions or data generation mechanisms, as these depend on the particular random variables and point-level models. In the following sections, we will provide specific details when dealing with Gaussian and Bernoulli-distributed response random variables.

## Gaussian case

In the Gaussian case, both the responses and predictors are assumed to follow a normal distribution. The *latent Gaussian model* for the process  $\{\eta(s)\}\$  remains consistent with Equation [4.](#page-7-0) We employ this model with the rationale that the latent process  $\{\eta(s)\}\$ is directly linked to the response of interest  ${Y(s)}$  in such a way that, in the absence of measurement error,  $Y(\mathbf{s}) = \eta(\mathbf{s})$ . Consequently, the aggregated model for any location  $c \subset$  **s** could be simply defined as  $Y(c) = |c|^{-1} \int_{s \in c} \eta(s) ds$ . Because that change of support is required directly on the latent process (i.e. an identity transformation), the support model with respect to an arbitrary region  $c \subset \mathcal{S}$  comprehend the following:

<span id="page-9-0"></span>
$$
W(c) = |c|^{-1} \int_{\mathbf{s} \in c} W(\mathbf{s}) d\mathbf{s},
$$
  
\n
$$
V_j(c) = |c|^{-1} \int_{\mathbf{s} \in c} V_j(\mathbf{s}) d\mathbf{s}, \text{ for } j = 1, ..., p,
$$
  
\n
$$
\eta(c) = \beta_0 + \mathbf{V}^{\mathsf{T}}(c)\beta_1 + W(c).
$$
\n(5)

Notice that, using spatially weighted spline functions, the integrals of the processes are reduced to the linear combinations of the integral with respect to the basis functions as presented in Section [3.1.](#page-4-2)

To define the *observation model*, it is important to note that  $\{\eta(s)\}\$  and  $\{\eta(c)\}\$  represent the process of interest at the point and aggregated levels without measurement error. Therefore, the response variables at the point and aggregated levels are simply a noisy version of the latent process  $\{\eta(s)\}\$ . The extent of measurement error depends on the scale of the sampling units and the measurement instruments associated with the sources of information. Thus, we assume that the characteristics of measurement errors are independent among different sources. Hence, considering  $l_{ki}^{[y]}$  as the location (point or geometry) of the *i*-th sampling unit in the  $k$ -th source of information for the response variable, the response model accounting for measurement error can be written as:

$$
Y_k(l_{ki}^{[y]}) = b_k + \eta(l_{ki}^{[y]}) + \varepsilon_k(l_{ki}^{[y]}), \quad \text{ for } k = 1, ..., K \text{ and } i = 1, ..., n_k,
$$

where  $b_k$  and  $\varepsilon_k(l_{ki}^{[y]}) \sim N(0, \tau_k^2(l_{ki}^{[y]}))$  are the intercept and error term of the k-th source of information, respectively. To ensure identifiability of the model, we set  $b_k$  to zero for the most reliable data source, and the remaining  $b_k$  terms are interpreted as mean biases relative to the reliable data source. The error term is assumed to be zero-mean and normally distributed with a variance function  $\tau_k^2(l)$ . If the sampling units for a source of information are of the same size, then the variance function can be defined as a constant (i.e.,  $\tau_k^2(l) = \tau_k^2$ ). However, if the sampling units are irregular in size, the variance function can be defined in terms of the size of the sampling units (e.g.,  $\tau_k^2(l) = \tau_k^2 \log(|l|)$ ).

Likewise, considering  $l_{ji}^{[x]}$  as the location of the *i*-th sampling unit for the *j*-th predictor, the predictor model accounting for measurement error can be expressed as:

$$
X_j(l_{ki}^{[x]}) = \alpha_j + V_j(l_{ji}^{[x]}) + \xi_j(l_{ji}^{[x]}), \quad \text{ for } j = 1, \dots, p \text{ and } i = 1, \dots, m_j,
$$
 (6)

where  $\alpha_j$  and  $\xi_j(l_{ji}^{[x]}) \sim N(0, \psi_j^2(l_{ji}^{[x]}))$  represent the intercept and error term of the j-th predictor, respectively. The variance function  $\psi_j^2(l)$  of the error term can also be defined with respect to the observed sampling units, as explained above.

## <span id="page-9-2"></span>Bernoulli case

Our approach can be used for modelling binary outcomes with spatial structure under a change of support. We initially describe the underlying relationship between the point and aggregate level models without measurement error before presenting the complete model.

Let  ${Y(s) : s \in S}$  represent a spatial process obtained by binarising the continuous latent process  $\{\eta(s)\}\$  with respect to an unknown threshold  $\gamma$ , as follows:

<span id="page-9-1"></span>
$$
Y(\mathbf{s}) = \begin{cases} 1, & \eta(\mathbf{s}) > \gamma, \\ 0, & \eta(\mathbf{s}) \le \gamma. \end{cases}
$$

Here,  $\{\eta(s)\}\$ is the latent process defined in Equation [\(4\)](#page-7-0). Under his model, the probability of success at location **s** is given by  $\Phi((\beta_0 - \gamma)/\sqrt{V[\eta(s)]})$ , where  $\Phi(\cdot)$  represents the cumulative distribution function of a standard normal distribution. This model is not identifiable due to two reasons: (i) an increase in the threshold  $\gamma$  can be offset by an increase in the intercept  $\beta_0$ , and (ii) a multiplicative factor in  $W(s)$  can be compensated by a multiplicative factor in  $\gamma$ ,  $\beta_0$ , and  $\beta$ . An identifiable model can be achieved by fixing a specific value for  $\gamma$  or  $\beta_0$ , and setting a constant variance for either  $W(s)$  or  $\varepsilon(s)$ . To define properly our point-level model, we set  $\gamma = 0$  and  $V[W(s)] = 1$ . It is worth noting that defining the threshold as  $\gamma = 0$  is equivalent to excluding  $\beta_0$  from the latent process  $\{\eta(s)\}\$  and using a threshold of  $-\beta_0$ .

Since the latent process  $\{\eta(s)\}\$ is inherently linked to the response binary process  $\{Y(s)\}\$ , it is natural to the define the aggregated spatial binary process  ${Y(c) : c \subset S}$  in terms of the aggregated latent process  $\{\eta(c): c \subset \mathcal{S}\}\$ . This definition is as follows:  $Y(c)$  $\int 1, \eta(c) > \gamma$ 0,  $\eta(c) \leq \gamma$ . Here, the binarisation of both point and aggregated levels depends on the same threshold  $\gamma$ . Consequently, the probability of success at location c is determined by  $\Phi((\beta_0 - \gamma)/\sqrt{V[\eta(c)]})$ . Because the aggregated model is derived from the point-level model, the assumptions are propagated. This results in both  $\gamma = 0$ , and a fixed value for  $V[W(c)]$ due to  $V[W(s)] = 1$ .

We use the previous mapping between the point-level and aggregated-level models to formulate the SLGM with a change of support for binary data. First, the *latent Gaussian* model is the same as in the general case (Equation [4\)](#page-7-0), with the restriction that  $V[W(s)] = 1$ . Second, the change of support model is the same as in the Gaussian case (Equation [5\)](#page-9-0) with fixed variance for  $W(c)$  due to  $V[W(s)] = 1$ .

To define the *observation model*, consider  $l_{ki}^{[y]}$  as the location (point or geometry) of the *i*-th sampling unit in the  $k$ -th source of information for the response variable. The response model can be expressed as:

$$
Y_k(l_{ki}^{[y]}) = \begin{cases} 1, & Z_k(l_{ki}^{[y]}) > 0, \\ 0, & Z_k(l_{ki}^{[y]}) \le 0. \end{cases} \text{ for } k = 1, ..., K \text{ and } i = 1, ..., n_k,
$$
  

$$
Z_k(l_{ki}^{[y]}) = b_k + \eta(l_{ki}^{[y]}) + \varepsilon_k(l_{ki}^{[y]}),
$$

where  $\{Z_k(\cdot)\}\$ is an auxiliary process, for the k-th source, that allows us to introduce biasrelated parameters  $b_k$  and error terms  $\varepsilon_k(\cdot)$  to account for measurement error. The inclusion of the additional intercept term  $b_k$  is equivalent to reducing the binarising threshold to  $\gamma - b_k$ . Both approaches can handle varying the likelihood of success among sources. Similar to the Gaussian case,  $b_k$  is set to zero to the most reliable source of information. The error term  $\varepsilon_k(l_{ki}^{[y]}) \sim N(0, \tau_k^2(l_{ki}^{[y]}))$  for the k-th source is assumed to be zero-mean normally distributed with a variance function  $\tau_k^2(l)$ , which may depend on the measure of geometry l. Finally, the predictor model that accounts for measurement error is defined as in Equation [\(6\)](#page-9-1).

## <span id="page-10-0"></span>4. Simulation Study

We performed both one-dimensional (Section [D.1,](#page-32-1) SM) and two-dimensional (Section [4.1\)](#page-11-0) simulation studies that involve various configurations of sampling units. Additionally, a simulation study for multiple binary data and aggregated predictors is presented in Section [4.2.](#page-13-0)

In Section [D.1](#page-32-1) and [4.1,](#page-11-0) we explore scenarios where data is observed in the following ways: regular grids, characterised by uniform sampling unit sizes and regular spacing across the entire area of interest; *irregular grids*, where sampling unit sizes vary, and spacing is nonuniform but coverage remains complete; *sparse sampling units*, featuring varying sampling unit sizes and sparse spatial distributions; and *overlapping sampling units*, where unit sizes differ, overlap, and coverage is incomplete. Our aim is to underscore the importance of properly considering spatial data support, showcase the adaptability of our approach to diverse scenarios, and account for measurement errors.

In Section [4.2,](#page-13-0) we simulate binary data with two sources of information and predictors, where all the sources have different spatial supports. We demonstrate that Bayesian inference and prediction are feasible using the methodology described above.

