Abstract. This work addresses flexibility in deep learning by means of transductive reasoning. For adaptation to new data and tasks, e.g., in continual learning, existing methods typically involve tuning learnable parameters or complete re-training from scratch, rendering such approaches unflexible in practice. We argue that the notion of separating computation from memory by the means of transduction can act as a stepping stone for solving these issues. We therefore propose PARMESAN (**parameter-free memory search and transduction**), a scalable method which leverages a memory module for solving dense prediction tasks. At inference, hidden representations in memory are being searched to find corresponding patterns. In contrast to other methods that rely on continuous training of learnable parameters, PARMESAN learns via memory consolidation simply by modifying stored contents. Our method is compatible with commonly used architectures and canonically transfers to 1D, 2D, and 3D grid-based data. The capabilities of our approach are demonstrated at the complex task of continual learning. PARMESAN learns by 3-4 orders of magnitude faster than established baselines while being on par in terms of predictive performance, hardware-efficiency, and knowledge retention.

Keywords: Transduction · Memory · Correspondence Matching · Fast Learning · Continual Learning

1 Introduction

For training task-specific deep learning (DL) models, both data and task are usually well-defined in advance. While this setup holds true in most cases, a major issue emerges when already existing models are required to adapt to new data and new tasks. Satisfying such a flexibility requirement is non-trivial, increasing the difficulty for solving a given problem. Although research in continual learning (CL) resulted in promising approaches, they still suffer from certain restrictions [9, 91] or focus on specific problem-niches [60]. Moreover, proposed solutions

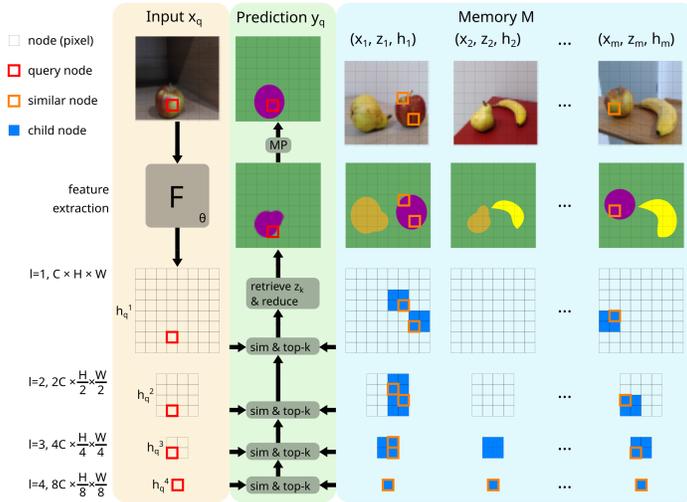

Fig. 1: Overview of our parameter-free transduction method for dense prediction tasks. A feature extractor F is applied to a query x_q to obtain hidden representations $(h)_q^l$. A memory M stores labeled samples along with their representations $(h)_j^l$. Our approach then performs a hierarchical search in M , where the objective is to find globally and locally similar nodes w.r.t. x_q . In each level l , we keep the top- k most similar nodes and retrieve their child nodes in level $l - 1$. Labels from most similar nodes are retrieved to obtain a raw prediction. Then, message passing (MP) is used to get a final prediction y_q .

are often unstable [7, 40, 39] and require domain experts for deployment and maintenance.

For example, a well established CL approach is replay training, which uses a memory module for knowledge retention [75, 63, 46, 68]. However, replay training turns out to be challenging in practice due to several reasons. First, models require high plasticity to learn and unlearn continually, which in turn limits their ability to retain knowledge. Forcing models to be robust, i.e., retain knowledge via replay training, is thus somewhat contradicting the plasticity requirement for learning new concepts. Second, all relevant knowledge has to be incorporated into model parameters via training, thereby rendering the available memory capacity irrelevant for inference. Third, the balancing of memory samples and new samples for training is non-trivial in practice and often leads to memory overfitting [46, 6, 90]. Finally, replay does not allow to unlearn specific examples easily, e.g., in case they are not needed anymore. We argue that simplicity and flexibility are not necessarily mutually exclusive properties of modern DL approaches. In contrast to common, induction-based approaches, where predictions are inferred from general, learned principles, we embrace transduction, which is characterized by reasoning from specific training cases to specific test cases [19].

