

Asset management with an ESG mandate

Michele Azzone*, Emilio Barucci†, Davide Stocco‡

March 19, 2024

Abstract

We investigate the portfolio frontier and risk premia in equilibrium when an institutional investor aims to minimize the tracking error variance and to attain an ESG score higher than the benchmark's one (ESG mandate). Provided that a negative ESG premium for stocks is priced by the market, we show that an ESG mandate can reduce the mean-variance inefficiency of the portfolio frontier when the asset manager targets a limited over-performance with respect to the benchmark. Instead, for a high over-performance target, an ESG mandate leads to a higher variance. The mean-variance improvement is due to the fact that the ESG mandate induces the asset manager to over-invest in assets with a high mean-standard deviation ratio. In equilibrium, with asset managers and mean-variance investors, a negative ESG premium arises if the ESG mandate is binding for asset managers. A result that is borne out by the data.

Keywords: ESG score, portfolio frontier, tracking error variance, Asset pricing.

1 Introduction

Asset managers are facing the challenge of introducing ESG goals in their portfolios. A process driven by the requests of investors and by the regulation that has introduced the ESG classification of financial products and disclosure requirements to enhance investors' awareness, e.g. see [12, 14, 28].

There are several approaches to incorporate ESG concerns in the asset management practice: positive/best-in-class screening, negative/exclusionary screening, ESG integration, impact investing, sustainable themed investing, see [22]. The ESG integration seems to be the most promising approach. It is not based on a 0-1 decision about the inclusion of an asset in the investment universe but it incorporates ESG considerations into the portfolio construction. An easy way to implement it is to rely on ESG scores introducing a constraint such that the portfolio is characterized by a certain ESG score. We refer to this type of constraint as the *ESG mandate*, a feature of the fund that is often disclosed to investors.

In this paper we address the consequences of the introduction of an ESG mandate for asset managers along two different perspectives: construction of the portfolio frontier and market equilibrium return. Our analysis deals with mutual funds at benchmark rather than absolute return funds (e.g., hedge funds). Asset managers are worried by an ESG mandate as it reduces the investment universe leading to less diversification and may conflict with a return target in case of a trade-off between ESG score and return, see the debate on carbon or green premium [2, 5, 9, 10]. This paper aims to investigate the effect of the introduction of an ESG mandate in the management of an institutional investor in a risk-return and in an equilibrium perspective. The main results of our analysis, supported by the empirical evidence, are that the ESG mandate does not necessarily undermine the fiduciary duties of the asset manager and that a negative ESG premium is priced by the market.

The ESG mandate for the asset manager is introduced assuming that she minimizes the Tracking Error Variance (TEV, hereafter) with respect to a market benchmark, as in [27], with the additional constraint of a portfolio's weighted ESG score greater than the benchmark's one. Minimization of TEV comes from the remuneration of asset managers that is related to the relative (to a benchmark) performance. The framework builds upon

the ones proposed in [23, 24]: the ESG score is provided by an ESG rating agency and the asset manager takes it as a datum, she does not question its quality and does not consider ESG score uncertainty. This is the key difference with respect to [1], where ESG scores are treated as random variables. The ESG score is a feature of the asset and is not properly a risk factor. Differently from [23, 24], we do not introduce a preference for ESG in the investor utility function but we include ESG considerations through a constraint on the weighted ESG score of the portfolio.

The papers closest to ours are [18, 30]. [30] consider the construction of the portfolio frontier (minimizing the variance and not the TEV) adding an equality constraint on the ESG score of the portfolio. [18] introduce three types of investors: ESG-unaware, ESG-aware, ESG-motivate. The latter type maximizes a mean-TEV utility including a function increasing in the ESG score's excess with respect to the benchmark as in [24]. We remark an important point, the introduction of preference for ESG *à la* [13] is a viable approach to deal with ESG considerations in asset management but has the limit that an estimation of the preference for ESG is needed. Our approach closely mimics the practice in the asset management industry including the ESG score as an additional constraint in portfolio optimization without quantifying any ESG preference.

As far as the portfolio frontier is concerned, we explore the connection among frontiers derived by minimizing portfolio variance, minimizing the TEV, and minimizing the TEV with the inclusion of an ESG mandate. We show that the integration of ESG considerations into the asset management optimization problem can contribute to mitigate the inefficiency of portfolios constructed minimizing the TEV. Under some conditions, for a limited over-performance target relative to the benchmark, an ESG mandate renders a smaller variance of the portfolio frontier. Instead, when the performance target is high enough, the ESG mandate renders a higher variance. These results are obtained if the ESG mandate constraint turns out to be binding for a positive over-performance target relative to the benchmark. This occurs when a negative relationship between expected returns and ESG scores holds true and the benchmark is not too challenging (high return and high ESG score). The introduction of an ESG mandate is similar to the TEV efficiency improvement obtained introducing a constraint on the β with respect to the benchmark, see [27], on total variance, see [17], or on the α with respect to the bench-

mark, see [4]. The main result is that an ESG mandate does not undermine fiduciary duties of the asset manager yielding a mean-variance improvement. The root of the result is that a binding ESG mandate induces the asset manager targeting the TEV of the portfolio to over-invest in assets with a high Mean-Standard Deviation (M-SD) ratio, and therefore in assets with a lower variance. Thanks to the use of different metrics (TEV and variance), this feature renders a mean-variance improvement of the portfolio.

The result is confirmed allowing the asset manager also to target an ESG over-performance. Curiously enough, a more socially responsible investor is able to reach a significant mean-variance improvement for a limited return over-performance target. Instead, a less socially responsible investor reaches a small mean-variance improvement for a high return over-performance target. Social responsibility pays in a risk-return perspective.

Empirically, for the US stock market, we do confirm that an ESG mandate leads to a mean-variance gain for a positive over-performance target thanks to the fact that there exists a negative relation between expected returns and ESG scores. The return-ESG score trade-off renders a binding ESG mandate but this is not detrimental in a mean-variance setting, actually a mean-variance improvement is observed if the return over-performance target is between 0 and 4.56%. For this range of values, an ESG mandate mitigates the inefficiencies associated with minimizing TEV. Instead, for a higher return target, the return-ESG trade-off leads to a less efficient portfolio.

As far as the equilibrium analysis is concerned, we expand the framework provided in [6], see [7, 15] for empirical insights. If asset managers maximize the mean-TEV utility with an ESG mandate and face mean-variance agents in the market, then a negative ESG premium (lower returns associated to higher ESG scores) arises in equilibrium if the ESG constraint for the asset manager is binding for a positive over-performance target. Empirically we provide positive evidence on this insight. This result adds to the literature on the presence of a ESG premium in stock markets, see e.g. [1, 5, 10, 19, 24]. The analysis provides an equilibrium model yielding a negative ESG premium, the rationale being the price pressure on stocks with high ESG score and low variance because institutional investors manage their assets according to an ESG mandate.

The two pieces of our analysis sustain each other: provided that a negative relation

between expected returns and ESG scores holds true, the ESG mandate is binding for institutional investors; in equilibrium with institutional investors dealing with a binding ESG mandate and retail investors, market returns are characterized by a negative ESG premium in equilibrium confirming the hypothesis.

The rest of the paper is organized as follows. In Section 2, we construct the TEV portfolio frontier with an ESG mandate. In Section 3, we study the portfolio composition of the frontier. In Section 4, we address the market equilibrium analysis. In Section 5, we provide the empirical analysis. In Section 6, we consider some extensions of the model with heterogeneous ESG mandates. Section 7 concludes.

2 Portfolio Frontier

Consider an economy with N risky assets. Following best practices in the asset management industry, we assume that the asset manager minimizes the TEV conditional on a given level of expected return, while achieving an ESG score greater than the benchmark's one.

We consider a benchmark $\mathbf{x}_0 \in \mathbb{R}^N$ and a portfolio of the assets $\mathbf{x} \in \mathbb{R}^N$. We denote by $\boldsymbol{\mu} \in \mathbb{R}^N$ the vector of expected returns, $\boldsymbol{\xi} \in \mathbb{R}^N$ the vector of ESG scores, $\Omega \in \mathbb{R}^{N \times N}$ the variance-covariance matrix, and $\mathbf{1} \in \mathbb{R}^N$ the unitary vector. G is the expected return target of the asset manager relative to the benchmark: $G > 0$ (< 0) means that the manager aims to over-perform (under-perform) the benchmark.

The ESG mandate is introduced imposing the ESG score of the portfolio to be greater or equal than that of the benchmark. Therefore, the TEV frontier with an ESG mandate (hereinafter TEV ESG frontier) is obtained solving the following problem:

$$\min_{\mathbf{x}} (\mathbf{x} - \mathbf{x}_0)^\top \Omega (\mathbf{x} - \mathbf{x}_0) \quad (1)$$

subject to

$$\mathbf{x}^\top \mathbf{1} = 1 \quad (2)$$

$$(\mathbf{x} - \mathbf{x}_0)^\top \boldsymbol{\xi} \geq 0 \quad (3)$$

$$(\mathbf{x} - \mathbf{x}_0)^\top \boldsymbol{\mu} = G. \quad (4)$$

In what follows, we refer to the constraint (3) as binding if it holds as an equality.

The portfolios of the frontier are identified in the following proposition.

Proposition 1. *The vector \mathbf{x}^* of portfolio weights of the TEV ESG frontier is*

$$\mathbf{x}^* = \mathbf{x}_0 - \frac{1}{2}\Omega^{-1}(\lambda_1\mathbf{1} + \lambda_2\boldsymbol{\xi} + \lambda_3\boldsymbol{\mu}) \quad (5)$$

where

$$\lambda_1 = \frac{2(E A_E - A B_E)G}{D_E}, \quad \lambda_2 = \frac{2(A A_E - E C)G}{D_E} \leq 0, \quad \lambda_3 = \frac{2(B_E C - A_E^2)G}{D_E} \quad (6)$$

if the constraint (3) is binding.

If the constraint (3) is not binding, then the vector of portfolio weights is

$$\mathbf{x}^* = \mathbf{x}_0 - \frac{1}{2}\Omega^{-1}(\hat{\lambda}_1\mathbf{1} + \hat{\lambda}_3\boldsymbol{\mu}) \quad (7)$$

$$\hat{\lambda}_1 = \frac{2AG}{D}, \quad \hat{\lambda}_3 = -\frac{2CG}{D}, \quad (8)$$

where,

$$D_E = -2A E A_E + A_E^2 B + A^2 B_E + E^2 C - B B_E C, \quad D = B C - A^2$$

and

$$\begin{aligned} A &= \mathbf{1}^\top \Omega^{-1} \boldsymbol{\mu}, \quad B = \boldsymbol{\mu}^\top \Omega^{-1} \boldsymbol{\mu}, \quad C = \mathbf{1}^\top \Omega^{-1} \mathbf{1} \\ A_E &= \mathbf{1}^\top \Omega^{-1} \boldsymbol{\xi}, \quad B_E = \boldsymbol{\xi}^\top \Omega^{-1} \boldsymbol{\xi}, \quad E = \boldsymbol{\xi}^\top \Omega^{-1} \boldsymbol{\mu}. \end{aligned}$$

Proof. The optimization problem is quadratic, a unique solution exists as the linear subspace satisfying the constraints is not empty and Ω is positive definite.

If $G = 0$, then the solution of the optimization problem is $\mathbf{x}^* = \mathbf{x}_0$. In what follows, we focus on $G \neq 0$.