#### <span id="page-11-0"></span>4.1. Two dimensional

Considering a set of sampling units  $\mathbf{c} = \{c_1, c_2, \ldots, c_n\}$  for any of the four configurations described above, the corresponding observations are treated as realisations of the process  $\{W(s)\}\$  over the sampling units  $c_i$  with an additional measurement error  $\varepsilon_i$ :

<span id="page-11-1"></span>
$$
Y_i = \int_{s \in c_i} W(s)ds + \varepsilon_i, \quad \varepsilon_i \sim N(0, \sigma_i^2). \tag{7}
$$

We assume that the variance of the measurement error is constant  $(\sigma_i^2 = \sigma^2)$  when the sampling units have the same size (regular grids). However, it becomes inversely proportional to the area  $(\sigma_i^2 = \sigma^2/|c_i|)$  when they do not (irregular grids, sparse sampling units, and overlapping sampling units). It is worth noting that under this assumption, the measurement error is also influenced by the sampling units.

We define the latent process  $W(s)$  using a linear combination of basis functions, as explained in Section [3.1.2.](#page-5-1) When sampling units are arranged in a regular grid, we compare two models: a naive model (M1) that uses the centroids of the regions  $c_i^*$  to model the data  $(Y_i = W(c_i^*) + \varepsilon_i)$  and a **support model** (M2) that considers the spatial sampling units, as shown in Equation [7.](#page-11-1) On the other hand, when dealing with irregular grids, sparse sampling units, and overlapping sampling units, we compare three models: the **naive model** (M1) as explained above, a heteroscedastic model (M2) that accounts for the dependence of measurement error on unit sizes, and a support and heteroscedastic model (M3) that simultaneously considers spatial support and measurement error heteroscedasticity.

Bayesian inference is carried out through Gibbs sampling. In all of our experiments, we generated 10,000 MCMC samples, removed the first 2,000 samples, and retained every 1 out of 5 samples. Subsequently, the continuous latent process is predicted using the MCMC samples and the basis functions associated with the sampling units. The models are compared by analysing the characteristics of the predicted mean function, the uncertainty associated with the prediction, and their posterior probability of overpredicting the true process at m locations within the study area, defined as:

$$
p(s_j) = \Pr(W(s_j) > w(s_j) \mid \mathbf{y}), \quad \text{for } j = 1, \dots, m. \tag{8}
$$

## Regular grid

For this experiment, we define the latent process  $W(s)$  using 400 basis functions of degree 2 and a GMRF of order 1 with a scale parameter of  $\kappa = 0.09$ . Similar to the 1-dimensional case, the support model (M2) outperforms the naive model (M1). Specifically, when examining the predicted mean of M1, it becomes evident that this model tends to underestimate the peaks and overestimate the valleys, resulting in more rapid changes (Figure [2,](#page-12-0) panels B1-B2). When analysing the posterior probability of overprediction, we observe that M1 exhibits more frequent values close to 1 and 0, indicating a tendency for overprediction and underprediction respectively (Figure [2-](#page-12-0)C1). Conversely, the support model demonstrates a higher frequency of probabilities of overprediction close to 0.5 (Figure [2-](#page-12-0)C2). This behaviour is also linked to the fact that the uncertainty tends to be underestimated for locations near the centroids of the sampling units in the naive model.

<span id="page-12-0"></span>Figure 2: Comparison between the naive model (M1) and the support model (M2) when data is observed in a regular grid. Panel A1 displays the process of interest, while panel A2 shows the observed data. Panels B1-B2 present the predicted mean, and panels C1-C2 feature histograms of the posterior probability of overpredicting the underlying process.

## Irregular grid, sparse sampling units and overlapping sampling units

For the irregular grid and sparse sampling units experiments, the latent process  $W(s)$  was defined with 400 basis functions, while 225 basis functions were used for the experiments with overlapping sampling units. In all three experiments, GMRFs of order 1 with a scale parameter of  $\kappa = 0.09$  were employed.

For all three experiments, we consistently observed that both the naive model (M1) and the heteroscedastic model (M2) tend to underestimate the mean function near peaks and overestimate it around valleys, a behaviour reminiscent of what was observed in regular grids (Figure [11,](#page-39-0) [12,](#page-40-0) [13](#page-41-0) in SM; panels B1-B2). Conversely, the support and heteroscedastic model (M3) consistently yields predicted means closer to the true process values for both peaks and valleys (Figure [11,](#page-39-0) [12,](#page-40-0) [13](#page-41-0) in SM; panels B3). As a result, the predicted mean range for the support and heteroscedastic model (M3) is generally wider compared to that of M1 and M2. This underestimation and overestimation tendency observed in M1 and M2 is reflected in the posterior probability of overprediction, which shows high-frequency values close to 0 and 1 (Figure [11,](#page-39-0) [12,](#page-40-0) [13](#page-41-0) in SM; panels C1-C2). In contrast, the support and heteroscedastic model (M3) exhibits significantly lower levels of overprediction and underprediction when compared to M1 and M2 (Figure [11,](#page-39-0) [12,](#page-40-0) [13](#page-41-0) in SM; panel C3).

A noteworthy attribute of the support and heteroscedastic model (M3) is its proficiency in modelling data acquired under various sampling unit configurations. It captures essential properties of the underlying process and provides a suitable uncertainty quantification, even with sparse and overlapping sampling units. This underscores the effectiveness of the model in predicting the continuous latent process when data are observed on aggregated units.

## <span id="page-13-0"></span>4.2. Multiple binary data and aggregated predictors

In this section, we present a more realistic scenario involving binary response data observed by two instruments, where the second includes a bias. Predictors are observed at two different aggregated resolutions. The objective is to recover the parameters of the system and perform predictions of the latent processes.

Panels (A) and (B) in Figure [3](#page-14-0) depict the latent processes  $V_1(\mathbf{s})$  and  $V_2(\mathbf{s})$  along with observations at regular sampling units with lengths of 5.71 and 2.22, respectively. Panel (C) presents the latent process  $\eta(s) = 0.7V_1(s) - 0.6V_1(s) + W(s)$ , with noisy values having unit lengths of 4 and 2.86, respectively. It is important to note that the second source includes a bias of 0.3. Finally, Panel (D) shows the binary observations from the two sources at resolutions 4 and 2.86, respectively. These observations are simply a binarisation around 0 of the noisy values shown in Panel (C).

We conducted Bayesian inference with the aggregated predictors and binary aggregated outcomes for the change of support model, as outlined in Section [3.2.3,](#page-9-2) using the Gibbs sampling algorithm explained in Section [C.2.2.](#page-30-0) The algorithm was executed with 10,000 iterations, discarding the initial 2,000 iterations and retaining every 10th iteration. In Panels (A), (B), and (D) of Figure [3,](#page-14-0) the predictive samples of the latent processes are shown as grey solid lines.

For the first predictor (Panel A), the predictive samples effectively capture the pattern of the latent process, and the uncertainty bounds appropriately cover the latent process. Regarding the second predictor (Panel B), the predictive samples also capture the patterns of the latent process, exhibit a realistic uncertainty, and show a small mean bias. This bias is being accounted for by the intercept parameter  $\alpha_2$ . The key results are observed in Panel (D), where the predictive samples of the latent process  $\eta(s)$  accurately capture its patterns. Importantly, these predictions from binary aggregated outcomes and aggregated predictors do not exhibit the problems of approaches that disregard the support discussed in previous sections. Additionally, the mean bias in the latent predictor  $V_2(\mathbf{s})$  does not introduce bias in the prediction of the main process of interest  $\eta(s)$ , as it is effectively compensated by the intercept parameter in the response variable.

<span id="page-14-0"></span>Figure 3: Scenario with two predictors and two binary data sources. Panels (A-B) depict latent processes with observed values at aggregated supports. Panel (C) illustrates the latent process  $\eta(s)$  with noisy change of support, and Panel (D) presents binary responses. Gray solid lines in all panels represent posterior predictive samples of the latent processes.

## <span id="page-15-0"></span>5. Land suitability modelling in Rhondda Cynon Taf

Land suitability refers to the appropriateness of a piece of land for a specific use or purpose [\(Jafari and Zaredar, 2010\)](#page-21-11). This concept is crucial in land use planning, resource management, and environmental conservation. While land suitability itself is not directly observable, it can be inferred through the examination of climatic, internal soil and external soil characteristics [\(Wang, 1994\)](#page-22-5). In this section, we employ land cover data and predictors at various resolutions to predict land suitability for improved grassland in Rhondda Cynon Taf, a county borough in Wales. The resulting predictions can be used for further analysis, as demonstrated, for example, in [Brown et al.](#page-20-2) [\(2022\)](#page-20-2), where land suitability surfaces are used as input to generate future scenarios in the British land use system.

## 5.1. Data description

The data employed in our land suitability modelling is depicted in Figure [4.](#page-16-0) In Panel (A), we showcase the land cover data extracted from the 2017 UK land cover map at a 25m resolution, comprising 884, 196 cells for our selected study area [\(Morton et al., 2020\)](#page-21-12). This dataset is provided by the UK Centre for Ecology and Hydrology (UKCEH) and can be accessed at <https://www.ceh.ac.uk/data/ukceh-land-cover-maps>. Moving to Panel (B), we present *elevation* data at a  $25m$  resolution comprising 884, 642 cells, supplied by Copernicus and available at [https://spacedata.copernicus.eu/collections/](https://spacedata.copernicus.eu/collections/copernicus-digital-elevation-model) [copernicus-digital-elevation-model](https://spacedata.copernicus.eu/collections/copernicus-digital-elevation-model). It is important to note that, despite both datasets having a resolution of 25m, their support does not align.

Panels (C-D) in Figure [4](#page-16-0) depict growing degree days (GDD) and soil moisture surplus (SMS) at 1km resolution comprising 549 cells. These variables play a significant role in determining land suitability and are available as annual means for a period of 20 years (1991- 2011) describing the general characteristics of the land. While air temperature variables (maximum, minimum, and mean) and soil moisture deficit (SMD) are also available, the former ones exhibit high correlation with growing degree days ( $\rho > 0.95$ ), and the latter is zero constant across the extent of Rhondda Cynon Taf; consequently, they were not included in our analysis. For detailed information on the computation of growing degree days refer to [Robinson et al.](#page-22-6) [\(2017,](#page-22-6) [2023a\)](#page-22-7). Soil moisture was computed using the method outlined by [Cosby et al.](#page-20-5) [\(1984\)](#page-20-5), incorporating evapotranspiration, precipitation, and available water content [\(Robinson et al., 2023b;](#page-22-8) [FAO/IIASA/ISRIC/ISS-CAS/JRC, 2012\)](#page-21-13).