Our Work: We propose PARMESAN (**p**arameter-free **m**emory **s**earch and **t**ransduction), an approach that separates computation from memory and extends transduction to dense prediction tasks while at the same time retaining high flexibility. Our method combines several concepts to perform hierarchical correspondence matching with a memory that contains task-specific, labeled data. Rather than requiring to incorporate all knowledge into learnable parameters, the memory in our method extends the capacity of existing models. We further propose a message passing approach to take advantage of correlations within a query sample, as well as a sparsity approach to retain memory efficiency.

PARMESAN is *parameter-free* in the sense that it does not have learnable parameters. Instead, learning can be easily performed via memory consolidation, i.e., adding, removing, or modifying memory samples. Our method allows for fast learning and unlearning of individual examples or parts thereof. Unlike most CL methods, our approach does not require any continual parameter-training by design. It therefore neither suffers from parameter-induced forgetting and memory overfitting, nor does it require complicated and energy-hungry training.

PARMESAN can handle various data dimensionalities such as 1D sequences, 2D images, 3D volumes, as well as spatio-temporal data. We do not impose major restrictions on memory size and allow flexible memory management. Our method can be applied in combination with common DL architectures, thereby enhancing learning speed. This is relevant, e.g., in test-time learning or when dealing with limited computational resources. It is also task-agnostic, i.e., it transfers to different dense prediction tasks as well as multi-tasking.

Our Contributions:

- A parameter-free transduction method for dense prediction tasks using hierarchical correspondence matching with a memory.
- A parameter-free message passing approach to take advantage of intra-query correlations.
- A novelty-sparsity approach to achieve high memory diversity while remaining hardware-efficient.
- A demonstration of our method’s flexibility by using it in combination with common DL architectures for semantic segmentation and depth estimation using the Cityscapes and JSRT Chest X-ray datasets.
- We show that our method can be successfully applied to CL, being on par with well-established baselines in terms of predictive performance and memory efficiency while at the same time learning by 3-4 orders of magnitude faster and having stable knowledge retention.

2 Related work

Our method is a novel combination of concepts from the following fields:

Memory Networks: Recently, memory networks experience renewed interest [27, 94, 22, 23, 62, 55, 1]. The notion of separating computation and memory [23] allows incorporating new information easily while at the same time enabling treatment of memory contents as variables. Memory consolidation [20, 3]

concerns the strategy for deciding which knowledge to keep in the presence of limited memory resources. A sophisticated memory consolidation method is novelty search [38], where only the most informative examples are kept. We expand on this approach when introducing sparsity to stored samples.

Transduction: Recently, transduction methods experience a revival due to their effectiveness in computer vision [2]. A well-established transduction method is k -nearest neighbors (k -NN) [14, 32], which aims to find similar examples w.r.t. common features. Transduction via k -NN was demonstrated to work well for image classification [54], where labeled training samples and their hidden representations are stored in memory. Moreover, k -NN in combination with vision transformers [89, 11] yielded promising results for dense out-of-distribution detection [18]. However, making k -NN scalable to dense prediction tasks at high resolutions remains underexplored.

Correspondence Matching: Dense correspondence matching [67, 93, 43, 48, 31, 28, 78, 12] is a fundamental problem in computer vision, often acting as a starting point for downstream tasks like optical flow and depth-estimation. In this context, promising methods to improve feature correlation have been proposed [85, 29, 50]. Also, feature pyramids were exploited for object detection [21, 42] and semantic feature matching [86, 98]. Recently, foundation models [4] have been applied for feature matching in one-shot semantic segmentation [44]. Many existing matching approaches use a single reference sample with known correspondences, but typically can not handle more than one reference sample. Moreover, most methods rely on specific assumptions commonly found in setups with videos or stereo / multi-view images. In contrast, our proposed method allows matching of arbitrary samples and does not require strong assumptions regarding the presence of correspondences.

Message Passing (MP): Graph neural networks [74, 10, 35] introduced the concept of MP to DL, where graph nodes are updated depending on received messages from connected nodes. MP was successfully applied, e.g., to various problems in bioinformatics, material science, and chemistry [97, 64].

Continual Learning (CL): The field of CL [84, 65, 83, 56, 9, 91, 96] studies the ability of an ML model to acquire, update, and accumulate knowledge in an incremental manner. This enables adaptation to data-distribution shifts [61, 79] and new tasks. CL is also relevant when frequent re-training is infeasible. Three CL scenarios of increasing difficulty have been proposed [88]: task-incremental (TI), domain-incremental (DI), and class-incremental (CI). The definition of the CI scenario is not limited to classification, but is characterized by the ability of a model to infer which task it is presented with.