The Lagrangian associated to the problem is

$$\mathcal{L}(\mathbf{x}, \lambda_1, \lambda_2, \lambda_3) = (\mathbf{x} - \mathbf{x}_0)^\top \Omega (\mathbf{x} - \mathbf{x}_0) + \lambda_1(\mathbf{x}^\top \mathbf{1} - 1) + \lambda_2(\mathbf{x} - \mathbf{x}_0)^\top \boldsymbol{\xi} + \lambda_3((\mathbf{x} - \mathbf{x}_0)^\top \boldsymbol{\mu} - G),$$

where λ_1 , λ_2 and λ_3 are the Lagrange multipliers. The gradient of the Lagrangian is

$$\begin{aligned} \frac{\partial \mathcal{L}}{\partial \lambda_1} &= \mathbf{x}^\top \mathbf{1} - 1 \\ \frac{\partial \mathcal{L}}{\partial \lambda_2} &= (\mathbf{x} - \mathbf{x}_0)^\top \boldsymbol{\xi} \\ \frac{\partial \mathcal{L}}{\partial \lambda_3} &= (\mathbf{x} - \mathbf{x}_0)^\top \boldsymbol{\mu} - G \\ \frac{\partial \mathcal{L}}{\partial \mathbf{x}} &= 2\Omega(\mathbf{x} - \mathbf{x}_0) + \lambda_1\mathbf{1} + \lambda_2\boldsymbol{\xi} + \lambda_3\boldsymbol{\mu}. \end{aligned}$$

The Kuhn-Tucker conditions, see [26], yield that

$$\lambda_2 \leq 0, \quad \lambda_2(\mathbf{x} - \mathbf{x}_0)^\top \boldsymbol{\xi} = 0.$$

Let us assume that the ESG constraint (3) is binding, then $\lambda_2 \leq 0$. Setting $\frac{\partial \mathcal{L}}{\partial \mathbf{x}} = 0$, we get the portfolio:

$$\mathbf{x}^* = \mathbf{x}_0 - \frac{1}{2}\Omega^{-1}(\lambda_1 \mathbf{1} + \lambda_2 \boldsymbol{\xi} + \lambda_3 \boldsymbol{\mu}).$$

Substituting \mathbf{x}^* in (3)-(4), we obtain the Lagrange multipliers in (6).

If the constraint (3) is not binding, then $\lambda_2 = 0$ and the minimization problem becomes:

$$\min_{\mathbf{x}} (\mathbf{x} - \mathbf{x}_0)^\top \Omega (\mathbf{x} - \mathbf{x}_0) \quad (9)$$

subject to

$$\mathbf{x}^\top \mathbf{1} = 1 \quad (10)$$

$$(\mathbf{x} - \mathbf{x}_0)^\top \boldsymbol{\mu} = G. \quad (11)$$

The Lagrangian of the problem is

$$\mathcal{L}(\mathbf{x}, \hat{\lambda}_1, \hat{\lambda}_3) = (\mathbf{x} - \mathbf{x}_0)^\top \Omega (\mathbf{x} - \mathbf{x}_0) + \hat{\lambda}_1(\mathbf{x}^\top \mathbf{1} - 1) + \hat{\lambda}_3((\mathbf{x} - \mathbf{x}_0)^\top \boldsymbol{\mu} - G).$$

Setting $\frac{\partial \mathcal{L}}{\partial \mathbf{x}} = 0$, the Lagrange multipliers in (8) are obtained and the optimal solution becomes:

$$\mathbf{x}^* = \mathbf{x}_0 - \frac{1}{2}\Omega^{-1} \left(\hat{\lambda}_1 \mathbf{1} + \hat{\lambda}_3 \boldsymbol{\mu} \right) \quad \square$$

Notice that in case of a non binding ESG constraint, the portfolio coincides with the one in [27] and \mathbf{x}^* is the rescaled difference between two portfolios: $\frac{\Omega^{-1}\mathbf{1}}{C}$ (Minimum Variance Portfolio, MVP) and $\frac{\Omega^{-1}\boldsymbol{\mu}}{A}$.

The following result holds true on the ESG constraint.

Corollary 2. *For $G = 0$, the ESG constraint (3) is always binding. For $G \neq 0$, it is binding in case*

$$\begin{cases} E - \frac{A}{C}A_E < 0, & G > 0 \\ E - \frac{A}{C}A_E > 0, & G < 0 \end{cases} . \quad (12)$$

If the constraint is binding, then $D_E < 0$.

Proof. If the ESG constraint (3) is binding, then the solution of the unconstrained optimization problem in (9) does not satisfy the constraint. By substituting (7) in (3) and checking when the inequality is not verified, we get the condition for a binding ESG constraint:

$$(C\boldsymbol{\mu} - A\mathbf{1})^\top \Omega^{-1} \boldsymbol{\xi} \frac{G}{D} < 0 .$$

Rearranging the terms and multiplying by D , we obtain

$$G(CE - AA_E) < 0 . \quad (13)$$

Dividing by $C > 0$ and $G \neq 0$, we get the condition in (12).

By the Kuhn-Tucker conditions, we have

$$\lambda_2 = \frac{2(AA_E - EC)G}{D_E} \leq 0 \quad (14)$$

if the constraint (3) is binding. Therefore, when the constraint (3) is binding, conditions (13) and (14) imply $D_E < 0$. \square

In what follows, we study the efficiency of the TEV ESG frontier. We compare three frontiers in the mean-variance plane: the standard mean-variance portfolio frontier [21], the TEV portfolio frontier [27] and the TEV ESG portfolio frontier.

The variance of a portfolio belonging to the standard frontier is

$$Var_{Front}(G) = \frac{C}{D} \left(G + \mathbf{x}_0^\top \boldsymbol{\mu} - \frac{A}{C} \right)^2 + \frac{1}{C} ,$$

where $G + \mathbf{x}_0^\top \boldsymbol{\mu}$ is the portfolio's expected return.

The variance of the frontier obtained minimizing the TEV is

$$Var_{TEV}(G) = \mathbf{x}_0^\top \Omega \mathbf{x}_0 - (\mathbf{x}_0^\top (\hat{\lambda}_1 \mathbf{1} + \hat{\lambda}_3 \boldsymbol{\mu})) + \frac{CG^2}{D} . \quad (15)$$

This frontier is obtained considering the case of a non binding ESG constraint for every G , see the portfolio in (7).

The variance of the TEV ESG frontier with a binding ESG constraint for $G \geq 0$ is

$$Var_{TEV_{ESG}}(G) = \begin{cases} \mathbf{x}_0^\top \Omega \mathbf{x}_0 - (\mathbf{x}_0^\top (\lambda_1 \mathbf{1} + \lambda_2 \boldsymbol{\xi} + \lambda_3 \boldsymbol{\mu})) + \frac{(A_E^2 - B_E C)G^2}{D_E} & G \geq 0 \\ \mathbf{x}_0^\top \Omega \mathbf{x}_0 - (\mathbf{x}_0^\top (\hat{\lambda}_1 \mathbf{1} + \hat{\lambda}_3 \boldsymbol{\mu})) + \frac{CG^2}{D} & G < 0 \end{cases} . \quad (16)$$

A specular expression for the TEV ESG frontier is obtained when the constraint is binding for $G \leq 0$.

By construction, the two frontiers $Var_{TEV}(G)$ and $Var_{TEV_{ESG}}(G)$ are on the right hand side of $Var_{Front}(G)$ in the mean-variance plane. While Var_{TEV} dominates $Var_{TEV_{ESG}}$ in the mean-TEV plane, it is more complex to establish their relationship in the mean-variance plane.

We observe that for a G such that the ESG constraint (3) is not binding, the two frontiers $Var_{TEV}(G)$ and $Var_{TEV_{ESG}}(G)$ coincide. For a G such that the ESG constraint is binding, the two frontiers coincide if

$$Var_{TEV}(G) - Var_{TEV_{ESG}}(G) = 0$$

yielding the condition

$$-(\mathbf{x}_0^\top (\hat{\lambda}_1 \mathbf{1} + \hat{\lambda}_3 \boldsymbol{\mu})) + \frac{CG^2}{D} + (x_0^\top (\lambda_1 \mathbf{1} + \lambda_2 \boldsymbol{\xi} + \lambda_3 \boldsymbol{\mu})) - \frac{(A_E^2 - B_EC)G^2}{D_E} = 0$$

which delivers up to two intersections 0 and G^* , where

$$G^* = \frac{2\mathbf{x}_0^\top ((AD_E - D(EA_E - AB_E))\mathbf{1} - D(AA_E - EC)\boldsymbol{\xi} - (D_EC + D(B_EC - A_E^2))\boldsymbol{\mu})}{D_EC - D(A_E^2 - B_EC)} \quad (17)$$

The second intersection is obtained if and only if the ESG constraint is binding for $G = G^*$. If this is not the case, then the two frontiers coincide in the non binding region while $Var_{TEV_{ESG}}(G)$ is dominated by $Var_{TEV}(G)$ in the binding one. In Figure 1, we plot the three frontiers when the ESG constraint is binding for $G > 0$ and either $G^* > 0$ (on the left hand side) or $G^* < 0$ (on the right hand side). In both cases, the two frontiers coincide for $G < 0$. In the first case, there are some values of $G > 0$ for which $Var_{TEV_{ESG}}(G)$ dominates $Var_{TEV}(G)$, in the latter, $Var_{TEV}(G)$ always dominates $Var_{TEV_{ESG}}(G)$ for $G > 0$.

If the constraint (3) is binding for $G > 0$ and $G^* > 0$, then, for sufficiently large G , $Var_{TEV_{ESG}}(G)$ is dominated by $Var_{TEV}(G)$ as shown in Figure 1. This can be proved analytically observing that the dominant term in the difference between the two variances for a large G is the quadratic term:

$$G^2 \left(\frac{(A_E^2 - B_EC)}{D_E} - \frac{C}{D} \right) = G^2 \frac{(AA_E - EC)^2}{-DD_E} > 0,$$

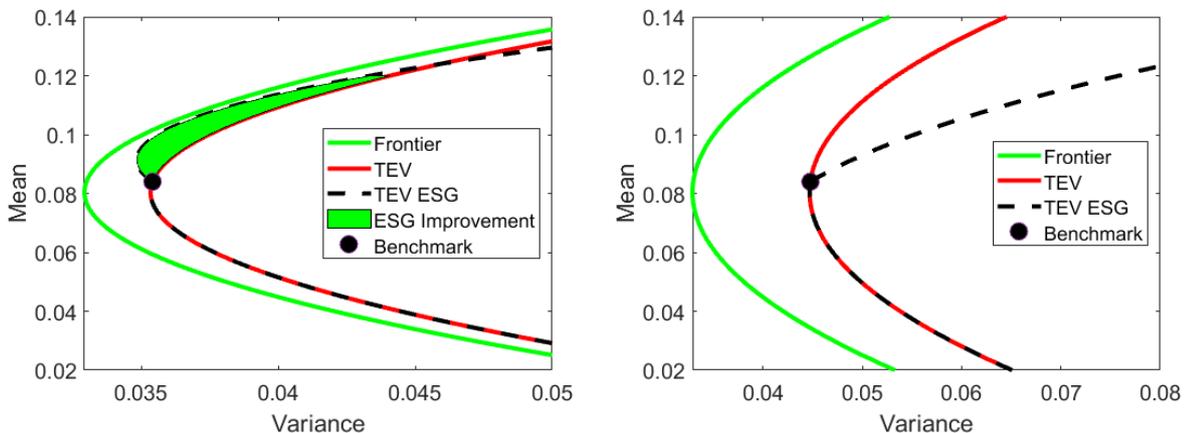

Figure 1: The three frontiers when the constraint (3) is binding for $G > 0$, $G^* > 0$ on the left hand side and $G^* < 0$ on the right hand side. The two figures are based on the assets considered in Section 3 and two different benchmarks ($\frac{A}{C} = 8\%$).

which is positive because D_E is negative and D is positive.