## <span id="page-15-1"></span>5.2. Modelling with change of support

Consider  $LC(c_i^{[y]})$  $\tilde{h}^{[y]}_i$  as the land class of interest at cell  $i = 1, \ldots, n$ , and  $X_j(c_{jk}^{[x]})$  as predictor  $j = 1, \ldots, p$  at cell k of the data source j  $(c_{jk}^{[x]})$ . The *observation model* defines land cover as a binarisation of a latent process  $\{Z(c_i^{[y]})\}$  $\{[\psi_i] \}$ } which depends on a spatial process  $\{\eta(c_i^{[y]})\}$  $\genfrac{\{}{\}}{0pt}{}{y]}{i}$ and an error term  $\varepsilon(c_i^{[y]})$  $\lambda_i^{[y]}$ ) ∼  $N(0, \tau^2)$ , and it defines the predictors  $X_j(c_{jk}^{[x]})$  in terms of latent

<span id="page-16-0"></span>Figure 4: Environmental variables of Rhondda Cynon Taf: (A-B) Land cover and elevation at 25m, and (C-D) Growing degree days (GDD) and soil moisture surplus (SMS) at 1km.

processes  $\{V_j(c_{jk}^{[x]})\}$  and an error term  $\xi_j(c_{jk}^{[x]}) \sim N(0, \psi_j^2)$ .

$$
LC(c_i^{[y]}) = \begin{cases} 1, & Z(c_i^{[y]}) > 0, \\ 0, & Z(c_i^{[y]}) \le 0. \end{cases}
$$
 for  $i = 1, ..., n$ ,  
\n
$$
Z(c_i^{[y]}) = \eta(c_i^{[y]}) + \varepsilon(c_i^{[y]}),
$$
  
\n
$$
X_j(c_{jk}^{[x]}) = \alpha_j + V_j(c_{jk}^{[x]}) + \xi_j(c_{jk}^{[x]}),
$$
 for  $j = 1, ..., p$  and  $k = 1, ..., m_j$ .

Note that  $\eta(c_i^{[y]})$  $\binom{[y]}{i}$  and  $V_j(c_{jk}^{[x]})$  capture that main spatial patterns presented in land cover  $LC(c_i^{[y]}$  $\binom{[y]}{i}$  and the predictor  $X_j(c_{jk}^{[x]})$ , respectively. These processes are related to continuous processes in the change of support model such as

$$
\eta(c_i^{[y]}) = \int_{\mathbf{s} \in c_i^{[y]}} \eta(\mathbf{s}) d\mathbf{s}, \qquad W(c_i^{[y]}) = \int_{\mathbf{s} \in c_i^{[y]}} W(\mathbf{s}) d\mathbf{s}, \qquad V_j(c_{jk}^{[x]}) = \int_{\mathbf{s} \in c_{jk}^{[x]}} V_j(\mathbf{s}) d\mathbf{s}.
$$

The relationship between the continuous latent processes of interest is defined in the *latent model.* Considering  $LS(s)$  as the land suitability at location s, then we define  $\eta(s)$  $\beta_0 + LS(\mathbf{s}) + W(\mathbf{s})$  and  $LS(\mathbf{s}) = V^{\dagger}(\mathbf{s})\beta_1$ . This implies that land suitability depends on the observed predictors through  $V(s)$  and influences land cover through  $\eta(s)$ . In this model, one of our primary interests is to predict the latent continuous process that defines land cover  $\{Z(\mathbf{s})\}$ . However, more importantly, we aim to predict the latent land suitability  $\{LS(\mathbf{s})\}$ at different supports while considering the associated uncertainty.

## 5.3. Results

Urban areas were masked out to avoid assuming that land suitability determined by the current urban status. This decision aligns with our objective to characterize land suitability based on climatic, internal soil, and external soil characteristics, aiming to capture the variability that influences land suitability beyond the presence of urban development. We did not include elevation as it was strongly correlated with GDD. The results described below are based on the model of Section [5.2](#page-15-1) including GDD and SMS as predictors.

#### Inference

Figure [16](#page-44-0) of SM illustrates the inference of the latent processes in the model. It can be observed that the mean of the latent process  $\{\delta_{v_1}\}$  captures the patterns observed in growing degree days (Figure [4-](#page-16-0)C), while the mean of  $\{\delta_{v_2}\}\)$  captures the patterns observed in soil moisture (Figure [4-](#page-16-0)D). The additional spatial variation not explained by either of the latent predictors is captured by  $\{\delta_w\}$ . On the bottom panels, we can also observe the uncertainty associated with these latent processes, with similar patterns for the uncertainty of GDD and SMS. The 95% estimated credible interval for the intercept is (−0.784, −0.647), related to the global proportion of observed cells with improved grassland. The latent predictor with respect to growing degree days has a positive effect (CI: 0.881, 1.04) in defining the chance of a cell being improved grassland, while the latent predictor related to soil moisture surplus has also a positive effect (CI: 0.12, 0.274).

## Prediction

Our model can provide predictions at different resolutions, considering the properties associated with changes in support. The prediction of the latent land cover at 100m, 500m, and 1km can be observed in Figure [5.](#page-18-1) All predictions capture the main patterns observed in the distribution of improved grassland (Figure [4-](#page-16-0)A). Particularly, it can be seen that north and west areas have lower levels of improved grassland, and uncertainty is higher in those areas. High levels of latent land cover are predicted even in areas where urban zones are present because we could easily mask out the urban cells and remove their influence. This task is not trivial if land-cover data is aggregated. Additionally, the standard deviation of predictions becomes smaller as we reduce the resolution of the process.

<span id="page-18-1"></span>Figure 5: Prediction of latent (continuous) land cover at 100m, 500m and 1km of resolution.

Although our model can predict the latent land cover, our primary goal is to predict land suitability, interpreted as the variability explained by intrinsic variables. Figure [6](#page-19-0) displays the mean and standard deviation of land suitability predictions for improved grassland at 100m, 500m, and 1km resolutions. We observe high levels of suitability in southern areas and low levels are evident in the western regions. Moderately low levels of suitability are found in the north-east. The uncertainty is higher in southern and western areas at different resolutions. Predictions at different resolutions are compatible due to the properties of our approach. These resulting surfaces at the desired resolution can be utilized to predict future scenarios or model land use systems, as demonstrated in [Brown et al.](#page-20-2) [\(2022\)](#page-20-2).

## <span id="page-18-0"></span>6. Discussion

We developed an extension of SLGM that can accommodate different spatial rectilinear supports for both response and predictor data sources. Our approach consists of three main components: the latent Gaussian model defining system relationships at a continuous level, the change of support model projecting latent processes to other supports, and the observa-

<span id="page-19-0"></span>Figure 6: Prediction of land suitability at 100m, 500m and 1km of resolution.

tion model describing data generation mechanisms while acknowledging possible mean biases between data sources and heteroscedasticity in measurement errors.

In this framework, employing a spatial process with a closed form to efficiently handle projection to other supports is crucial. We proposed the use of a linear combination of Gaussian Markov random fields (GMRF) and basis splines, ensuring that the projection to other supports depends only on the GMRF and the integral of basis splines over geometries of interest. This approach provides computational advantages, as the projection does not need approximations on rectilinear grids. The transparent relationship between the continuous process and the aggregated process is facilitated through the defined GMRF. The model is computationally efficient, leveraging the sparse properties of GMRFs and basis splines, enabling inference and prediction with change of support for large datasets.

Through data simulation, we assessed the efficacy of our model in one and two-dimensional spaces, considering regular grids, irregular grids, sparse sampling units, and overlapping sampling units. Consistently, we observed that models neglecting the support introduce biases in mean and uncertainty quantification and are more prone to over and underprediction. Conversely, our model captures the main trends of the underlying processes, providing reliable estimates of uncertainty and exhibiting low levels of over and underprediction. We

further evaluated the adequacy of our model on a more complex simulated dataset with binary outcomes, different supports for two data sources, and predictors observed at varying resolutions. Our model not only provided predictions about the latent processes but also recovered patterns in the latent response process with reliable uncertainty quantification.

Furthermore, we demonstrated the applicability of our approach in modeling land cover at a 25m resolution in Rhondda Cynon Taf (Wales), utilizing elevation (25m), growing degree days (1km), and soil moisture surplus (1km). Our model predicted spatial latent processes behind these variables and provided predictions of latent land cover and land suitability for improved grassland at various resolutions (100m, 250m, and 1km) along with associated uncertainties. Our results improved upon previous analyses conducted at a 1km resolution, addressing differences in support and computational challenges.

Future avenues involve approximating the change of support onto irregular geometries using a quadtree representation or efficient Monte Carlo integration. Additionally, we aim to extend this work to spatial point processes, and model jointly with aggregated count data. This requires establishing an appropriate relationship between aggregated and continuous processes in under transformations of latent processes. Efficient sampling algorithms for the full model are also required due to the presence of several latent processes, which can be achieved by marginalizing some of the latent processes.

# Supplementary Material

In this supplementary material, we delve into theoretical insights and proofs regarding the integral of basis splines in Section [A.](#page-23-0) We then explore common spatial stochastic processes utilized in spatial latent Gaussian models (SLGM) in Section [B.](#page-26-1) Additionally, we discuss the theory of SLGM with change of support in Section [C,](#page-28-1) covering Bayesian inference and spatial prediction. Further details on simulation studies are provided in Section [D.](#page-32-2) The MCMC algorithm chains for our case study are showcased in Section [E.](#page-41-1) Lastly, spatial prediction of the latent processes for land suitability is presented in Section [F.](#page-43-0)

## <span id="page-23-0"></span>A. Basis splines

## A.1. Introduction

**Definition 1.** Let  $\xi := (\xi)_1^{l+1}$  be a strictly increasing break sequence, and  $\nu := (\nu)_2^l$  represent homogeneous conditions. Then,  $\Pi \leq k, \xi, \nu$  is defined as the space of piecewise k-th order polynomial functions.