Prominent CL approaches are based on regularization [36, 41], parameter-isolation [49, 72], and replay [75, 63, 46, 68, 37]. In contrast to biological neural networks, replay in ML is used for regularization, where the idea is to learn from new data in tandem with data that is stored in a memory.

In CL, the notion of knowledge retention [24] plays a major role in learning. Forgetting is affected by aspects such as capacity, plasticity, and the quality as well as diversity of training data. The catastrophic forgetting problem in CL

[52, 16, 51, 17, 36] refers to learnable parameters adapting to the most recently seen training data, thereby discarding knowledge from old data. Note that storing sensitive data such as patient information in a memory raises privacy concerns due to the possibility of reconstruction attacks [15, 77]. The field of data-free CL [41] using generated [75] or distilled [92, 25] data has emerged as a viable extension when privacy-preservation is needed.

3 Method

In this section we describe our parameter-free transduction method (cf. Fig. 1) in more detail. First, we provide an overview of our method and describe the individual components of our model, which consists of a frozen feature extractor, a memory, and a transduction module (Section 3.1). Given a query input, we perform dense hierarchical correspondence matching with memory contents and take advantage of intra-query correlations via message passing (Section 3.2). Finally, we improve memory efficiency by introducing sparsity to stored samples (Section 3.3).

3.1 General Setup of PARMESAN

Our proposed method requires a pre-trained feature extractor F . Let F be a neural network with learnable parameters θ consisting of an encoder-like or encoder-decoder-like architecture (e.g., [69, 73, 80]) that delivers a feature pyramid $(h)^l$ of hidden representations with levels $l = 1, \dots, n$. We refer to h^1 as the hidden representation of $l = 1$ (high-res) and h^n as the hidden representation of $l = n$ (low-res). Individual “pixels” in $(h)^l$ with their respective features are called “nodes”. The total number of nodes for level l is $p^l = \prod_{dim} res_{dim}^l$, where dim refers to the data dimension and res^l to the grid resolutions. Our method is designed to perform CL with frozen parameters θ . F can be pre-trained in a supervised or unsupervised manner, or can be taken from public repositories. Although not strictly required, we recommend pre-training F on a dense prediction task in order to enrich features with dense information.

Let X , H , and Z be the input-, latent-, and output spaces, respectively. Densely labeled data is referred to as (x, z) with inputs $x \in X$ and labels $z \in Z$. We define a solver $S : X \rightarrow Z$ as the combination of a feature extractor $F : X \rightarrow H$, a memory M , and a parameter-free transduction module $G : H \rightarrow Z$. Given a query input x_q and a memory M that stores m labeled samples, G predicts $y_q = G(F(x_q; \theta), M)$. G performs hierarchical correspondence matching between a query feature pyramid $(h)_q^l$ and memory contents, followed by label-retrieval and postprocessing. We use M for both learning and long-term knowledge retention. Knowledge in M can be modified explicitly, allowing for nuanced and sensible management of what to learn, what to retain, and what to forget. Note that this setup shifts the plasticity-robustness trade-off from learnable parameters with parameter-induced forgetting to a memory with memory-induced forgetting.

Algorithm 1 PARMESAN model inference

Require: dim, ϕ ▷ hyperparameters
Require: $x_q, (h)_j^l, z_j ; j = 1, \dots, m ; l = 1, \dots, n$ ▷ input
 $(h)_q^l \leftarrow F(x_q; \theta) ; l = 1, \dots, n$ ▷ encode query

init (in parallel for all p^n query nodes):
 $k \leftarrow m$
 $id_{k,par} \leftarrow p^n \times [0, 1, 2, \dots, k]$ ▷ parent indices
 $s_{k,par} \leftarrow p^n \times [1., 1., 1., \dots, 1.]$ ▷ parent similarities

memory search (in parallel for all p^l query nodes):
for $l = n, 1$ **do**
 $id_{comp} \leftarrow get_children(l + 1, id_{k,par})$ ▷ $[p^l \times k \cdot 2^{dim}]$
 $s^l \leftarrow calc_sim(h_q^l, h_j^l[id_{comp}])$ ▷ $[p^l \times k \cdot 2^{dim}]$
 $s_{acc}^l \leftarrow s^l \cdot s_{k,par}$ ▷ update, $[p^l \times k \cdot 2^{dim}]$
if $l > 1$ **then**
 $k \leftarrow \lfloor \phi \cdot k \rfloor$ ▷ reduce
end if
 $id_{keep} \leftarrow get_topk(s_{acc}^l, k)$ ▷ find top- k , $[p^l \times k]$
 $id_{k,par} \leftarrow id_{comp}[id_{keep}]$ ▷ update, $[p^{l-1} \times k]$
 $s_{k,par} \leftarrow s_{acc}^l[id_{keep}]$ ▷ update, $[p^{l-1} \times k]$
end for