In Figure 2, we plot the three frontiers when the constraint is binding for $G > 0$ and $G^* > 0$. We consider a benchmark with an expected return below $\frac{A}{C}$ (left hand side) and one above (right hand side). As shown analytically above, in both cases the $Var_{TEV_{ESG}}(G)$ frontier dominates the $Var_{TEV}(G)$ frontier for positive and low values of G and the opposite holds true for a sufficiently large G . Therefore, adding an ESG constraint to the minimization of TEV leads to a mean-variance improvement for a low positive value G .

When the ESG constraint (3) is binding for negative G the results are mirrored on the inefficient part of the frontier. The two frontiers coincide for $G \geq 0$ and there is an intersection in $G = G^*$ if $G^* < 0$. In Figure 3, we present an example in which the ESG constraint is binding for $G < 0$ and $G^* < 0$. The TEV ESG frontier intersects the TEV frontier in the non efficient region for $G = 0$ and $G^* < 0$. In this setting, adding an ESG constraint to the minimization of TEV does not yield a mean-variance improvement.

In [24], the authors conduct a similar analysis comparing the standard portfolio frontier, i.e., $Var_{Front}(G)$, with the one obtained adding an ESG mandate. They show that the two frontiers share a (tangent) portfolio. Our setting is different because the ESG constraint (3) concerns the ESG improvement with respect to the benchmark, and not the portfolio itself, moreover we minimize the TEV instead of the variance.

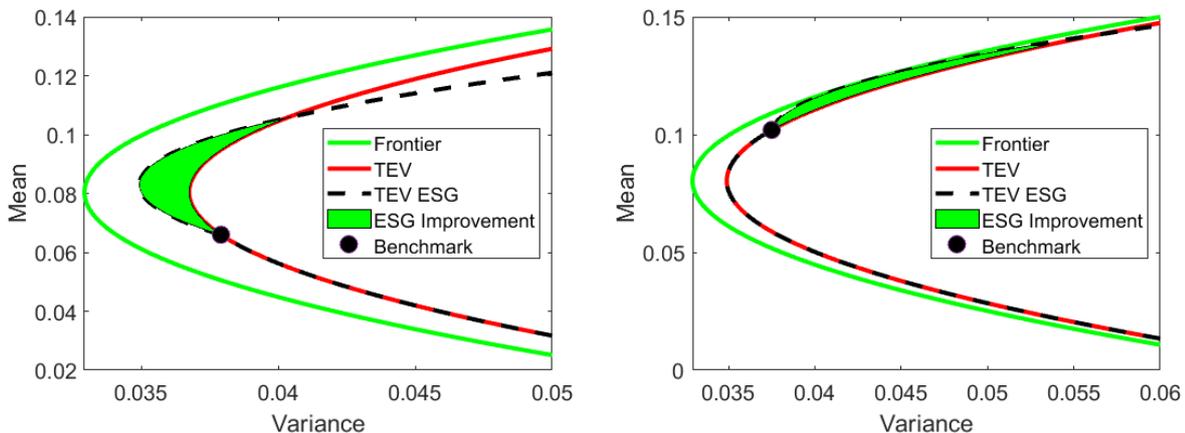

Figure 2: The three frontiers when the constraint (3) is binding for $G > 0$ and $G^* > 0$. The two figures are based on the assets considered in Section 3 and two different benchmarks ($\frac{A}{C} = 8\%$).

It is not straightforward to interpret condition (12) that discriminates the values of G for which the ESG constraint (3) is binding. In what follows, we discuss two particular cases focusing our attention on an ESG constraint binding for $G > 0$.

First, let us consider a diagonal Ω matrix, i.e., asset returns are not correlated. We denote the diagonal elements of the inverse matrix as $v_n = v_{n,n}$, $n = 1, \dots, N$. Condition (12) for a binding constraint for a positive G reduces to

$$\sum_{i=1}^N \xi_i v_i \left(\mu_i - \frac{A}{C} \right) < 0 .$$

Hence, if the average of the assets' expected returns in excess of the return of the MVP weighted by the ESG scores divided by the return variances is negative, then the ESG constraint is binding for a positive G . Therefore, the ESG constraint is binding when the assets with high expected returns are characterized by low ESG scores and high variances.

Second, let us consider a linear relation between ξ and μ , i.e., $\xi = \gamma\mu$. We can show that

$$E - \frac{A}{C} A_E < 0 \iff \gamma < 0 .$$

The ESG constraint (3) is binding for $G > 0$ if and only if $\gamma < 0$. The interpretation of this result is straightforward. If the asset manager targets an extra return with respect

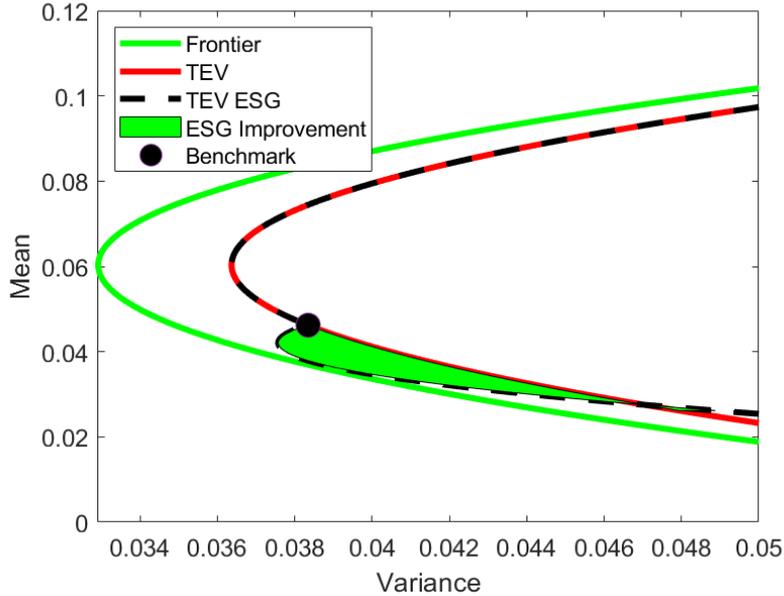

Figure 3: The three frontiers when the ESG constraint is binding for $G < 0$ and $G^* < 0$ ($\frac{A}{C} = 6\%$).

to the benchmark and the ESG score goes up with the expected return ($\gamma > 0$) then the ESG mandate constraint (3) is not binding. A binding constraint is obtained when an inverse relation holds true ($\gamma < 0$).

Both these examples are aligned with the interpretation that the ESG mandate is binding if and only if a negative relationship between the ESG score and the expected return holds true. If this is the case, then a return and an ESG over-performance target are in conflict with each other but the interesting result of our analysis is that we may observe a mean-variance improvement for a limited over-performance target and, therefore, the ESG mandate does not undermine the fiduciary duties of asset managers towards investors.

3 TEV ESG portfolios

In what follows, we investigate the portfolio frontiers considering an illustrative example of four assets. We utilize these assets in all the examples on the frontier analysis in the rest of the paper, they were also considered in the examples of Section 2. In Table 1, we report the mean, M-SD ratio and ESG score of the assets. We also include the same pieces of information for the MVP and two different benchmarks that were considered in

Figure 2. The two benchmarks lead to a different effect on the TEV frontier. We refer to the first one (on the left hand side in Figure 2) as a *Risk Reducer* benchmark (B-RR), as it allows to reach a lower global variance compared to the TEV frontier, and to the second one as a *Return Enhancer* (B-RE).

	A	B	C	D	B-RR	B-RE	MVP
Mean	0.15	0.10	0.05	0.02	0.08	0.10	0.08
M-SD ratio	0.61	0.45	0.18	0.08	0.45	0.53	0.44
ESG score	0.07	0.10	0.17	0.67	0.22	0.16	0.31

Table 1: Mean, M-SD ratio and ESG score values of the four assets (A, B, C and D), of the B-RR and B-RE portfolios and of the MVP.

The returns of the four assets are characterized by the following variance-covariance matrix

$$\Omega = \begin{bmatrix} 0.06 & 0.04 & 0.02 & 0.01 \\ 0.04 & 0.05 & 0.03 & 0.02 \\ 0.02 & 0.03 & 0.08 & 0.03 \\ 0.01 & 0.02 & 0.03 & 0.06 \end{bmatrix}.$$

In Figure 4, we plot the ESG score and the M-SD ratio of the four assets (A, B, C, D), of the B-RE, B-RR portfolios and of the MVP. Asset A is characterized by high M-SD ratio and low ESG score, while asset D has low M-SD ratio and high ESG score. The four assets show a negative relationship between expected returns and ESG scores, this entails that the ESG mandate is binding for a positive over-performance target. The B-RE benchmark is characterized by a higher M-SD ratio and a lower ESG score than the B-RR benchmark and the MVP.

In Figures 5 and 6, on the left hand side, we plot the M-SD ratio-ESG score combinations for portfolios belonging to the TEV frontier (red curve) and to the TEV ESG frontier (dashed black line), and, in the histograms on the right hand side, we show the portfolio weights of the MVP, TEV, TEV ESG portfolios for $G = 1.5\%$ and $G = 4\%$,

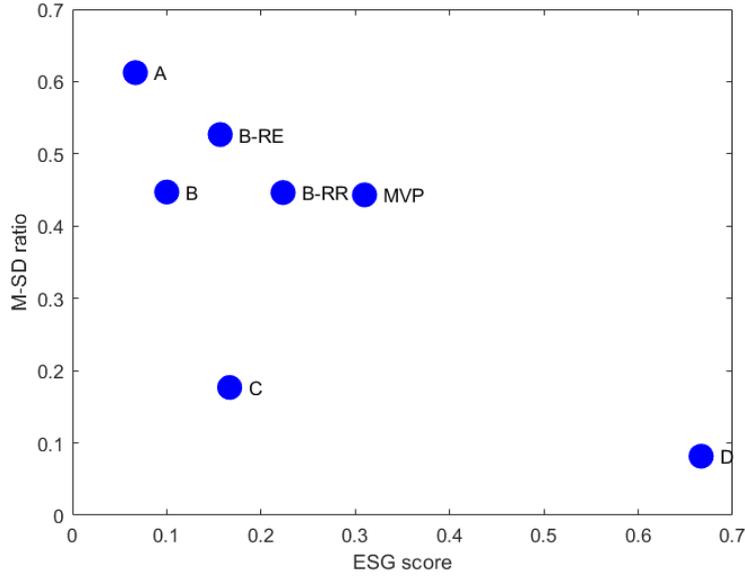

Figure 4: ESG score and M-SD ratio of the four assets (A, B, C, D), of the B-RE, B-RR portfolios and of the MVP.

and B-RR, B-RE benchmark, respectively. In both cases, the over-performance target is smaller than G^* and therefore the ESG constraint is binding and allows to reach a lower portfolio variance with respect to the minimization of TEV. For each asset, in bracket, we report the M-SD ratio difference with respect to the TEV portfolio for the same ESG score.