A function belonging to the space  $\Pi_{\leq k,\boldsymbol{\xi},\boldsymbol{\nu}}$  is characterized by k-order polynomials from  $\xi_i$  to  $\xi_{i+1}$  and satisfies homogeneous conditions, specifically  $p_i^{(j-1)}$  $j_i^{(j-1)}(\xi_i) = p_{i+1}^{(j-1)}(\xi_i)$  for  $j =$  $1, \ldots, \nu_i$  and  $i = 2, \ldots, l$ . As an example, when  $k = 4$  and  $\nu_i^l = 3$ , this space is associated with natural cubic splines.

Basis splines or B-splines, defined over a non-decreasing sequence of knots  $t$ , serve as efficient basis functions for the space of piecewise polynomial functions  $\Pi_{\leq k,\xi,\nu}$  [\(de Boor,](#page-20-6) [2001\)](#page-20-6). The knots **t** are determined by  $\xi$  and  $\nu$  in such a way that  $\xi_i$  occurs  $k - \nu_i$  times in t. Note that in the case of natural cubic splines, the breaks  $\xi_i$  occur only once in t.

<span id="page-23-1"></span>**Definition 2.** Considering a non-decreasing sequence of knots  $t$ , the j-th basis spline of order k is defined as

$$
B_{j,k}(x) = (t_{j+k} - t_j)[t_j, \dots, t_{j+k}] (\cdot - x)_{+}^{k-1}, \quad x \in \mathbb{R},
$$

which is equal to

$$
B_{j,k}(x) = [t_{j+1}, \ldots, t_{j+k}] (\cdot - x)_{+}^{k-1} - [t_j, \ldots, t_{j+k-1}] (\cdot - x)_{+}^{k-1}.
$$

The operator  $[t_j, \ldots, t_{j+k}]$ g represents the k-th divided difference of the function g, which is defined as the leading coefficient of the  $k+1$  order polynomial function that agrees with g at knots  $t_j, \ldots, t_{j+k}$ . Additionally,  $(-x)_+ = \max(-x)$ , 0 represents the truncated function of  $(-x)$  at x. While the above definition is useful for proving properties of basis splines, for implementation, it is better to use the following representation.

**Theorem 1.** Let **t** be a non-decreasing sequence. The basis splines of order 1 are given by

$$
B_{j1}(x) = \begin{cases} 1, & \text{if } t_j \le x < t_{j+1}; \\ 0, & \text{otherwise.} \end{cases}
$$

Additionally, the basis splines of order  $k > 1$  can be recursively expressed as

$$
B_{jk}(x) = \omega_{jk}(x)B_{j,k-1}(x) + (1 - \omega_{j+1,k}(x))B_{j+1,k-1}(x),
$$

where  $\omega_{ik}(x) = (x - t_i)/(t_{i+k-1} - t_i)$ .

The basis spline of order one is directly derived from Definition [2,](#page-23-1) and the recursive relationship is established by applying the properties of the  $k$ -th divided difference [\(de Boor,](#page-20-6) [2001\)](#page-20-6).

**Definition 3.** A spline function of order k belonging to the space  $\Pi_{\leq k,\xi,\nu}$  and corresponding knot sequence  $t$  is defined as a linear combination of basis splines,

$$
f(x) = \sum_{j} \alpha_j B_{jk}(x), \quad \alpha_j \in \mathbb{R},
$$

where  $B_{ik}(x)$  is build with respect to the knot sequence **t**.

Out interest in to use spline functions to represent latent processes using stochastic weights  $\{\alpha_i\}$ . In the following sections, we analyse the differentiation and integration of basis splines and spline functions.

## A.2. Differentiation

<span id="page-24-0"></span>**Theorem 2.** Let  $B_{jk}(x)$  be a basis spline of order k starting at knot  $t_j$ . Then, the derivative can be expressed with respect to the basis splines of order  $k - 1$  as follows:

$$
DB_{jk}(x) = (k-1) \left( \frac{B_{j,k-1}(x)}{t_{j+k-1} - t_j} - \frac{B_{j+1,k-1}(x)}{t_{j+k} - t_{j+1}} \right)
$$

.

Proof. Consider the expanded version of Definition [2](#page-23-1) for basis splines and apply the derivative to both terms:

$$
DB_{jk}(x) = [t_{j+1}, \dots, t_{j+k}]D(\cdot - x)_{+}^{k-1} - [t_j, \dots, t_{j+k-1}]D(\cdot - x)_{+}^{k-1}
$$
  
= -(k-1)[t\_{j+1}, \dots, t\_{j+k}] (\cdot - x)\_{+}^{k-2} + (k-1)[t\_j, \dots, t\_{j+k-1}] (\cdot - x)\_{+}^{k-2}.

Notice that, using Definition [2,](#page-23-1) we can express the  $k-1$  divided difference as basis splines of order  $k-1$ , i.e.,  $[t_{j+1},...,t_{j+k}]$  $(-x)^{k-2}$  =  $B_{j+1,k-1}(x)/(t_j + k - t_{j+1})$  and similarly for  $[t_j, \ldots, t_{j+k-1}]$  $\cdot - x)_{+}^{k-2} = B_{j,k-1}(x)/(t_{j+k-1} - t_j).$ 

**Corollary 1.** Let  $f(x)$  be a spline function of order k and corresponding knot sequence **t** with coefficients  $\alpha_j \neq 0$  when  $r \leq j \leq s$ , then the derivative of  $f(x)$  is

$$
D\left(\sum_{j=r}^{s} \alpha_j B_{jk}(x)\right) = \sum_{j=r}^{s+1} (k-1) \left(\frac{\alpha_j - \alpha_{j-1}}{t_{j+k-1} - t_j}\right) B_{j,k-1}(x).
$$

Proof.

$$
D\left(\sum_{j=r}^{s} \alpha_{j} B_{jk}(x)\right) = \sum_{j=r}^{s} \alpha_{j} DB_{jk}(x)
$$
  
= 
$$
\sum_{j=r}^{s} \alpha_{j}(k-1) \left(\frac{B_{j,k-1}(x)}{t_{j+k-1} - t_{j}} - \frac{B_{j+1,k-1}(x)}{t_{j+k} - t_{j+1}}\right)
$$
 (by Theorem 2)  
= 
$$
\sum_{j=r}^{s} \alpha_{j}(k-1) \left(\frac{B_{j,k-1}(x)}{t_{j+k-1} - t_{j}}\right) - \sum_{j=r+1}^{s+1} \alpha_{j-1}(k-1) \left(\frac{B_{j,k-1}(x)}{t_{j+k-1} - t_{j}}\right)
$$
  
= 
$$
\sum_{j=r}^{s+1} (k-1) \left(\frac{\alpha_{j} - \alpha_{j-1}}{t_{j+k-1} - t_{j}}\right) B_{j,k-1}(x).
$$

The last equality holds because  $\alpha_{r-1} = 0$  and  $\alpha_{s+1} = 0$ .

 $\Box$ 

#### A.3. Integration

<span id="page-25-0"></span>**Theorem 3.** Let  $B_{jk}(t)$  be a basis spline of order k starting at knot  $t_j$ . Then, the integral  $\int_{t_j}^{x} B_{j,k}(t)dt$  for  $t_j \leq x \leq t_{j+k}$  can be expressed with respect to the basis splines of order  $k+1$ as follows:

$$
\int_{t_j}^{x} B_{j,k}(t)dt = \frac{t_{j+k} - t_j}{k} \sum_{i=j}^{s-1} B_{i,k+1}(x),
$$

where  $s : t_{s-1} < x < t_s$ .

*Proof.* Given that the basis spline  $B_{jk}(x)$  is non-zero from  $t_j$  to  $t_{j+k}$ , then we can evaluate the integral from  $t_j$  to an arbitrary value  $t_j \leq x \leq t_{j+k}$ . Using Theorem [2](#page-24-0) to the basis function  $B_{i,k+1}(x)$ , we obtain that

$$
DB_{j,k+1}(x) = k \left( \frac{B_{j,k}(x)}{t_{j+k} - t_j} - \frac{B_{j+1,k}(x)}{t_{j+k+1} - t_{j+1}} \right),
$$
  

$$
\int_{t_j}^x DB_{j,k+1}(t)dt = \frac{k}{t_{j+k} - t_j} \int_{t_j}^x B_{j,k}(t)dt - \frac{k}{t_{j+k+1} - t_{j+1}} \int_{t_j}^x B_{j+1,k}(t)dt,
$$
  

$$
\frac{k}{t_{j+k} - t_j} \int_{t_j}^x B_{j,k}(t)dt = B_{j,k+1}(x) + \frac{k}{t_{j+k+1} - t_{j+1}} \int_{t_{j+1}}^x B_{j+1,k}(t)dt,
$$
  

$$
\int_{t_j}^x B_{j,k}(t)dt = \frac{t_{j+k} - t_j}{k} B_{j,k+1}(x) + \frac{t_{j+k} - t_j}{t_{j+k+1} - t_{j+1}} \int_{t_{j+1}}^x B_{j+1,k}(t)dt.
$$

Replacing  $\int_{t_{j+1}}^{x} B_{j+1,k}(t) dt$  using the above equivalence, then

$$
\int_{t_j}^{x} B_{j,k}(t)dt = \frac{t_{j+k} - t_j}{k} B_{j,k+1}(x) +
$$
\n
$$
\frac{t_{j+k} - t_j}{t_{j+k+1} - t_{j+1}} \left( \frac{t_{j+k+1} - t_{j+1}}{k} B_{j+1,k+1}(x) + \frac{t_{j+k+1} - t_{j+1}}{t_{j+k+2} - t_{j+2}} \int_{t_{j+2}}^{x} B_{j+2,k}(t)dt \right),
$$
\n
$$
= \frac{t_{j+k} - t_j}{k} B_{j,k+1}(x) + \frac{t_{j+k} - t_j}{k} B_{j+1,k+1}(x) + \frac{t_{j+k} - t_j}{t_{j+k+2} - t_{j+2}} \int_{t_{j+2}}^{x} B_{j+2,k}(t)dt,
$$
\n
$$
= \frac{t_{j+k} - t_j}{k} \sum_{i=j}^{\infty} B_{i,k+1}(x) = \frac{t_{j+k} - t_j}{k} \sum_{i=j}^{s-1} B_{i,k+1}(x).
$$

For s such as  $t_{s-1} < x \leq t_s$ . The previous result holds because  $B_{i,k+1}(x) = 0$  for  $i \geq s$ .  $\Box$ 

**Corollary 2.** Let  $B_{jk}(t)$  be a basis spline of order k starting at knot  $t_j$ . Then, the integral  $\int_{t_i}^{x} B_{j,k}(t)dt$  for  $j \leq i$  and  $t_i < x \leq t_{j+k}$  can be expressed with respect to the basis splines of order  $k + 1$  as follows:

$$
\int_{t_i}^x B_{j,k}(t)dt = \frac{t_{j+k} - t_j}{k} \left( \sum_{r=0}^{s-1} B_{j+r,k+1}(x) - \sum_{r=0}^{i-j-1} B_{j+r,k+1}(t_i) \right),
$$

where  $s : t_{s-1} < x < t_s$ .