label-retrieval and reduction:
 $id_z \leftarrow get_children(l = 1, id_{k,par})$
 $y_{q,raw} \leftarrow sum(softmax(s_{k,par})_k \cdot z_j[id_z])_k$
return $y_{q,raw}$ ▷ raw prediction

In contrast to other approaches, our method is designed to learn fast in the sense that it does not require adapting θ to perform complex tasks such as CL. Our method only requires memory consolidation, which in our case means saving examples in M and extracting their feature pyramids $(h)_j^l$ in a single forward pass with frozen θ .

We assume grid-based data structures such as images, volumes, and time series. Although we focus on orthogonal grids in this work, our method can be transferred to irregular, adaptive, and isometric grids. We do not impose any restrictions on label-space growth, such as requiring to pre-define the number of output channels, the number of dimensions, or the numerical data type. When taken to extremes, individual tokens of labels can even represent entire data structures such as sets, series, or graphs.

3.2 Correspondence Matching and Intra-Query Transduction

We initialize our model by filling M with m labeled samples $(x, z, (h)_j^l)_j$, where $j = 1, \dots, m$ and $l = 1, \dots, n$. Leaf nodes in $l = 0$ refer to z_j . Next, we define connectivity kernels which define children-parent relations across different levels. Kernels remain fixed for every sample and every level (also see Appendix A).

We formalize the forward pass of our method in Algorithm 1. First, a query x_q is encoded by F to get $(h)_q^l$. Then, G takes $(h)_q^l$ together with stored $(h)_j^l$ and z_j as inputs. The overall objective is to find globally and locally similar patterns in M w.r.t. x_q . Traversing levels backwards starting from $l = n$, we compare queries h_q^l with keys h_j^l , followed by retrieving the children (within $l - 1$) of the

top- k most similar nodes of h_j^l . We use cosine similarity by default, where the accumulated similarity s_{acc}^l between two nodes at level l is the product of their similarities s^l at level l and the similarities $s_{k,par}$ of their respective parents across all higher levels:

$$s_{acc}^l = \prod_{u=l}^n sim(h_q^u, h_j^u) = \prod_{u=l}^n \frac{h_q^u \cdot h_j^u}{\|h_q^u\| \|h_j^u\|} . \quad (1)$$

For each of the p^l query nodes, we use s_{acc}^l for comparisons. The top- k most similar nodes in l become parents for $l - 1$. Children in $l - 1$ are required for processing $l - 1$, thereby forming a hierarchy across levels. The reduction rate $\phi \in (0.0, 1.0]$ controls k , i.e., how many nodes are retained in each level. A variable number of nodes can be retained in different memory samples. Memory search results in a dense correspondence map between a query x_q and, for every query node, their top- k most similar memory nodes $i_{k,par}$. We use these matches to retrieve task-specific labels z_k from M . We obtain a raw prediction by weighting retrieved labels with softmax-normalized similarities $s_{k,par}$ of all matches.

Considering the data dimension dim and the grid resolutions res^l , exhaustive search would result in a computational complexity of $\mathcal{O}((\prod_{dim} res_{dim}^l)^2)$ for level l . In contrast, our method performs local search and has a complexity of only $\mathcal{O}(n_{ch} \cdot (\prod_{dim} res_{dim}^l))$ with n_{ch} being the number of children of nodes in $l + 1$. Search is performed independently and in parallel for every query node, making our approach scalable to high resolutions. Moreover, since h^l are strongly correlated across levels, there is a high chance that similarities to query nodes are also strongly correlated across levels. In other words, searching locally pre-filters nodes that are unlikely to be among the top- k most similar nodes in the next level anyway.