The region below the curves in the pictures on the left hand side denotes the M-SD ratio-ESG score combinations that are dominated, in a M-SD ratio-ESG score sense, by the portfolios on the TEV frontier while the region above the curve denotes combinations that dominate the TEV frontier. Above the red curve there are ESG score-M-SD ratio combinations that yield a ratio higher than that of the TEV portfolio for a given ESG score. Some of them are attainable through a portfolio (they are on the right of mean-variance frontier) and therefore, when the ESG constraint is introduced, a higher M-SD ratio can be achieved thanks to the fact that different metrics (TEV and variance) are considered, i.e., adding an additional constraint to a TEV minimization problem can lead to a better variance outcome. This is shown by the dashed vertical line in correspondence of the two benchmarks, where the maximum M-SD ratio attainable through a portfolio is marked by the highest point of the dashed line.

Let us notice that assets A and D dominate the TEV frontier while assets B and C are dominated. A binding ESG mandate induces the institutional investor to over-invest in assets with higher M-SD ratio (lower variance and higher expected return) with respect to the simple TEV minimization. Compared to the TEV frontier, the TEV ESG portfolios are more concentrated on assets with a high M-SD ratio for a given ESG score, see the picture on the right hand side. In our setting, the ESG mandate induces the asset manager to over-invest in assets A and D. On the other hand, TEV portfolios are more concentrated in inefficient assets (B and C).

As it is shown in Figure 2, comparing the extension of the dashed black lines in the two figures, we observe that there is more space for a M-SD improvement in case of the B-RR benchmark than for the B-RE benchmark. The interpretation of this result is straightforward: if the benchmark is already characterized by a high M-SD ratio then there is less space to get a smaller variance thanks to the ESG mandate because portfolios are strongly concentrated.

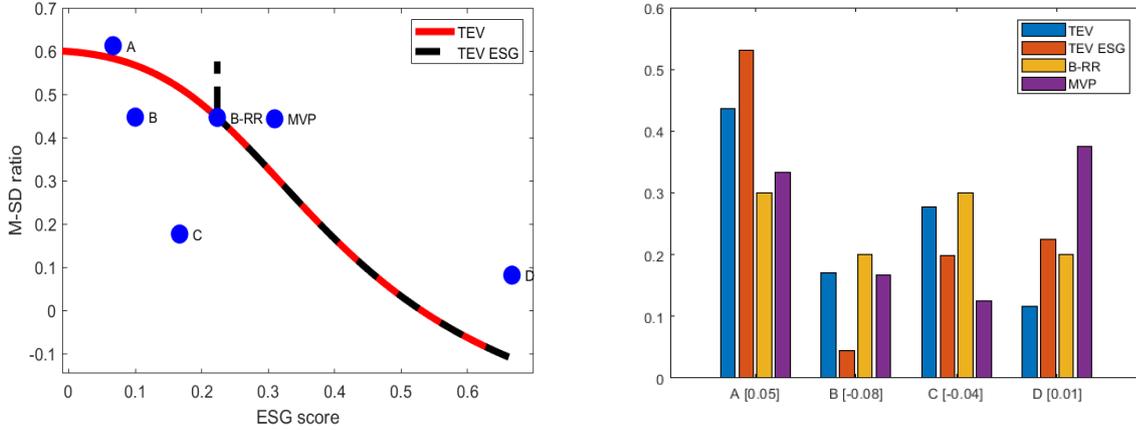

Figure 5: M-SD ratio-ESG score combinations for portfolios belonging to the TEV frontier (red curve) and to the TEV ESG frontier (dashed black line) and portfolio weights of TEV, TEV ESG portfolios for $G = 1.5\%$, MVP and the B-RR benchmark. For each asset, in bracket, we report the M-SD ratio difference with respect to the TEV portfolio for the same ESG score.

In Section 2, we highlighted that for the same set of assets and different benchmarks, we can either observe a mean-variance improvement due to an ESG mandate or not, depending on G^* that can be positive or negative for different benchmarks. From equation

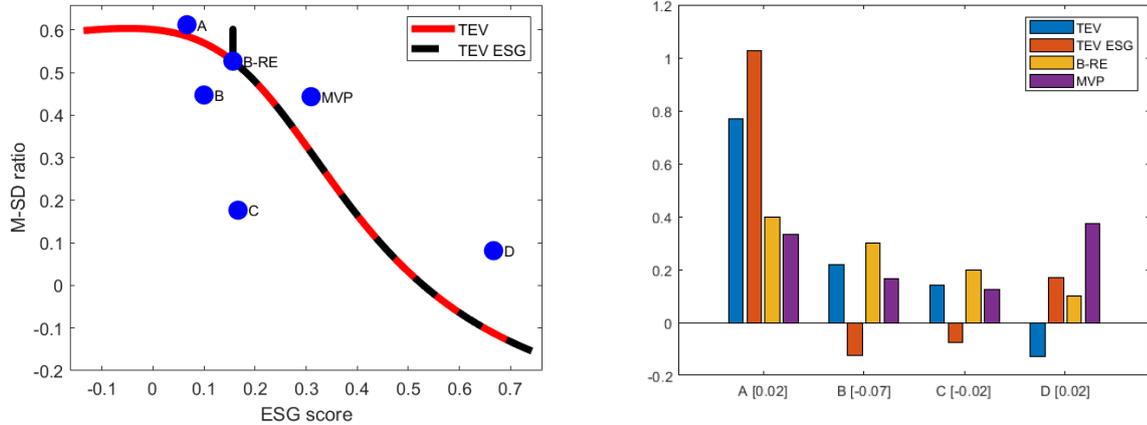

Figure 6: M-SD ratio-ESG score combinations for portfolios belonging to the TEV frontier (red curve) and to the TEV ESG frontier (dashed black line) and the portfolio weights of TEV, TEV ESG portfolios for $G = 1.5\%$, MVP and the B-RE benchmark. For each asset, in bracket, we report the M-SD ratio difference with respect to the TEV portfolio for the same ESG score.

(17), we notice that

$$G^* = d_1 + d_2 \mathbf{x}_0^\top \boldsymbol{\mu} + d_3 \mathbf{x}_0^\top \boldsymbol{\xi}$$

for some parameters d_1 , d_2 and d_3 , where d_2 , $d_3 > 0$. Consequently, the separation between positive and negative values of G^* is defined by a straight line with a negative slope in the plane ESG score-expected return of the benchmark, see Figure 7, where the green area represents the combinations that yield a mean-variance improvement. The picture shows that a mean-variance improvement is attainable thanks to an ESG mandate if the benchmark is not challenging both in terms of return and ESG score.

These results go to the heart of the mean-variance improvement associated with an ESG mandate. A negative relation between ESG scores and expected returns leads to a conflict between a return over-performance and an ESG target for the asset manager. However, this is not necessarily detrimental: the ESG mandate leads to a mean-variance improvement if the expected return and the ESG score of the benchmark are not too high. If the benchmark's expected return is low enough (e.g. lower than that of the MVP), then the ESG mandate even leads to a reduction of the minimum variance attainable by minimizing the TEV, otherwise it contributes to reach higher returns. In both cases, the mean-variance improvement is due to the fact that a binding ESG constraint leads the asset manager to over-invest in assets with higher M-SD ratios yielding a mean-variance

improvement.

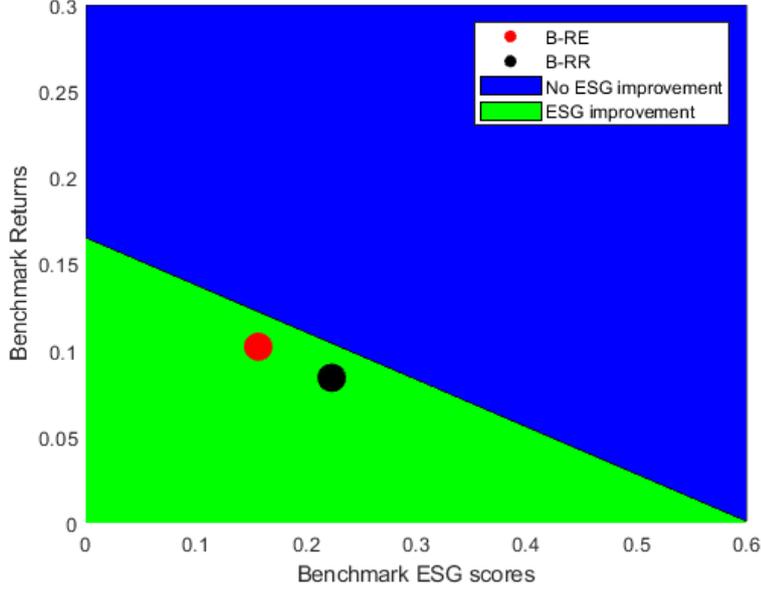

Figure 7: Region of mean-variance improvement of an ESG mandate (green area) in the plane ESG score-mean return of the benchmark. B-RE and B-RR portfolios are represented by the red and the black dot, respectively.

4 Market equilibrium

We consider the market model in [6, 7] introducing an ESG mandate for institutional investors. We consider an economy with N risky assets and a risk-free asset with return r_f . Retail investors maximize a mean-variance utility and can also invest in the risk-free asset. Institutional investors are remunerated according to their performance relative to the benchmark, and therefore they maximize a mean-variance utility defined with respect to the tracking error (mean-TEV utility) and can only invest in risky assets. We keep the number and the wealth of retail and institutional investors constant.

The i^{th} institutional investor ($i = 1, \dots, I$) maximizes the mean-TEV utility defined

with respect to the benchmark \mathbf{x}_{0i} subject to the ESG mandate:

$$\max_{\mathbf{x}_i} (\mathbf{x}_i - \mathbf{x}_{0i})^\top \boldsymbol{\mu} - \frac{a_i}{2} (\mathbf{x}_i - \mathbf{x}_{0i})^\top \Omega (\mathbf{x}_i - \mathbf{x}_{0i}) \quad (18)$$

subject to

$$\mathbf{x}_i^\top \mathbf{1} = 1 \quad (19)$$

$$(\mathbf{x}_i - \mathbf{x}_{0i})^\top \boldsymbol{\xi} \geq 0 \quad , \quad (20)$$

where a_i is the coefficient of absolute risk aversion. The constraint (20) is the key novelty with respect to the framework in [6, 7]. The following proposition holds true for the optimal portfolio.

Proposition 3. *The optimal portfolio for the institutional investor is*

$$\mathbf{x}_i^* = \mathbf{x}_{0i} + \frac{1}{a_i} \Omega^{-1} (\boldsymbol{\mu} - \omega_1 \mathbf{1} - \omega_2 \boldsymbol{\xi}) \quad , \quad (21)$$

where

$$\begin{cases} \omega_1 = \frac{A}{C} - \omega_2 Z, & \omega_2 = \frac{(\boldsymbol{\mu} - \frac{A}{C} \mathbf{1})^\top \Omega^{-1} \boldsymbol{\xi}}{(\boldsymbol{\xi} - Z \mathbf{1})^\top \Omega^{-1} \boldsymbol{\xi}} & \text{if (20) is binding} \\ \omega_1 = \frac{A}{C}, & \omega_2 = 0 & \text{otherwise} \end{cases}$$

and $Z = \frac{\boldsymbol{\xi}^\top \Omega^{-1} \mathbf{1}}{\mathbf{1}^\top \Omega^{-1} \mathbf{1}}$.