Proof. This result holds by separating the integral in two parts

$$
\int_{t_i}^{x} B_{j,k}(t)dt = \int_{t_j}^{x} B_{j,k}(t)dt - \int_{t_j}^{t_i} B_{j,k}(t)dt
$$

and applying Theorem [3](#page-25-0) for both sides.

**Corollary 3.** Let  $f(x)$  be a spline function of order k and corresponding knot sequence **t** with coefficients  $\alpha_j \neq 0$  when  $r \leq j \leq n$ , then the integral of  $f(x)$  is

$$
\int_{t_r}^{x} \left( \sum_{i=r}^{n} \alpha_i B_{ik}(t) \right) dt = \sum_{i=r}^{s-1} \left( \sum_{j=r}^{i} \alpha_j (t_{j+k} - t_j) / k \right) B_{i,k+1}(x),
$$

where  $s : t_{s-1} < x < t_s$ .

*Proof.* Noticing that all basis splines  $B_{ik}(t)$  for  $i > s$ , where  $s : t_{s-1} < x < t_s$ , are zero in the interval  $[t_r, x]$ , then

$$
\int_{t_r}^{x} \left( \sum_{i=r}^{n} \alpha_i B_{ik}(t) \right) dt = \int_{t_r}^{x} \left( \sum_{i=r}^{s-1} \alpha_i B_{ik}(t) \right) dt
$$
  
\n
$$
= \sum_{i=r}^{s-1} \alpha_i \int_{t_r}^{x} B_{ik}(t) dt
$$
  
\n
$$
= \sum_{i=r}^{s-1} \alpha_i \int_{t_i}^{x} B_{ik}(t) dt
$$
  
\n
$$
= \sum_{i=r}^{s-1} \alpha_i \frac{t_{i+k} - t_i}{k} \sum_{j=i}^{s-1} B_{j,k+1}(x)
$$
 (Using Theorem 3)  
\n
$$
= \sum_{i=r}^{s-1} \sum_{j=i}^{s-1} \left( \frac{\alpha_i (t_{i+k} - t_i)}{k} \right) B_{j,k+1}(x)
$$
  
\n
$$
= \sum_{j=r}^{s-1} \sum_{i=r}^{j} \left( \frac{\alpha_i (t_{i+k} - t_i)}{k} \right) B_{j,k+1}(x)
$$
  
\n
$$
= \sum_{j=r}^{s-1} \left( \sum_{i=r}^{j} \frac{\alpha_i (t_{i+k} - t_i)}{k} \right) B_{j,k+1}(x)
$$
  
\n
$$
= \sum_{i=r}^{s-1} \left( \sum_{j=r}^{i} \alpha_j (t_{j+k} - t_j) / k \right) B_{i,k+1}(x).
$$

## <span id="page-26-1"></span>B. Spatial latent Gaussian models

#### <span id="page-26-0"></span>B.1. Spatial Stochastic Processes

Spatial stochastic processes are essential for the definition of SLGMs. In this section, we provide more information about Gaussian processes, Gaussian Markov random fields, and

 $\Box$ 

 $\Box$ 

linear transformations of basis functions which are essential stochastic processes for spatial modelling.

## Gaussian Processes

A spatial Gaussian process (GP) is a stochastic process  $\{W(\mathbf{s}) : \mathbf{s} \in \mathcal{D} \subset \mathbb{R}^2\}$  with a continuous index set. It is characterised by the property that any finite subset of random variables follows a multivariate Gaussian distribution [\(Rasmussen and Williams, 2005;](#page-21-14) [Diggle](#page-20-7) [and Ribeiro, 2007\)](#page-20-7). The process  $GP(\mu(\mathbf{s}), \kappa(\mathbf{s}, \mathbf{s}^*))$  is defined by a mean function  $\mu(\mathbf{s})$  and a covariance function, also known as a kernel function, denoted as  $Cov[W(s), W(s^*)] = \kappa(s, s^*)$ for any pair of locations  $s, s^* \in \mathcal{D}$ . Gaussian processes are widely utilised for modelling spatial data due to their ability to model dependencies using kernel functions, facilitate statistical inference (both classical and Bayesian), and provide predictions with uncertainty quantification which is crucial for decision-making.

## Gaussian Markov Random Fields

A spatial Gaussian Markov random field (GMRF) is a stochastic process  $\{W(c): c \in C\}$  with a discrete index set  $\mathcal{C} = \{c_1, \ldots, c_n\}$  where each  $c_i$  represents a non-overlapping region. Let the connectivity of the index set C be defined by the undirected graph  $\mathcal{G} = (\mathcal{V}, \mathcal{E})$  with nodes V and edges  $\mathcal{E} = \{\{i, j\}; i, j \in \mathcal{V}\}\$ . Then, the random vector  $W_c = [W(c_1), \ldots, W(c_n)]^{\mathsf{T}}$ follows a multivariate Gaussian distribution with mean  $\mu$  and precision matrix  $Q > 0$  such as

$$
Q_{ij} \neq 0 \Longleftrightarrow \{i, j\} \in \mathcal{E} \text{ for all } i \neq j. \tag{9}
$$

In cases where Q is a semidefinite matrix with rank  $(n - k)$ , the process is known as an intrinsic Gaussian Markov random field (IGMRF) with density

$$
f(\boldsymbol{x}) = (2\pi)^{-(n-k)/2} |\boldsymbol{Q}^*|^{1/2} \exp\left(-\frac{1}{2}(\boldsymbol{x}-\boldsymbol{\mu})^{\mathsf{T}} \boldsymbol{Q}(\boldsymbol{x}-\boldsymbol{\mu})\right), \tag{10}
$$

where |·|<sup>∗</sup> denotes the generalised determinant [\(Rue and Held, 2005\)](#page-22-9). The precision matrix can usually be decomposed as the product of a scalar precision parameter  $\kappa$  and a structure matrix  $\boldsymbol{P}$ .

Gaussian Markov random fields are used because they capture the spatial structure based on the connectivity of the index elements, resulting in a sparse precision matrix  $Q$ . This sparsity leads to lower computational costs compared to Gaussian processes. The applicability of GMRF is limited to discrete index sets. However, they can also be used to represent Gaussian processes through their connection with stochastic partial differential equations [\(Lindgren et al., 2011\)](#page-21-15).

## Linear Combinations of Spatial Basis Functions

Another type of continuous-index spatial stochastic process  $\{W(\mathbf{s}) : \mathbf{s} \in \mathcal{D} \subset \mathbb{R}^2\}$  can be obtained as a linear combination of q spatial basis functions  $b_i(\mathbf{s})$  such as  $W(\mathbf{s}) = \sum_{i=1}^q \delta_i b_i(\mathbf{s})$ . Where  $\delta_i$ , for  $i = 1, \ldots, q$ , are the weights associated to the basis functions. In particular, we focus on the case where the basis functions  $b_i(s)$  are locally defined and the spatial structure is introduced by defining  $\{\delta_i\}$  as a GMRF with a two-dimensional regular grid as an index set. More specifically, consider the regular grid with  $q_1$  and  $q_2$  knots corresponding to basis splines  ${B_{jk}^1(\cdot): j = 1, \ldots, q_1}$  and  ${B_{lk}^2(\cdot): l = 1, \ldots, q_2}$  of order k for the first and second coordinates, respectively. Then, the spatial process can be written as

$$
W(s) = \sum_{j=1}^{q_1} \sum_{l=1}^{q_2} \delta_{jl} B_{jk}^1(s_1) B_{lk}^2(s_2) = \mathbf{b}^\mathsf{T}(\mathbf{s}) \delta,
$$
\n(11)

where  $\delta$  is a q-dimensional GMRF and  $b(s)$  is a vector containing the two-dimensional basis functions  $b_{jl}(s) = B_{jk}^1(s_1)B_{lk}^2(s_2)$  expressed as the tensor product of two sets of onedimensional basis splines of order  $k$ . The advantage of using locally defined basis functions and GMRF is that  $\{W(s)\}\$ has also sparse properties leading to lower computational costs.

## <span id="page-28-1"></span>C. Spatial latent Gaussian model with change of support

## C.1. Change of Support on Stochastic Processes

#### <span id="page-28-0"></span>Gaussian Processes

Inference: Using the properties of a GP for change of support, we can express the likelihood function for observations with sampling units as points and/or regions to estimate the parameters  $\theta$  defined in the mean function  $\mu(\mathbf{s})$  and the covariance function  $\kappa(\mathbf{s}, \mathbf{s}^*)$ . However, it is important to acknowledge that in the most commonly used models, the elements of the covariance matrix cannot be obtained analytically. Therefore, approximation methods, with Monte Carlo integration being the most common, are employed to estimate these quantities at each iteration of the algorithm to obtain the estimates or to obtain samples from the posterior distribution.