Up until this point, no intra-query correlations had been exploited by using geometric or smoothness priors. Strong local correlations are common in grid-based data and should be exploited if possible. We therefore propose a content-aware, parameter-free message passing (MP) approach to account for local correlations within the query and achieve pixel-exact predictions. Re-using our hierarchical search without memory content, top- κ nearest neighbor nodes within the query itself are found. Similarity scores between a query node i and its nearest neighbors j are referred to as edges e_{ij} . MP is then performed to refine raw predictions $y_{q,raw}$. Considering a query node state $y_{q,i}$, we define the equations for the edges e_{ij} , the aggregated message $\hat{y}_{q,i}$, and the node update from step $t \rightarrow t + 1$ as

$$e_{ij} = \frac{\exp(s_{acc,j}^1)}{\sum_{j=1}^{\kappa} \exp(s_{acc,j}^1)} , \quad (2)$$

$$\hat{y}_{q,i} = \sum_{j=1}^{\kappa} e_{ij} y_{q,j}^t , \quad (3)$$

$$y_{q,i}^{t+1} = (1 - \lambda) y_{q,i}^t + \lambda \hat{y}_{q,i} . \quad (4)$$

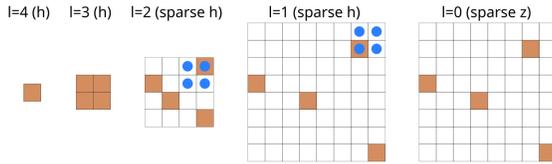

Fig. 2: Memory sample feature pyramid with $n_{sp} = 2$ sparse levels obtained via iterative, local novelty search (indicated by circles). Filled nodes are kept in M .

The hyperparameter $\lambda \in (0.0, 1.0]$ controls the overall strength of MP per step. We apply Equations (3) and (4) repeatedly for all query nodes in level $l = 0$ until convergence [100], i.e., when $\|y_{q,i}^{t+1} - y_{q,i}^t\| \rightarrow 0$. The resulting prediction y_q then contains fewer artifacts and is spatially more consistent compared to $y_{q,raw}$.

3.3 Memory-Efficiency via Sparsity and Novelty

In its basic setup, PARMESAN requires considerable hardware memory resources to operate. We thus introduce sparsity, i.e., a reduction of the number of patterns per stored sample, to become exponentially more memory efficient (see Fig. 2). Sparsity effectively reduces spatial resolutions of stored samples and is applied to both $(h)_j^l$ and z_j after feature extraction of full-resolution inputs x_j . Starting from $l = 1$, the number of sparse levels n_{sp} defines the overall degree of sparsity. Naive sparsity can be achieved by random subsampling of nodes in levels $l = 1, \dots, n_{sp}$. However, we apply local novelty search to retain high diversity in memory contents. Starting from $l = 1$, we keep the most novel node in every 2^{dim} patch such that sparsified resolution $res_{sp,dim}^1 = res_{dim}^2$. After applying sparsity to $l = 2$ such that $res_{sp,dim}^2 = res_{dim}^3$, we discard previously kept nodes in $l = 1$ such that $res_{sp,dim}^1 = res_{sp,dim}^2 = res_{dim}^3$. We repeat this procedure for every sparse level and independently for all memory samples.

4 Experiments and Results

We demonstrate the capabilities of our method in ablation studies (Section 4.1) and CL experiments (Section 4.2). For ablations, we aim to demonstrate flexibility and efficiency while simplifying and speeding up learning. For CL, we study knowledge retention and overall performance. More details regarding applied models, training and evaluation, and additional results are provided in Appendix B.1 and B.2.

Datasets: We use the Cityscapes (CITY) dataset [8] for semantic segmentation and monocular depth estimation. Segmentation masks comprise fine and coarse labels. Disparity maps are given for depth estimation. We also use the JSRT Chest X-ray dataset [76] for semantic segmentation.

Method: We employ a U-Net variant as our default DL model and feature extractor F . Some experiments use a ConvNeXt Tiny [45] encoder pre-trained

on ADE20K [99]. If M is used, we select memory samples randomly from the training split while keeping the random generation process fixed across all experiments. For PARMESAN, we set $m=2975$, $\phi=0.5$, $n_{sp}=3$ ($m=199$, $\phi=0.8$, $n_{sp}=3$ for JSRT), apply message passing (MP), and take decoder features from F unless stated otherwise. CL is performed by memory consolidation of training samples. We also use test-time augmentation (TTA) to boost performance [31].

Baselines: We select baselines with the premise to compare to representative and well-established methods in the field. Joint training (JOINT) refers to training on all training data, thus representing the default supervised learning setup and the upper bound for CL [88]. Due to catastrophic forgetting, fine-tuning (FT) is regarded as the lower bound for CL [88]. We employ classical replay (REPLAY) [75, 63, 46, 68], greedy-sampling dumb learning (GDUMB) [60], and Modeling the Background (MiB) [5] as additional CL baselines. Training via GDUMB is performed from scratch for each individual CL step, thereby exclusively using memory samples. For fair and consistent comparisons, we implement all baselines and adjust method-specific hyperparameters to our data setup.