The ESG constraint (20) is binding if and only if

$$E - \frac{A}{C} A_E < 0 \quad . \quad (22)$$

Proof. Let us assume that the constraint (20) is binding.

In this case the Lagrangian is

$$\mathcal{L}(\mathbf{x}_i, \omega_1, \omega_2) = (\mathbf{x}_i - \mathbf{x}_{0i})^\top \boldsymbol{\mu} - \frac{a_i}{2} (\mathbf{x}_i - \mathbf{x}_{0i})^\top \Omega (\mathbf{x}_i - \mathbf{x}_{0i}) + \omega_1 (\mathbf{x}_i^\top \mathbf{1} - 1) + \omega_2 (\mathbf{x}_i^\top \boldsymbol{\xi} - \mathbf{x}_{0i}^\top \boldsymbol{\xi}) \quad ,$$

where ω_1 and ω_2 are the Lagrange multiplier. First order conditions render

$$\mathbf{x}_i^* = \mathbf{x}_{0i} + \frac{1}{a_i} \Omega^{-1} (\boldsymbol{\mu} - \omega_1 \mathbf{1} - \omega_2 \boldsymbol{\xi}) \quad .$$

Substituting \mathbf{x}_i^* in the constraints, we get

$$\begin{aligned} \left(\mathbf{x}_{0i} + \frac{1}{a_i} \Omega^{-1} (\boldsymbol{\mu} - \omega_1 \mathbf{1} - \omega_2 \boldsymbol{\xi}) \right)^\top \mathbf{1} &= 1 \\ \left(\mathbf{x}_{0i} + \frac{1}{a_i} \Omega^{-1} (\boldsymbol{\mu} - \omega_1 \mathbf{1} - \omega_2 \boldsymbol{\xi}) \right)^\top \boldsymbol{\xi} &= \mathbf{x}_{0i}^\top \boldsymbol{\xi} \quad . \end{aligned}$$

Solving for ω_1 and ω_2 , we obtain

$$\begin{aligned}\omega_1 &= \frac{(\boldsymbol{\mu} - \omega_2 \boldsymbol{\xi})^\top \Omega^{-1} \mathbf{1}}{\mathbf{1}^\top \Omega^{-1} \mathbf{1}} = \frac{A}{C} - \omega_2 Z \\ \omega_2 &= \frac{\boldsymbol{\mu}^\top \Omega^{-1} \boldsymbol{\xi} - \frac{\boldsymbol{\mu}^\top \Omega^{-1} \mathbf{1}}{\mathbf{1}^\top \Omega^{-1} \mathbf{1}} \mathbf{1}^\top \Omega^{-1} \boldsymbol{\xi}}{\boldsymbol{\xi}^\top \Omega^{-1} \boldsymbol{\xi} - \mathbf{1}^\top \Omega^{-1} \boldsymbol{\xi} \frac{\boldsymbol{\xi}^\top \Omega^{-1} \mathbf{1}}{\mathbf{1}^\top \Omega^{-1} \mathbf{1}}} = \frac{(\boldsymbol{\mu} - \frac{A}{C} \mathbf{1})^\top \Omega^{-1} \boldsymbol{\xi}}{(\boldsymbol{\xi} - Z \mathbf{1})^\top \Omega^{-1} \boldsymbol{\xi}}.\end{aligned}$$

If the ESG constraint is not binding, then the Lagrangian becomes

$$\mathcal{L}(\mathbf{x}_i, \omega_1) = (\mathbf{x}_i - \mathbf{x}_{0i})^\top \boldsymbol{\mu} - \frac{a_i}{2} (\mathbf{x}_i - \mathbf{x}_{0i})^\top \Omega (\mathbf{x}_i - \mathbf{x}_{0i}) + \omega_1 (\mathbf{x}_i^\top \mathbf{1} - 1).$$

First order conditions render

$$\mathbf{x}_i^* = \mathbf{x}_{0i} + \frac{1}{a_i} \Omega^{-1} (\boldsymbol{\mu} - \omega_1 \mathbf{1}) . \quad (23)$$

Substituting \mathbf{x}_i^* in (20) we get

$$\left(\mathbf{x}_{0i} + \frac{1}{a_i} \Omega^{-1} (\boldsymbol{\mu} - \omega_1 \mathbf{1}) \right)^\top \mathbf{1} = 1 .$$

yielding $\omega_1 = \frac{A}{C}$.

The ESG constraint is binding if the optimal portfolio in (23) does not satisfy the constraint (20), i.e., $\mathbf{x}_i^{*\top} \boldsymbol{\xi} < \mathbf{x}_{0i}^\top \boldsymbol{\xi}$:

$$\left(\mathbf{x}_{0i} + \frac{1}{a_i} \Omega^{-1} (\boldsymbol{\mu} - \frac{A}{C} \mathbf{1}) \right)^\top \boldsymbol{\xi} < \mathbf{x}_{0i}^\top \boldsymbol{\xi} . \quad (24)$$

Rearranging the terms, and multiplying by a_i , we get condition (22). \square

As expected, the ESG constraint is binding if and only condition (12) is verified for $G \geq 0$. As a matter of fact, the portfolio of the mean-TEV optimizer belongs to the efficient part of the TEV ESG frontier which is different from the TEV frontier only if the ESG constraint is binding for $G > 0$.

The optimal portfolio of the institutional investor in (21) corresponds to the one in [7] and does not depend on the ESG score of the assets if the ESG constraint is not binding. Instead, if the ESG constraint is binding, then the optimal portfolio belongs to the TEV ESG frontier built in the previous section with ω_1 and ω_2 dependent on the ESG score.

The l^{th} retail investor ($l = 1, \dots, L$) does not take into account the ESG score and maximizes the standard mean-variance utility function:

$$\max_{\mathbf{y}_l} \mathbf{y}_l^\top (\boldsymbol{\mu} - r_f \mathbf{1}) - \frac{a_l}{2} \mathbf{y}_l^\top \Omega \mathbf{y}_l , \quad (25)$$

where a_l is the coefficient of absolute risk aversion. The problem is equivalent to the one considered in [7] and the optimal portfolio is given by:

$$\mathbf{y}_1^* = \frac{1}{a_l} \Omega^{-1} (\boldsymbol{\mu} - r_f \mathbf{1}) . \quad (26)$$

Let W_i and W_l the exogenous wealth of the i^{th} institutional investor and of the l^{th} individual investor, then in equilibrium we have:

$$W_m \mathbf{x}_m = \sum_{i=1}^I W_i \mathbf{x}_i + \sum_{l=1}^L W_l \mathbf{y}_l , \quad (27)$$

where W_m is the market wealth ($W_m = \sum_{i=1}^I W_i + \sum_{l=1}^L W_l$) and \mathbf{x}_m is the market portfolio.

The following result can be obtained for the expected returns of the assets in equilibrium.

Proposition 4. *In equilibrium, if the ESG constraint is binding, then*

$$\boldsymbol{\mu} = r_f^* \mathbf{1} + \theta_1 \Omega \mathbf{x}_m - \theta_2 \Omega \mathbf{x}_0 - \Gamma \boldsymbol{\xi} , \quad (28)$$

where r_f^* , θ_1 , θ_2 and Γ are constants defined as follows:

$$i. \ r_f^* = \frac{(\omega_1 \sum_{i=1}^I \frac{W_i}{a_i} + \sum_{l=1}^L \frac{W_l}{a_l} r_f)}{\delta}$$

$$ii. \ \theta_1 = \frac{W_m}{\delta}$$

$$iii. \ \theta_2 = \frac{\sum_{i=1}^I W_i}{\delta}$$

$$iv. \ \Gamma = - \frac{\sum_{i=1}^I \frac{W_i \omega_2}{a_i}}{\delta}$$

$$\text{and } \delta = \sum_{i=1}^I \frac{W_i}{a_i} + \sum_{l=1}^L \frac{W_l}{a_l} .$$

Proof. By substituting (21) and (26) into (27), we obtain

$$\boldsymbol{\mu} = \frac{W_m \Omega \mathbf{x}_m + \left(\omega_1 \sum_{i=1}^I \frac{W_i}{a_i} + \sum_{l=1}^L \frac{W_l}{a_l} r_f \right) \mathbf{1} - \sum_{i=1}^I W_i \Omega \mathbf{x}_0 + \sum_{i=1}^I \frac{W_i \omega_2}{a_i} \boldsymbol{\xi}}{\sum_{i=1}^I \frac{W_i}{a_i} + \sum_{l=1}^L \frac{W_l}{a_l}} \quad (29)$$

$$=: r_f^* \mathbf{1} + \theta_1 \Omega \mathbf{x}_m - \theta_2 \Omega \mathbf{x}_0 - \Gamma \boldsymbol{\xi} , \quad (30)$$

where $\mathbf{x}_0 = \sum_{i=1}^I W_i \mathbf{x}_{0i}$ is the aggregate benchmark portfolio of institutional investors. \square

The beta of asset j with respect to the market is $\beta_{mj} := \frac{\text{Cov}(r_m, r_j)}{\text{Var}(r_m)} = \Omega_j \mathbf{x}_m$, where r_m is the return of the market portfolio, r_j is the return of asset j and Ω_j is the j^{th} row of matrix Ω . The beta of asset j with the benchmark is $\beta_{bj} := \frac{\text{Cov}(r_{be}, r_j)}{\text{Var}(r_{be})} = \Omega_j \mathbf{x}_0$, where r_{be} is the benchmark return. Hence, for asset j it holds that

$$\mu_j = r_j^* + \theta_1^* \beta_{mj} \mu_m - \theta_2^* \beta_{bj} \mu_{be} - \Gamma \xi_j, \quad j = 1, \dots, N, \quad (31)$$

where $\theta_1^* = \theta_1 \sigma_m^2$, $\theta_2^* = \theta_2 \sigma_{be}^2$, σ_m^2 and σ_{be}^2 are the market and the benchmark variance, respectively.

Notice that the ESG score of asset j enters the expected return through the term $-\Gamma \xi_j$. Γ is the same for all assets and is positive because ω_2 , the Lagrange multiplier associated to the binding ESG constraint, is negative.

A negative ESG premium has been already established in the literature, see [1, 23], the main novelty of our analysis is the mechanism inducing the negative ESG premium which is not due to a preference for ESG assets by investors but to the constraint for asset managers introduced via the ESG mandate. The negative ESG premium arises in equilibrium if the ESG constraint is binding for institutional investors maximizing a mean-TEV utility and facing retail mean-variance investors. Actually, in Section 2 we have shown that the constraint is binding if market data exhibits a negative relationship between ESG score and return. Consequently, this equilibrium result and the condition for a binding constraint complement each other.

5 Empirical analysis

In what follows, we provide an empirical analysis focusing on the US market.