**Prediction:** Let us consider a setting where we desire predictions at new points and/or regions  $\mathcal{A}^* = \{\mathbf{s}_1^*, \ldots, \mathbf{s}_{m_s}^*, c_1^*, \ldots, c_{m_c}^*\}$ . Predictions at these new locations, given a set of observations at points and/or regions  $(W_{a^*} | W_a = w)$ , follow a multivariate normal distribution with mean vector and covariance matrix

$$
\begin{aligned} \boldsymbol{\mu}_{a^*|a} &= \boldsymbol{\mu}_{a^*} + \boldsymbol{\Sigma}_{a^*a}^\intercal \boldsymbol{\Sigma}_{a}^{-1} (\boldsymbol{w} - \boldsymbol{\mu}_a), \\ \boldsymbol{\Sigma}_{a^*|a} &= \boldsymbol{\Sigma}_{a^*} - \boldsymbol{\Sigma}_{aa^*}^\intercal \boldsymbol{\Sigma}_{a}^{-1} \boldsymbol{\Sigma}_{aa^*}. \end{aligned}
$$

The covariance matrices  $\Sigma_a$  and  $\Sigma_{a^*}$  are defined as usual, while the cross-covariance matrix is defined as

$$
\Sigma_{aa*} = \left[\frac{\Sigma_{ss^*} \mid \Sigma_{sc^*}}{\Sigma_{cs^*} \mid \Sigma_{cc^*}}\right],\tag{12}
$$

which depends of the covariance under change of support. Therefore, the predictive distribution at any set of points and/or regions can be derived. However, as in the inference case, approximation methods are required to compute the mean and covariance of the predictive distribution with Monte Carlo integration being the most common.

#### <span id="page-29-1"></span>Linear Combinations of Spatial Basis Functions

**Inference:** Consider a set of point-level  $y_c$  and region-level  $y_s$  observations coming from the following random vectors  $Y_{\mathcal{S}} \mid W_{\mathcal{S}} \sim \mathcal{N}(W_{\mathcal{S}}, \sigma_{\mathcal{S}}^2 I)$  and  $Y_{\mathcal{C}} \mid W_{\mathcal{C}} \sim \mathcal{N}(W_{\mathcal{C}}, \sigma_{\mathcal{C}}^2 I)$ . Due to the connection of  $W_{\mathcal{S}}$  and  $W_{\mathcal{C}}$  through  $\delta$ , the conditional joint density of  $Y = [Y_{\mathcal{S}}]$  $\stackrel{_\prime}{_\mathcal{S}}, \mathbf{Y}_{\mathcal{C}}^\intercal$  $\left[\begin{smallmatrix} 1 \\ C \end{smallmatrix}\right]$ <sup>T</sup> is also a normal distribution  $\mathcal{N}(\boldsymbol{W}, D)$  with mean and covariance

$$
\boldsymbol{W} = \left[ \begin{array}{c} \boldsymbol{B}_{\mathcal{C}} \\ \boldsymbol{B}_{\mathcal{S}} \end{array} \right] \boldsymbol{\delta}, \quad \boldsymbol{D} = \text{BlockDiagonal}(\sigma_{\mathcal{S}}^2 \boldsymbol{I}, \sigma_{\mathcal{C}}^2 \boldsymbol{I}). \tag{13}
$$

Given that  $\delta$  is also normally distributed, the likelihood associated with the point-level and region-level observations is  $\mathcal{N}(0, B^{\dagger}Q^{-1}B)$ , where each row of the design matrix  $B^{\dagger}$  =  $[\breve{\bm{B}_S^{\intercal}}]$  $\stackrel{\tau}{\mathcal{S}}, \boldsymbol{B}_{\mathcal{C}}^{\intercal}$  $\mathcal{C}^{\mathsf{T}}$  is related to the basis functions evaluated at point-level or region-level. Inference is feasible using maximum likelihood or Bayesian inference.

**Prediction:** Assuming that we can only observe  $W_{\mathcal{S}}$  and  $W_{\mathcal{C}}$  through  $Y_{\mathcal{S}} \sim \mathcal{N}(W_{\mathcal{S}}, \sigma_{\mathcal{S}}^2 I)$ and  $Y_c \sim \mathcal{N}(W_c, \sigma_c^2 I)$ , respectively, then the predictive distribution at new locations and regions  $W^*$  given the realizations at point-level  $y_S$  and aggregated-level  $y_C$  is

$$
\pi\left(\mathbf{W}_{\mathcal{S}}^*,\mathbf{W}_{\mathcal{C}}^*\mid\mathbf{y}_{\mathcal{S}},\mathbf{y}_{\mathcal{C}}\right)=\int\pi\left(\boldsymbol{\delta}\mid\mathbf{y}_{\mathcal{S}},\mathbf{y}_{\mathcal{C}}\right)\pi\left(\mathbf{W}_{\mathcal{S}}^*,\mathbf{W}_{\mathcal{C}}^*\mid\boldsymbol{\delta}\right)d\boldsymbol{\delta}.
$$

The second term inside the integral is defined by

<span id="page-29-2"></span>
$$
\boldsymbol{W}^* = \left[ \begin{array}{c} \boldsymbol{B}_\mathcal{C}^* \\ \boldsymbol{B}_\mathcal{S}^* \end{array} \right] \boldsymbol{\delta},\tag{14}
$$

while the first term is the posterior distribution of  $\delta$ , which is a normal distribution with covariance matrix and mean as follows

$$
\begin{aligned} \boldsymbol{\Sigma}_{\delta/y_s} &= \left(\frac{\boldsymbol{B}_\mathcal{S}^\intercal \boldsymbol{B}_\mathcal{S}}{\sigma^2_\mathcal{S}} + \frac{\boldsymbol{B}_\mathcal{C}^\intercal \boldsymbol{B}_\mathcal{C}}{\sigma^2_\mathcal{C}} + \kappa \boldsymbol{P}\right)^{-1}, \\ \boldsymbol{\mu}_{\delta/y_s} &= \boldsymbol{\Sigma}_{\delta/y_s} \left(\frac{\boldsymbol{B}_\mathcal{S}^\intercal \boldsymbol{y}_\mathcal{S}}{\sigma^2_\mathcal{S}} + \frac{\boldsymbol{B}_\mathcal{C}^\intercal \boldsymbol{y}_\mathcal{C}}{\sigma^2_\mathcal{C}}\right). \end{aligned}
$$

We obtain realisations of the prediction by sampling from the posterior of  $\delta$  and later applying the corresponding linear transformation with Equation [14.](#page-29-2)

## <span id="page-29-0"></span>C.2. Bayesian inference and prediction

We introduce the matrix formulation of the spatial latent Gaussian model for binary outcomes under a change of support and subsequently, elucidate a Gibbs sampling scheme to draw samples from the posterior distribution.

## Model

Consider  $L_k^{[y]}$  $\frac{y}{k}$  as the set of sampling units for the response variable in the k–th data source for  $k = 1, \ldots, K$ , and  $L_i^{[x]}$  $j^{[x]}$ , for  $j = 1, \ldots, p$ , as the predictor set. The matrix form of the model for binary outcomes under a change of support can expressed as follows:

$$
\mathbf{Y}_k = I(\mathbf{Z}_k > 0), \quad \text{for } k = 1, ..., K,
$$
  

$$
\mathbf{Z}_k = b_k \mathbf{1}_{n_k} + \beta_0 \mathbf{1}_{n_k} + \sum_{j=1}^p \beta_j \mathbf{B}_j(L_k^{[y]}) \boldsymbol{\delta}_{v_j} + \mathbf{B}_w(L_k^{[y]}) \boldsymbol{\delta}_w + \boldsymbol{\varepsilon}_k,
$$
  

$$
\mathbf{X}_j = \alpha_j \mathbf{1}_{m_j} + \mathbf{B}_j(L_j^{[x]}) \boldsymbol{\delta}_{v_j} + \boldsymbol{\xi}_j, \quad \text{for } j = 1, ..., p.
$$

Here  $Y_k$ ,  $Z_k$  and  $\varepsilon_k$  are random vectors of response variables, auxiliary variables and error terms corresponding to the observations  $y_k$  for the k-th source. Similarly  $X_i$  and  $\xi_i$  are the random vectors of predictor variables and error terms corresponding to the observed predictor values  $\boldsymbol{x}_j$ .  $\boldsymbol{B}_j(L_k^{[y]})$  $\bm{B}_j (L_j^{[x]}) , \bm{B}_j (L_j^{[x]}$  $\bm{B}_w(L_k^{[y]})$  and  $\bm{B}_w(L_k^{[y]})$  $\binom{[y]}{k}$  are basis functions evaluated at specified location sets, which are associated to the latent processes  $\bm{\delta}_{v_j} \sim \text{GMRF}(\bm{0}, \kappa_{v_j} \bm{P}_{v_j})$  and  $\bm{\delta}_w \sim$ GMRF(0,  $\kappa_w \mathbf{P}_w$ ). The error terms are assumed to be normally distributed with diagonal covariance matrices such as  $\varepsilon_k \sim \mathcal{N}(0, \sigma_{y_k}^2 D_{y_k})$  and  $\xi_j \sim \mathcal{N}(0, \sigma_{x_j}^2 D_{x_j})$ . Notice that the auxiliary variables can also be written as  $\bm{Z}_k = \left[ \begin{array}{c|c} 1 & A_k & V_k \end{array} \right] \bm{\beta}^* {+} \bm{B}_w (L_k^{[y]})$  $\bm{h}_k^{[y]})\bm{\delta}_w{+}\bm{\varepsilon}_k,$  where  $\bm{A}_k$ is a design matrix of dummy variables k, and  $\mathbf{V}_k$  is the design matrix of latent predictors for the locations of the k-th source, and  $\boldsymbol{\beta}^* = [\beta_0, b_1, \dots, b_{K-1}, \beta_1, \dots, \beta_p]^{\mathsf{T}}$  the set of coefficient parameters.