The data set consists of the stocks belonging to the Russell3000 index at least one year in the 2017 – 2022 period. We consider monthly stock total returns and collect monthly ESG scores from Refinitiv. The Refinitiv ESG score is a widely used sustainability rating system, it covers most of the Russell3000 index market capitalization starting from 2017, see [25]. In Table 2, we provide a summary statistics of the stocks of the Russell3000 endowed with an ESG score and, therefore, included in the sample for each year (from January 2017 to December 2022). We remove from the analysis the stocks that have no ESG score in any year of the sample. The availability of ESG data increases over time

Year	# stocks	% stocks	% market capitalization
2017	954	32.23 %	84.96 %
2018	1575	52.29 %	92.28 %
2019	2145	71.69 %	95.46 %
2020	2422	79.18 %	94.16 %
2021	2294	74.84 %	94.35 %
2022	2159	72.86 %	95.03 %

Table 2: Number of stocks with available Refinitiv ESG score, fraction of the Russell3000 stocks with available Refinitiv ESG score, fraction of the market capitalization of the Russell3000 stocks covered by the data set.

covering more than 70% of Russell3000 stocks from 2019 onward. However, already in 2017, the market capitalization of stocks with an ESG score is higher than 80% of the market capitalization of the index.

At each point in time, we consider the monthly stock return and the latest available ESG score. ESG scores are published on an annual basis but on different dates. In our monthly time-series we consider a constant ESG score from one release to the next one. If an ESG score is missing for a given month we replace it with the previous observation. Similarly to [11, 29, 20], we normalize the ESG scores: for each month, we subtract the average ESG score of all the stocks from each stock’s ESG score.

As far as monthly returns is concerned, we notice high volatility and outliers in February 2020, corresponding to the onset of the global COVID-19 pandemic, and in February 2022 in correspondence of the Russian invasion of Ukraine. To tackle this issue, we perform a winsorization on returns, which limits extreme values in the data set. We adopt a 95% winsorization which sets all observations below the 2.5th percentile equal to the 2.5th percentile, and all observations above the 97.5th percentile equal to the 97.5th percentile. Following this procedure, we do not eliminate outliers but we limit their effect, for more details on the technique see [3].

The first step of our analysis consists in verifying whether the ESG constraint is binding for a positive or a negative G . We need to check whether condition (12) is verified for

$G > 0$ or $G < 0$. Given the very large sample size of the data set, we cannot estimate the variance-covariance matrix for the full sample of stocks. Hence, we consider eleven equally weighted portfolios based on the sectors of the Refinitive Business Classification (TRBC sectors). We discard the stocks with low market capitalization that present also sparser ESG data, we only consider the 75% highest capitalized stocks. As market benchmark, we consider the value weighted portfolio composed of the 500 highest capitalized stocks in December 2022. As far as the ESG score is concerned, we consider its average over the sample period. The computation renders

$$E - \frac{A}{C}A_E = -0.27$$

and, therefore, the constraint (12) is binding for $G > 0$. We also obtain $G^* = 4.56\% > 0$, and therefore, the $Var_{TEV_{ESG}}$ dominates the Var_{TEV} for $G \in (0, 4.56\%)$, while the opposite holds true for a $G > G^*$. In this case, the TEV frontier with an ESG mandate is less efficient than the TEV one. In Figure 8, we report the variance difference between $Var_{TEV_{ESG}}$ and Var_{TEV} varying $G \geq 0$. The risk improvement associated with an ESG mandate amounts up to 1% of the variance of the MVP.

As a robustness check, we perform the analysis including only the top 70%, 60%, 40% and 20% stocks of the data set, sorted according to the market capitalization. For the sake of consistency, when computing portfolios based on the TRBC sectors for different levels of market capitalization, we exclude portfolios that are formed only by 5 or less stocks. We perform the same analysis considering portfolios of stocks sorted for ten quantiles according to the ESG score. In Table 3, we report $E - \frac{A}{C}A_E$ and G^* for the two different portfolio selection criteria (TRBC sectors and ESG score). In all the cases, $E - \frac{A}{C}A_E$ turns out to be negative, its absolute value increases as the capitalization of stocks increases. In the fourth and the fifth column of the table, we report the value of G^* for the same portfolios. G^* is consistently positive. These results show that the return-variance gain associated with an ESG mandate is borne by the data.

The second step in our empirical analysis concerns the equilibrium model introduced in Section 4. The main prediction of the model is a negative ESG risk premium in equilibrium if and only if there are asset managers with a positive over-performance target and the ESG constraint is binding for it. To test the equilibrium model in (28), we follow a procedure similar to the one in [7].

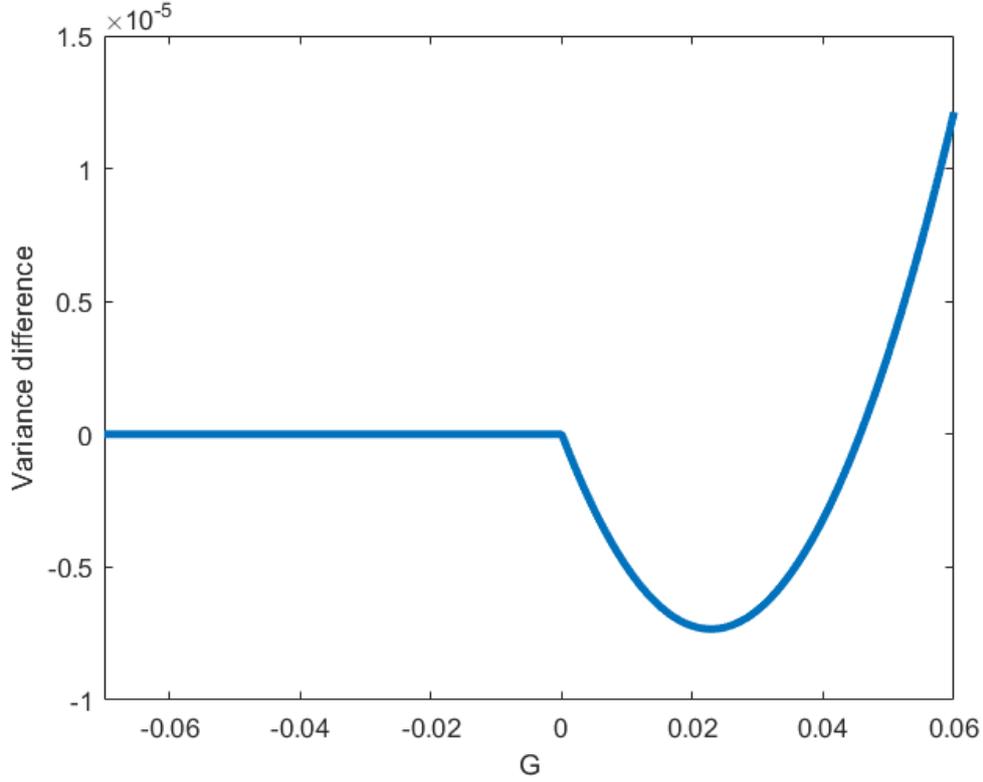

Figure 8: $Var_{TEV_{ESG}} - Var_{TEV}$ for the eleven equally weighted portfolios based on the sectors of the Refinitive Business Classification (TRBC sectors).

% stocks	$E - \frac{A}{C}A_E$		G^*	
	TRBC sectors	ESG score	TRBC sectors	ESG score
75%	-0.27	-6.87	4.56%	1.1%
70%	-0.26	-7.74	6.23%	1.67%
60%	-0.46	-6.98	3.77%	2.25%
40%	-1.19	-12.36	9.2%	1.26%
20%	-3.79	-15.47	4.11%	0.05%

Table 3: value of $E - \frac{A}{C}A_E$ (second and third column) and of G^* (fourth and fifth column) for portfolios built through the TRBC sectors and considering 10 quantiles of the ESG scores. Portfolios include the top 75%, 70%, 60%, 40% and 20% stocks sorted by market capitalization.

First, we estimate the residuals from the regression of the benchmark return on the market return:

$$r_{be}(t) - r_f = \beta_{mb}(r_m(t) - r_f) + e(t),$$

where $r_{be}(t)$ and $r_m(t)$ are the return of the benchmark and of the market, respectively. Consistently with the analysis of the TEV ESG frontier conducted above, we proxy the market return with the weighted average of the returns of the stocks in our data set and the benchmark return with the weighted average of the returns of the 500 highest capitalized stocks. The estimated beta is 99% consistently with the results obtained in [7].

As a second step, for each stock j we compute the betas of the stock with the market return and the residuals from the above regression: β_{mj} as defined in Section 4 and $\beta_{ej} = \frac{Cov(e, r_j)}{Var(e)}$, respectively. As observed in [7], we notice that

$$\begin{aligned} \beta_{bj} &= \frac{Cov(r_{be}(t), r_j(t))}{Var(r_{be}(t))} = \frac{\beta_{mb}Cov(r_m(t), r_j(t)) + Cov(e(t), r_j(t))}{Var(r_{be}(t))} \\ &= \beta_{mb}\beta_{mj} \frac{Var(r_m(t))}{Var(r_{be}(t))} + \beta_{ej} \frac{Var(e(t))}{Var(r_{be}(t))}, \end{aligned}$$

then, as in [7], we substitute this expression for β_{bj} in the equilibrium model (31) obtaining

$$\mu_j = a + b_1\beta_{mj} - b_2\beta_{ej} - \Gamma\xi_j, j = 1, \dots, N, \quad (32)$$

where a , b_1 , b_2 and Γ are positive constants. At this point, we estimate a cross-sectional regression on the average returns of the stocks in our data set to verify whether the equilibrium model, and in particular the negative ESG risk premium, is observed in market data. In Table 4, we report the estimated parameters. We repeat the analysis including 75%, 70%, 60%, 40% and 20% stocks sorted by market capitalization from our data set. In all cases, the estimated $\hat{\Gamma}$ is positive, statistically significant at 0.1%, the R^2 is close to 10% and goes up as we restrict our attention to well capitalized stocks. Notice that \hat{b}_2 is negative, in [7] a positive or negative coefficient is obtained depending on the period and on the size of companies.

The equilibrium model with asset managers and an ESG mandate in Section 4 provides a straightforward implication: a negative ESG risk premium is obtained if and only the ESG mandate is binding for a positive return over-performance target. A condition that

	20%	40%	60%	70%	75%
\hat{a}	0.4836*** (0.1253)	0.6199*** (0.0859)	0.5512*** (0.0729)	0.5398*** (0.0679)	0.5134*** (0.0656)
\hat{b}_1	1.001*** (0.1186)	0.7837*** (0.0841)	0.7257*** (0.0713)	0.6751*** (0.0661)	0.6568*** (0.0639)

$\hat{\Gamma}$	1.2034*** (0.2309)	1.2881*** (0.1585)	1.0842*** (0.1395)	0.9477*** (0.1321)	0.8385*** (0.1277)
R_{adj}^2	16.4	12.8	9.77	8.32	7.71

Note: *p<0.10, **p<0.05, ***p<0.01

Table 4: Coefficients of the cross-sectional regression (32) including the top 20%, 40%, 60%, 70% and 75% stocks sorted by market capitalization in the data set.

is ensured precisely by a negative relationship between expected returns and ESG scores. Therefore, the negative risk premium obtained in the cross-sectional regression provides positive evidence on the joint hypothesis of the presence of asset managers targeting a mean-TEV utility and of a binding ESG mandate with a positive over-performance target.

To evaluate the relevance of the ESG factor, we consider the CAPM model cross-sectionally:

$$\mu_j = a + b_1\beta_{mj}, \quad j = 1, \dots, N, \quad (33)$$

and the five factors Fama and French model, see [13], with and without the ESG component following the approach used to estimate the regression in (32):

$$\mu_j = a + b_1\beta_{mj} + b_{SMB}SMB + b_{HML}HML + b_{RMW}RMW + b_{CMA}CMA - b_2\beta_{ej} - \Gamma\xi_j, \quad (34)$$

where SMB (Small Minus Big) is the average return on nine small-minus-big stock portfolios, HML (High Minus Low) is the average return on two value-minus-growth portfolios, RMW (Robust Minus Weak) is the average return on two robust-minus-weak operating profitability portfolios and CMA (Conservative Minus Aggressive) is the average return on two conservative-minus-aggressive investment portfolios.

Results of the regressions are reported in Table 5 for top 75% stocks sorted by market capitalization in the data set. We report the results for the CAPM, Fama and French 3 factors model, i.e., only the first three factors (FF3), Fama and French 5 factors model (FF5), the model in [7] (TEV), a model only including ESG scores (ESG), the CAPM including also the ESG score (CAPM + ESG), the TEV model (TEV), the TEV model considering also the ESG scores (TEV + ESG) and the Fama and French model with TEV investors and ESG score (FF5+TEV ESG).

Comparing the TEV and the CAPM regressions, we observe that the model with institutional investors targeting a benchmark significantly improves the regression in terms of R^2 . Adding an ESG factor (TEV+ESG), we observe a further improvement in the regression performance. This result highlights that the model proposed in our analysis is well grounded from an empirical point of view.

Considering the Fama and French model we do confirm the positive sign for Γ , and therefore that a negative ESG premium is priced by the market, but the R^2 improvement is limited. Notice that we are not able to provide a theoretical model incorporating TEV investors and the ESG component in the multifactor model, we may interpret this evidence as a robustness check of the main result of the analysis centered on the CAPM.

To provide an illustrative evidence of the presence of a negative ESG premium, in Figure 9, we represent the scatter plot of average ESG score and average monthly return over the full time-interval of the 20% largest stocks by market capitalization and the regression line of the ESG model in Table 5 (ESG column). The sample includes 529 stocks and is a good proxy of the S&P 500 index. The estimated $\hat{\Gamma}$ is negative consistently with a negative ESG risk premium.

6 On the ESG mandate's target

We extend the model in two directions. As far as the portfolio frontier is concerned, we consider an ESG mandate with an over-performance target with respect to the benchmark as for the return. In the equilibrium analysis we include asset managers with heterogeneous ESG targets.

	CAPM	FF3	FF5	TEV	ESG	CAPM+ESG	TEV + ESG	FF5+TEV ESG

Table 5: Coefficients of the cross-sectional regressions (33) and (34) including the top 75% stocks sorted by market capitalization in the data set. We report the results for the CAPM, Fama and French 3 factors model (FF3), Fama and French 5 factors model (FF5), the model with institutional investors (TEV), a model including only the ESG score (ESG), the CAPM with ESG score (CAPM + ESG), the TEV model with ESG mandate (TEV + ESG) and the model including the risk factors of Fama and French, TEV and ESG score (FF5+TEV ESG).

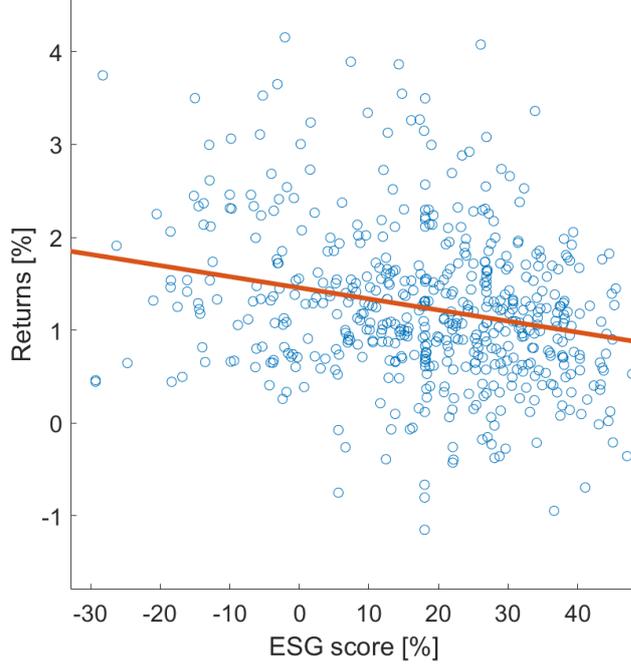

Figure 9: Average ESG score and average return over the time-interval of the 20% top capitalized stocks (dots) and the estimated regression ESG in Table 5 (continuous line).

6.1 Portfolio frontier: ESG target over-performance

We derive the TEV ESG frontier when the ESG mandate also includes an ESG over-performance target $H \in \mathbb{R}$. As noticed in [1], norm-constrained institutions like pension funds are likely to have a positive H , other asset managers like hedge funds tend to have a negative H . A fund with a negative H aims to outperform the benchmark and doesn't care of ESG considerations; a fund with a positive H is a socially responsible player and targets a high ESG score.

The optimization problem becomes:

$$\min_{\mathbf{x}} (\mathbf{x} - \mathbf{x}_0)^\top \Omega (\mathbf{x} - \mathbf{x}_0) \quad (35)$$

subject to

$$\mathbf{x}^\top \mathbf{1} = 1 \quad (36)$$

$$(\mathbf{x} - \mathbf{x}_0)^\top \boldsymbol{\xi} \geq H \quad (37)$$

$$(\mathbf{x} - \mathbf{x}_0)^\top \boldsymbol{\mu} = G. \quad (38)$$

The vector of portfolio weights of the TEV ESG frontier is

$$\mathbf{x}^* = \mathbf{x}_0 - \frac{1}{2}\Omega^{-1}(\lambda_1\mathbf{1} + \lambda_2\boldsymbol{\xi} + \lambda_3\boldsymbol{\mu}) \quad (39)$$

where

$$\lambda_1 = \frac{2(E A_E - A B_E)G + (A E - A_E B)H}{D_E}, \quad (40)$$

$$\lambda_2 = \frac{2(A A_E - E C)G + D H}{D_E} \leq 0, \quad (41)$$

$$\lambda_3 = \frac{2(B_E C - A_E^2)G + (A_E A - E C)H}{D_E} \quad (42)$$

if the constraint (37) is binding, and

$$\begin{aligned} \mathbf{x}^* &= \mathbf{x}_0 - \frac{1}{2}\Omega^{-1}(\hat{\lambda}_1\mathbf{1} + \hat{\lambda}_3\boldsymbol{\mu}) \\ \hat{\lambda}_1 &= \frac{2A G}{D}, \quad \hat{\lambda}_3 = -\frac{2C G}{D}, \end{aligned} \quad (43)$$

if the constraint (37) is not binding.

The ESG constraint (37) is binding in case

$$\left(E - \frac{A}{C}A_E\right)\frac{CG}{D} < H. \quad (44)$$

We restrict our attention to the case $E - \frac{A}{C}A_E < 0$, a condition that is borne by the data. The ESG constraint (37) is always binding if $G, H > 0$, i.e., the asset manager has both a positive return and a positive ESG target. Instead, negative return-ESG targets ($G, H < 0$) are never binding, and the mixed cases ($G > 0, H < 0$ and $G < 0, H > 0$) can lead to a binding or a non binding ESG constraint.

The variance of the TEV ESG frontier is:

$$Var_{TEV_{ESG}}(G) \quad (45)$$

$$= \begin{cases} \mathbf{x}_0^\top \Omega \mathbf{x}_0 - (\mathbf{x}_0^\top (\lambda_1 \mathbf{1} + \lambda_2 \boldsymbol{\xi} + \lambda_3 \boldsymbol{\mu})) + \frac{(A_E^2 - B_E C)G^2 + (2EC - 2AA_E)GH - DH^2}{D_E} & G \geq \frac{HD}{C(E-A/CA_E)} \\ \mathbf{x}_0^\top \Omega \mathbf{x}_0 - (\mathbf{x}_0^\top (\hat{\lambda}_1 \mathbf{1} + \hat{\lambda}_3 \boldsymbol{\mu})) + \frac{CG^2}{D} & G < \frac{HD}{C(E-A/CA_E)} \end{cases} \quad (46)$$

Similarly to the setting in Section 2, the two frontiers intersect in $\frac{HD}{C(E-A/CA_E)}$ and $\hat{G}(G, H, \boldsymbol{\mu}, \boldsymbol{\xi}, \Omega, \mathbf{x}_0)$ if $\hat{G} > \frac{HD}{C(E-A/CA_E)}$ or only in $\frac{HD}{C(E-A/CA_E)}$ if $\hat{G} \leq \frac{HD}{C(E-A/CA_E)}$. Only

in the first case we observe a mean-variance improvement. In Figure 10, we plot the three frontiers for different values of H . As $\hat{G} > \frac{HD}{C(E-\frac{A}{C}A_E)}$, in all the cases we observe a mean-variance improvement due to the ESG mandate. In Figure 12, we report the frontiers when $\hat{G} \leq \frac{HD}{C(E-\frac{A}{C}A_E)}$. For all examples we use the same assets as in Section 3.

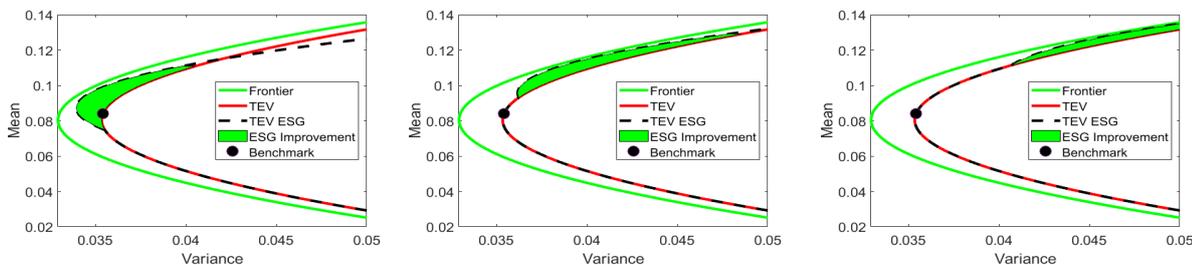

Figure 10: The three frontiers when $E - A/C A_E < 0$ and $\hat{G} > \frac{HD}{C(E-\frac{A}{C}A_E)}$, $H = 0.1$ on the left, $H = -0.1$ in the middle and $H = -0.3$ on the right ($\mathbf{x}_0^\top \boldsymbol{\mu} = 10\%$, $\frac{A}{C} = 8\%$).

As already discussed, the condition $E - \frac{A}{C} A_E < 0$ means that there is a negative ESG premium, i.e., assets with a high premium are characterized by a low ESG score. In this setting, a return and an ESG over-performance target are in conflict with each other but there is space for a mean-variance improvement because a binding ESG constraint induces the asset manager to hold a portfolio with a higher M-SD ratio and therefore a lower variance.

In Figure 10 we observe that increasing the threshold of the ESG constraint (from the right to the left) there is more space for mean-variance improvement. So a stronger ESG constraint is beneficial in a mean-variance perspective. The result hinges on the mechanism described in Section 3: the ESG constraint induces the asset manager to over-invest in assets with a high M-SD ratio. In Figure 11, we report the M-SD ratio-ESG score combination for portfolios belonging to the TEV frontier (red curve) and to the TEV ESG frontier (dashed black line) with $H = 0.1$ on the left hand side, and $H = -0.3$ on the right side. We notice that in the first case the space for a M-SD improvement significantly increases.