The Bayesian model is fully specified by imposing a normal prior distribution for  $\beta^*$ ,  $\mathcal{N}(\mathbf{0}, \Sigma_{\beta})$ . An inverse-gamma prior distribution for the error variances, such as  $\sigma_{y_k}^2 \sim$  $IG(a_{y_k}, b_{y_k})$  and  $\sigma_{x_j}^2 \sim IG(a_{x_j}, b_{x_j})$ . Finally, the scale parameters of the GMRFs are  $\kappa_{v_j} \sim G(a_{v_j}, b_{v_j})$ . We do not impose a prior distribution on  $\kappa_w$  because it needs to be fixed as explained in Section [3.2.3.](#page-9-2)

## <span id="page-30-0"></span>Inference

The posterior distribution of the specified model in the previous section is proportional to:

$$
\prod_{k=1}^K \pi\left(\boldsymbol{y}_k \mid \boldsymbol{z}_k\right) \prod_{k=1}^K \pi\left(\boldsymbol{z}_k \mid \{\boldsymbol{\delta}_{v_j}\}, \boldsymbol{\delta}_w, \boldsymbol{\beta}^*, \sigma_{y_k}^2\right) \prod_{j=1}^p \pi\left(\boldsymbol{x}_j \mid \boldsymbol{\delta}_{v_j}, \alpha_j, \sigma_{x_j}^2\right) \prod_{j=1}^p \pi\left(\boldsymbol{\delta}_{v_j} \mid \kappa_{v_j}\right) \\ \pi\left(\boldsymbol{\delta}_w\right) \pi\left(\boldsymbol{\beta}^*\right) \pi\left(\{\alpha_j\}\right) \pi\left(\{\sigma_{y_k}^2\}\right) \pi\left(\{\sigma_{x_j}^2\}\right) \pi\left(\{\kappa_{v_j}\}\right).
$$

We can sample from the posterior distribution using Gibbs sampling taking advantage of conjugacy on the conditional posterior distributions. The posterior conditional distributions are presented in Section [E](#page-41-1) of the supplementary material.

For instance, the conditional posterior for the latent random vectors  $\mathbf{Z}_k$  is a truncated multivariate normal distribution:

$$
\pi(z_k | \cdot) \propto \pi(\mathbf{y}_k | z_k) \pi(z_k | \{\delta_{v_j}\}, \delta_w, \beta^*, \sigma_{y_k}^2) \qquad \text{(truncated normal)}
$$
\n
$$
= \left(\prod_{i=1}^{n_k} \mathbb{1}_{(z_{ki} \geq 0)}^{y_{ki}} \mathbb{1}_{(z_{ki} < 0)}^{1 - y_{ki}}\right) \mathcal{N}(\mathbf{V}_k^* \beta^* + \mathbf{B}_w(L_k^{[y]}) \delta_w, \sigma_{y_k}^2 \mathbf{D}_{y_k}).
$$

On the other hand, the conditional posterior distributions for the latent GMRFs  $\delta_w$  and  $\delta_{v_j}$  are multivariate normals. For the former, the posterior uses data available from the K

response data sources:

$$
\pi\left(\boldsymbol{\delta}_{w} \mid \cdot\right) \propto \prod_{k=1}^{K} \pi\left(\boldsymbol{z}_{k} \mid \{\boldsymbol{\delta}_{v_{j}}\}, \boldsymbol{\delta}_{w}, \boldsymbol{\beta}^{*}\right) \pi\left(\boldsymbol{\delta}_{w}\right) \qquad \qquad \text{(normal)}\n\boldsymbol{\Sigma}_{\delta_{w}\mid\cdot} = \left(\sum_{k=1}^{K} \sigma_{y_{k}}^{-2} \boldsymbol{B}_{w}(L_{k}^{[y]})^{\intercal} \boldsymbol{D}_{y_{k}}^{-1} \boldsymbol{B}_{w}(L_{k}^{[y]}) + \kappa_{w} \boldsymbol{P}_{w}\right)^{-1},\n\boldsymbol{\mu}_{\delta_{w}\mid\cdot} = \boldsymbol{\Sigma}_{\delta_{w}\mid\cdot} \left(\sum_{k=1}^{K} \sigma_{y_{k}}^{-2} \boldsymbol{B}_{w}(L_{k}^{[y]})^{\intercal} \boldsymbol{D}_{y_{k}}^{-1} (\boldsymbol{z}_{k} - \boldsymbol{V}_{k}^{*} \boldsymbol{\beta}^{*})\right).
$$

The conditional posterior of  $\delta_w$  uses information from the K response data sources but also from the  $j$ -th predictor:

$$
\pi\left(\boldsymbol{\delta}_{v_{j}}\mid\cdot\right)\propto\prod_{k=1}^{K}\pi\left(\boldsymbol{z}_{k}\mid\{\boldsymbol{\delta}_{v_{j}}\},\boldsymbol{\delta}_{w},\boldsymbol{\beta}^{*},\sigma_{y_{k}}^{2}\right)\pi\left(\boldsymbol{x}_{j}\mid\boldsymbol{\delta}_{v_{j}},\alpha_{j},\sigma_{x_{j}}^{2}\right)\pi\left(\boldsymbol{\delta}_{v_{j}}\mid\kappa_{v_{j}}\right) \qquad \text{(normal)}\\ \boldsymbol{\Sigma}_{\delta_{v_{j}}\mid\cdot}=\left(\sum_{k=1}^{K}\frac{\beta_{j}^{2}\boldsymbol{B}_{j}(L_{k}^{[y]})^{\intercal}\boldsymbol{D}_{y_{k}}^{-1}\boldsymbol{B}_{j}(L_{k}^{[y]})}{\sigma_{y_{k}}^{2}}+\frac{\boldsymbol{B}_{j}(L_{j}^{[x]})^{\intercal}\boldsymbol{D}_{x_{j}}^{-1}\boldsymbol{B}_{j}(L_{j}^{[x]})}{\sigma_{x_{j}}^{2}}+\kappa_{v_{j}}\boldsymbol{P}_{v_{j}}\right)^{-1},\\ \boldsymbol{\mu}_{\delta_{v_{j}}\mid\cdot}=\boldsymbol{\Sigma}_{\delta_{v_{j}}\mid\cdot}\left(\sum_{k=1}^{K}\sigma_{y_{k}}^{-2}\beta_{j}\boldsymbol{B}_{j}(L_{k}^{[y]})^{\intercal}\boldsymbol{D}_{y_{k}}^{-1}\left(\boldsymbol{z}_{k}-b_{k}\boldsymbol{1}-\beta_{0}\boldsymbol{1}-\sum_{q\neq j}\beta_{q}\boldsymbol{B}_{q}(L_{k}^{[y]})\boldsymbol{\delta}_{v_{q}}-\boldsymbol{B}_{w}(L_{k}^{[y]})\boldsymbol{\delta}_{w}\right)+\\ \sigma_{x_{j}}^{-2}\boldsymbol{B}_{j}(L_{j}^{[x]})^{\intercal}\boldsymbol{D}_{x_{j}}^{-1}(\boldsymbol{x}_{j}-\alpha_{j}\boldsymbol{1})\right).
$$

The conditional posterior for the regression coefficients  $\beta$  is obtained as follows:

$$
\pi(\boldsymbol{\beta}^* \mid \cdot) \propto \prod_{k=1}^K \pi\left(\boldsymbol{z}_k \mid \{\boldsymbol{\delta}_{v_j}\}, \boldsymbol{\delta}_w, \boldsymbol{\beta}^*, \sigma_{y_k}^2\right) \pi(\boldsymbol{\beta}^*)
$$
\n(normal)

\n
$$
\boldsymbol{\Sigma}_{\beta|} = \left(\sum_{k=1}^K \sigma_{y_k}^{-2} \boldsymbol{V}_k^{*T} \boldsymbol{D}_{y_k}^{-1} \boldsymbol{V}_k^* + \boldsymbol{\Sigma}_{\beta}^{-1}\right)^{-1},
$$
\n
$$
\boldsymbol{\mu}_{\beta|} = \boldsymbol{\Sigma}_{\beta|} \cdot \left(\sum_{k=1}^K \sigma_{y_k}^{-2} \boldsymbol{V}_k^{*T} \boldsymbol{D}_{y_k}^{-1} (\boldsymbol{z}_k - \boldsymbol{B}_w(L_k^{[y]}) \boldsymbol{\delta}_w)\right).
$$

Similarly, the conditional posterior distribution for the intercept coefficients of the predictors are:

$$
\pi(\alpha_j \mid \cdot) \propto \pi\left(\boldsymbol{x}_j \mid \boldsymbol{\delta}_{v_j}, \alpha_j, \sigma_{x_j}^2\right) \pi(\alpha_j)
$$
\n(normal)

\n
$$
\sigma_{\alpha_j|\cdot}^2 = \left(\sigma_{x_j}^{-2} \mathbf{1}^\mathsf{T} \boldsymbol{D}_{x_j}^{-1} \mathbf{1} + \sigma_{\alpha_j}^{-2}\right)^{-1},
$$
\n
$$
\mu_{\alpha_j|\cdot} = \sigma_{\alpha_j|\cdot}^2 \left(\sigma_{x_j}^{-2} \mathbf{1}^\mathsf{T} \boldsymbol{D}_{x_j}^{-1} (\boldsymbol{x}_j - \boldsymbol{B}_j(l_j^{[x]}) \boldsymbol{\delta}_{v_j})\right).
$$
\n(normal)