A high ESG target leads to a risk reduction effect of an ESG mandate: an ESG responsible asset manager is able to reach a lower level of variance for a limited expected return over-performance target. Instead, a non-ESG responsible asset manager reaches a lower level of variance for a high expected return over-performance target. When $E -$

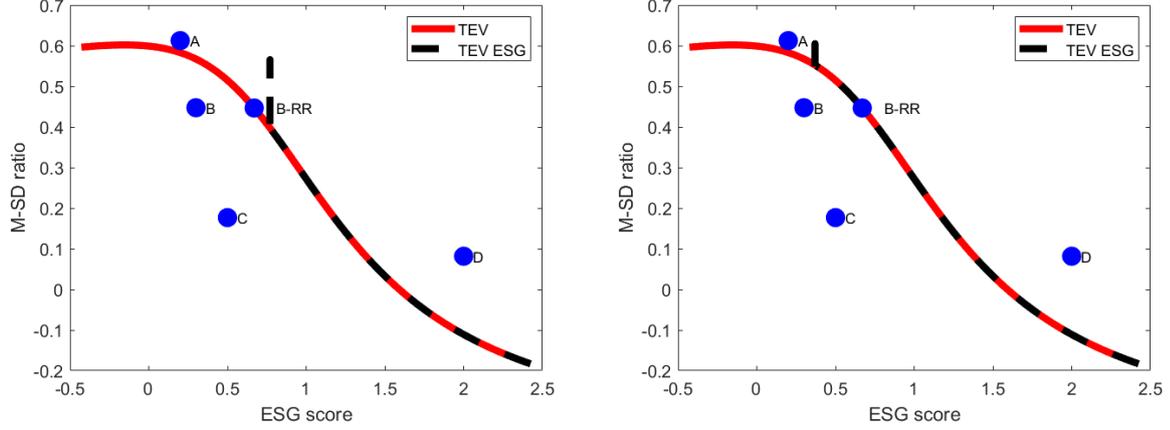

Figure 11: M-SD ratio-ESG score combinations for portfolios belonging to the TEV frontier (red curve) and to the TEV ESG frontier (dashed black line). $H = 0.1$ on the left, and $H = -0.3$ on the right.

$\frac{A}{C}A_E < 0$ and $\hat{G} > \frac{HD}{C(E-\frac{A}{C}A_E)}$, the mean-variance improvement allows to reduce the global minimum variance if $H > 0$. A socially responsible fund can achieve a significant ESG improvement for a small G , or even a negative G , while a hedge fund reaches a small improvement only for a large positive G . A positive ESG over-performance target acts as a risk reducer, instead a negative ESG over-performance target is a risk enhancer.

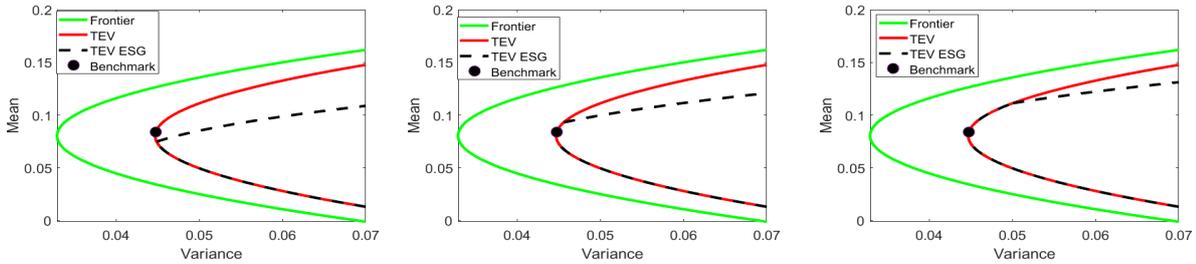

Figure 12: The three frontiers when $E - A/C A_E < 0$ and $\hat{G} \leq \frac{HD}{C(E-\frac{A}{C}A_E)}$, $H = 0.1$ on the left, $H = -0.1$ in the middle and $H = -0.3$ on the right ($\mathbf{x}_0^\top \boldsymbol{\mu} = 8.4\%$, $\frac{A}{C} = 8\%$).

6.2 Equilibrium analysis with heterogeneous ESG targets

A negative ESG premium in equilibrium is a quite robust result. In particular, it is confirmed considering heterogeneous ESG mandates for the asset managers.

Let us assume that the i^{th} institutional investor ($i = 1, \dots, I$) maximizes the mean-TEV utility subject to the constraint that the ESG score of the portfolio has to be larger

than that of the benchmark by a constant $H_i \in \mathbb{R}$. The optimization problem is:

$$\max_{\mathbf{x}_i} (\mathbf{x}_i - \mathbf{x}_{0i})^\top \boldsymbol{\mu} - \frac{a_i}{2} (\mathbf{x}_i - \mathbf{x}_{0i})^\top \boldsymbol{\Omega} (\mathbf{x}_i - \mathbf{x}_{0i}) \quad (47)$$

subject to

$$\mathbf{x}_i^\top \mathbf{1} = 1 \quad (48)$$

$$(\mathbf{x}_i - \mathbf{x}_{0i})^\top \boldsymbol{\xi} \geq H_i . \quad (49)$$

The optimal portfolio for the institutional investor is

$$\mathbf{x}_i^* = \mathbf{x}_{0i} + \frac{1}{a_i} \boldsymbol{\Omega}^{-1} (\boldsymbol{\mu} - \tilde{\omega}_1^i \mathbf{1} - \tilde{\omega}_2^i \boldsymbol{\xi}) , \quad (50)$$

where

$$\begin{cases} \tilde{\omega}_1^i = \frac{A}{C} - \tilde{\omega}_2^i Z & \& \tilde{\omega}_2^i = \frac{(\boldsymbol{\mu} - \frac{A}{C} \mathbf{1})^\top \boldsymbol{\Omega}^{-1} \boldsymbol{\xi} + H_i a_i}{(\boldsymbol{\xi} - Z \mathbf{1})^\top \boldsymbol{\Omega}^{-1} \boldsymbol{\xi}} & \text{if (20) is binding} \\ \tilde{\omega}_1^i = \frac{A}{C} & \& \tilde{\omega}_2^i = 0 & \text{otherwise} \end{cases} .$$

Notice that $\tilde{\omega}_2^i < 0$ if the ESG constraint is binding.

Without loss of generality, we assume that $I^{(1)}$ funds have an binding ESG constraint, each with wealth W_i and risk aversion coefficient a_i ($i = 1, \dots, I^{(1)}$), and $I - I^{(1)}$ funds have a non binding constraint with wealth \tilde{W}_i and risk aversion coefficient \tilde{a}_i . In equilibrium we have:

$$W_m \mathbf{x}_m = \sum_{i=1}^{I^{(1)}} W_i \mathbf{x}_i + \sum_{i=1}^{I - I^{(1)}} \tilde{W}_i \tilde{\mathbf{x}}_i + \sum_{l=1}^L W_l \mathbf{y}_l . \quad (51)$$

The equilibrium analysis yields the following:

$$\begin{aligned} \boldsymbol{\mu} &= \frac{W_m \boldsymbol{\Omega} \mathbf{x}_m + \left(\sum_{i=1}^{I^{(1)}} \tilde{\omega}_1^i \frac{W_i}{a_i} + \sum_{i=1}^{I - I^{(1)}} \tilde{\omega}_1 \frac{\tilde{W}_i}{\tilde{a}_i} + \sum_{l=1}^L \frac{W_l}{a_l} r_f \right) \mathbf{1} - \sum_{i=1}^{I^{(1)}} W_i \boldsymbol{\Omega} \mathbf{x}_0 + \sum_{i=1}^{I^{(1)}} \frac{W_i}{a_i} \tilde{\omega}_2^i \boldsymbol{\xi}}{\sum_{i=1}^{I^{(1)}} \frac{W_i}{a_i} + \sum_{i=1}^{I - I^{(1)}} \frac{\tilde{W}_i}{\tilde{a}_i} + \sum_{l=1}^L \frac{W_l}{a_l}} \\ &= r_f^* \mathbf{1} + \tilde{\theta}_1 \boldsymbol{\Omega} \mathbf{x}_m - \tilde{\theta}_2 \boldsymbol{\Omega} \mathbf{x}_0 - \tilde{\Gamma} \boldsymbol{\xi} , \end{aligned} \quad (52)$$

$$\text{i. } r_f^* = \frac{\sum_{i=1}^{I^{(1)}} \tilde{\omega}_1^i \frac{W_i}{a_i} + \sum_{i=1}^{I - I^{(1)}} \tilde{\omega}_1 \frac{\tilde{W}_i}{\tilde{a}_i} + \sum_{l=1}^L \frac{W_l}{a_l} r_f}{\tilde{\delta}}$$

$$\text{ii. } \tilde{\theta}_1 = \frac{W_m}{\tilde{\delta}}$$

$$\text{iii. } \tilde{\theta}_2 = \frac{\sum_{i=1}^{I^{(1)}} W_i}{\tilde{\delta}}$$

$$\text{iv. } \tilde{\Gamma} = - \frac{\sum_{i=1}^{I^{(1)}} \frac{W_i}{a_i} \tilde{\omega}_2^i}{\tilde{\delta}}$$

$$\text{and } \tilde{\delta} = \sum_{i=1}^{I^{(1)}} \frac{W_i}{a_i} + \sum_{i=1}^{I - I^{(1)}} \frac{\tilde{W}_i}{\tilde{a}_i} + \sum_{l=1}^L \frac{W_l}{a_l} .$$

Notice that $\tilde{\Gamma}$ is positive confirming the presence of a negative ESG premium.

7 Conclusions

This paper deals with the introduction of an ESG mandate for asset managers. We consider an asset manager who aims to minimize the tracking error variance and to maximize the expected over-performance with respect to the benchmark under the constraint that the ESG score of the portfolio is greater than that of the benchmark.

We have explored the connection among frontiers derived by minimizing portfolio variance, the TEV and adding an ESG constraint. Our findings show that ESG integration in asset management can mitigate inefficiencies in portfolios constructed by minimizing TEV resulting in a smaller variance if there exists a negative relation between expected returns and ESG scores. For a moderate over-performance target, in our empirical analysis between 0% and 5%, an ESG mandate renders an improvement of the portfolio frontier in terms of mean-variance efficiency. Instead, for a high over-performance target, the ESG mandate leads to a worsening in terms of mean-variance efficiency of the portfolio frontier. The result comes from the fact that a binding ESG mandate induces the asset manager to over-invest in assets with a high mean-standard deviation ratio, and therefore in assets with a low variance.

We expand the market equilibrium model introduced [6] to the case in which the fund manager is also subject to an ESG constraint. We prove that the market equilibrium, in the case of a binding ESG mandate, implies a negative ESG premium which means that lower returns are associated to higher ESG scores. This negative ESG risk premium is consistently confirmed by the empirical evidence.

The two pieces of our analysis (mean-variance improvement and negative ESG premium in equilibrium) sustain each other: provided that a negative relation between expected returns and ESG scores holds true, then the ESG mandate is binding for institutional investors; in equilibrium with institutional investors dealing with a binding ESG mandate and retail investors, market returns are characterized by negative ESG premium confirming the hypothesis.