We also take advantage of conjugacy for the error variance parameters  $\sigma_{y_k}^2$ ,  $\sigma_{x_j}^2$ , and the scale parameters  $\kappa_{v_j}$ . For the response error variances  $\sigma_{y_k}^2$ , the conditionals are inversegamma distributions:

$$
\pi\left(\sigma_{y_k}^2|\cdot\right) \propto \pi\left(\mathbf{z}_k \mid \{\boldsymbol{\delta}_{v_j}\}, \boldsymbol{\delta}_w, \boldsymbol{\beta}^*, \sigma_{y_k}^2\right) \pi\left(\sigma_{y_k}^2\right) \qquad \text{(inverse gamma)}
$$
\n
$$
a_{y_k}^* = a_{y_k} + n_k/2,
$$
\n
$$
b_{y_k}^* = b_{y_k} + \frac{1}{2}\left(\mathbf{z}_k - \mathbf{V}_k^*\boldsymbol{\beta}^* - \mathbf{B}_w(\boldsymbol{L}_k^{[y]})\boldsymbol{\delta}_w\right)^\mathsf{T} \mathbf{D}_{y_k}^{-1}\left(\mathbf{z}_k - \mathbf{V}_k^*\boldsymbol{\beta}^* - \mathbf{B}_w(\boldsymbol{L}_k^{[y]})\boldsymbol{\delta}_w\right),
$$

and similarly for the predictor error variances  $\sigma_{x_j}^2$ ,

 $\pi$ 

$$
\pi\left(\sigma_{x_j}^2|\cdot\right) \propto \pi\left(\boldsymbol{x}_j \mid \boldsymbol{\delta}_{v_j}, \alpha_j, \sigma_{x_j}^2\right) \pi\left(\sigma_{x_j}^2\right)
$$
 (inverse gamma)  
\n
$$
a_{x_j}^* = a_{x_j} + m_j/2,
$$
  
\n
$$
b_{x_j}^* = b_{x_j} + \frac{1}{2}\left(\boldsymbol{x}_j - \alpha_j \mathbf{1} - \boldsymbol{B}_j(L_j^{[x]}) \boldsymbol{\delta}_{v_j}\right)^{\mathsf{T}} \boldsymbol{D}_{x_j}^{-1}\left(\boldsymbol{x}_j - \alpha_j \mathbf{1} - \boldsymbol{B}_j(L_j^{[x]}) \boldsymbol{\delta}_{v_j}\right).
$$

Finally, the conditional posteriors for the scale parameters  $\kappa_j$  are gamma distributed:

$$
(\kappa_{v_j} \mid \cdot) \propto \pi \left( \boldsymbol{\delta}_{v_j} \mid \kappa_{v_j} \right) \pi \left( \kappa_{v_j} \right)
$$
\n
$$
a^* = a + \frac{1}{2} \text{rank}(\boldsymbol{P}_{v_j}),
$$
\n
$$
b^* = b + \frac{1}{2} \boldsymbol{\delta}_{v_j}^{\mathsf{T}} \boldsymbol{P}_{v_j} \boldsymbol{\delta}_{v_j}.
$$
\n(gamma)

## <span id="page-32-0"></span>C.3. Spatial prediction

Our main interest for spatial prediction is to infer the latent process  $\{\eta(s)\}\$ at new locations L<sup>\*</sup> (point or geometries). Denoting the associated random vector as  $\eta(L^*)$  with values  $\eta_{L^*}$ , the posterior predictive distribution is:

$$
\pi(\boldsymbol{\eta}_{L^*} \mid \{\boldsymbol{y}_k\}, \{\boldsymbol{x}_j\}) = \int \pi(\boldsymbol{\eta}_{L^*}, \boldsymbol{\beta}, \{\boldsymbol{\delta}_{v_j}\}, \boldsymbol{\delta}_w \mid \{\boldsymbol{y}_k\}, \{\boldsymbol{x}_j\}) d\boldsymbol{\beta} d\{\boldsymbol{\delta}_{v_j}\} d\boldsymbol{\delta}_w, = \int \pi(\boldsymbol{\beta}, \{\boldsymbol{\delta}_{v_j}\}, \boldsymbol{\delta}_w \mid \{\boldsymbol{y}_k\}, \{\boldsymbol{x}_j\}) \pi(\boldsymbol{\eta}_{L^*} \mid \boldsymbol{\beta}, \{\boldsymbol{\delta}_{v_j}\}, \boldsymbol{\delta}_w) d\boldsymbol{\beta} d\{\boldsymbol{\delta}_{v_j}\} d\boldsymbol{\delta}_w.
$$

Where the first term on the right-hand side is the marginal posterior distribution for  $\beta$ ,  $\{\boldsymbol{\delta}_{v_j}\}$ and  $\boldsymbol{\delta}_w$ , while the second term is simply a deterministic relationship:  $\boldsymbol{\eta}_{L^*} = \beta_0 \mathbf{1} + \sum_{j=1}^p \beta_j \boldsymbol{B}_j (L^*) \boldsymbol{\delta}_{v_j} +$  $B_w(L^*)\delta_w$ . Samples from the predictive distribution are obtained by taking the samples for  $\beta, \{\delta_{v_j}\}\$  and  $\delta_w$  from the posterior and using it to generate samples for  $\eta_{L^*}$  with the deterministic expression provided above.

## <span id="page-32-2"></span>D. Simulation studies

## <span id="page-32-1"></span>D.1. One dimensional

In the one-dimensional experiments, we used the same scenarios and models explained in Section [4.1.](#page-11-0) We observe results consistent with the two-dimensional case, with some findings that are more pronounced in 2D due to the larger spatial coverage and increased fluctuations of the simulated latent process. The key findings are summarised in the following sections.

## Regular grid

For this experiment, we define  $W(s)$  using 100 basis functions of degree 2 and a GMRF of order 1 with a scale parameter of  $\kappa = 1$ . The primary differences observed between the naive model and the support model are described based on the behaviour of the predicted mean, the uncertainty quantification, and their tendency to either overpredict or underpredict the true underlying process.

- Predicted mean: In the naive model (M1), the predicted mean exhibits abrupt changes and tends to overfit the data because it assumes that observations are associated with the centroids of the sampling units (Figure [7-](#page-34-0)A1). In contrast, the support model (M2) yields a more gradual change in the predicted mean, as it aims to find a function whose integral over the sampling units closely matches the observed data.
- Uncertainty quantification: The naive model (M1) tends to underestimate uncertainty, particularly near the sampling unit centroids (Figure [7-](#page-34-0)A1). In contrast, the support model (M2) provides more accurate uncertainty estimates, effectively encompassing the true underlying process (Figure [7-](#page-34-0)A2). These differences stem from the approach of the support model for finding functions whose integrals closely match the data.
- Over and under prediction: The naive model (M1) exhibits more frequent values where the probability of overprediction is close to 1 and close to 0 (indicating underprediction), as seen in Figure [7-](#page-34-0)B1. In contrast, the support model (M2) features a higher frequency of predictions around the value of 0.5 (Figure [7-](#page-34-0)B2). This suggests that the support model provides more accurate predictions of the underlying true process.

<span id="page-34-0"></span>Figure 7: Comparison between the **naive model** (M1) and the **support model** (M2) when data is observed in a regular grid. Panels A1 and A2 show the predictive MCMC samples for the underlying latent process  $\{W(s)\}\$ , while panels B1 and B2 show histograms of the posterior probability of overpredicting the underlying process  $(p = Pr(W(s) > w(s) | \mathbf{y}))$ .

## Irregular grid, sparse sampling units and overlapping sampling units

For the irregular grid experiment, the latent process  $W(s)$  was defined with 50 basis functions, while 100 basis functions were used for the experiments with sparse and overlapping sampling units. In all three experiments, GMRFs of order 1 with a scale parameter of  $\kappa = 1$ were employed. The differences between the models observed in Figures [9,](#page-37-0) [10,](#page-38-0) and [8](#page-36-0) are described below.

**Predicted mean:** In the experiment with irregular grids, the naive model (M1) exhibits overfitting similar to the previous experiment with regular grids. It is significantly biased by certain observations due to the lack of accounting for measurement error heteroscedasticity (e.g. for  $s \approx 20$  in Figure [9-](#page-37-0)A1). The heteroscedastic model (M2) performs better by considering observation importance based on support size. In the case of sparse sampling units, both the naive model (M1) and the heteroscedastic model (M2) exhibit abrupt changes in the predicted mean, especially evident in sparse locations like  $s \in [-50, 0]$  in Figure [10,](#page-38-0) panels A1-A2. In an attempt to fit the data, these models react strongly to the absence of surrounding information. For overlapping sampling units, the predicted mean of the naive model (M1) and the heteroscedastic model (M2) does not overfit when units are close, but

in mixed sparse and overlapping regions, they exhibit abrupt changes and overfitting (e.g. for around  $s \approx 50$  in Figure [8,](#page-36-0) panels A1-A2). Across all three experiments, the support and heteroscedastic model (M3) outperform the naive model (M1) and the heterocedastic model (M2). It yields smoother variation of the predicted mean, avoids overfitting, remains unaffected by high-error observations, and accurately captures primary trends of the underlying true process.

Uncertainty quantification: In the case of irregular grids, the naive model (M1) tends to overestimate uncertainty because it attempts to increase the variability to capture complex data generation mechanisms. In contrast, the heteroscedastic model (M2) underestimates uncertainty near the sampling unit centroids for sample units of larger size (e.g.,  $s \approx 35$  in Figure [9-](#page-37-0)A2). For sparse sampling units, both the naive model (M1) and the heteroscedastic model (M2) tend to underestimate uncertainty for locations near the centroids and locations with sparse data (e.g.  $s \approx -50$  in Figure [10,](#page-38-0) panels A1-A2). In the case of overlapping sampling units, both the naive model (M1) and the heteroscedastic model (M2) tend to underestimate uncertainty for locations near the centroids. For all three experiments, the support and heteroscedastic model (M3) consistently quantifies uncertainty effectively without underestimating it for locations close to the centroids, as observed in M1 and M2, or overestimating it. M3 provides a more accurate quantification of uncertainty, effectively enveloping the underlying true process.

Over and under prediction: In all the conducted experiments, we observed a higher proportion of posterior probabilities close to 1 or 0 for the naive model (M1) and the heteroscedastic model (M2), as shown in panels B1-B3 of Figures [9,](#page-37-0) [10,](#page-38-0) and [8.](#page-36-0) In contrast, the support and heteroscedastic model (M3) consistently exhibits lower levels of overprediction and underprediction when compared to models M1 and M2, with more frequent probabilities centred around 0.5. This suggests that M3 provides more accurate predictions of the underlying true process.