Evaluation: We use the mean Intersection over Union of classes ($mIoU_{cl}$) and categories ($mIoU_{cat}$) as evaluation metrics for semantic segmentation and Root-Mean-Square Error (RMSE) in meters for depth estimation. We report best performances on the CITY validation set and on the JSRT test set, since labels for the CITY test set are not publicly available. For a given hardware setup, the learning speed τ_l is the average wall-clock time required to learn a training sample. The total learning time for n samples is then $T = n \cdot \tau_l$.

4.1 Ablation Studies

We perform ablation studies of various components to analyze the impact on learning speed and predictive performance, as well as demonstrating the flexibility of our method with different architectures of F (see Table 1).

Performance of our method is on-par with JOINT (A0 / A1, A9 / A10, A12 / A13) while greatly enhancing flexibility and learning speed. Learning with PARMESAN can be done in $\tau_l \simeq 0.01$ seconds per sample, thereby mitigating the demand for additional computational costs when attached to existing models. Using only the encoder (A4) or even random weights (A5) yields promising results already, indicating that G imposes useful inductive biases. PARMESAN can be successfully used for transfer learning when using a publicly available ConvNeXt pre-trained on ADE20K (A8, A11) or pre-training on coarse labels (A7). MP and TTA (A1 / A2 / A3) considerably improve raw predictions and succeed in reducing small artifacts while retaining sharp corners of predicted segments (see Fig. 3).

In general, we observe global and local semantic correspondence of retrieved nearest neighbors from M , allowing for future work on various topics related to interpretability and explainability of predictions. Moreover, since every retrieved node comes with its similarity score w.r.t. the query, our method provides pixel-

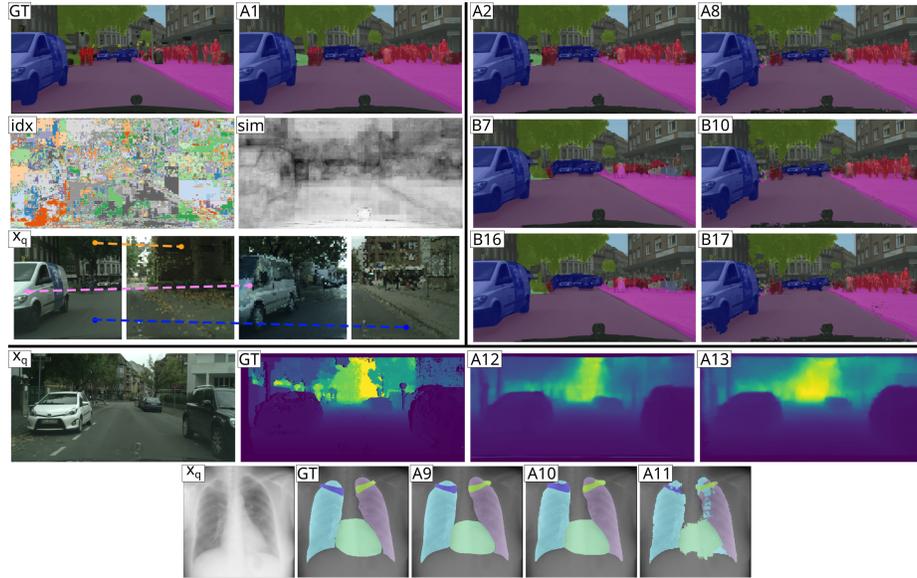

Fig. 3: Model predictions and analysis of PARMESAN. **Left:** We study top-1 nearest neighbors from experiment A1. The *idx* panel visualizes indices of retrieved nearest neighbor nodes from M . Similar colors indicate labels retrieved from close-by memory locations, most likely from within same samples. The *sim* panel visualizes s_{acc}^1 , where bright regions refer to high similarities. We also show 3 query pixels and their matches in M , indicating both global and local semantic correspondence. **Right:** Flexible use of PARMESAN in various setups. **Bottom:** Depth estimation on CITY and semantic segmentation on JSRT.

exact indications for uncertainty. As visible in the *sim* panel in Fig. 3, similarity scores seem to be correlated with the heterogeneity of regions in the image.

In Fig. 4, we demonstrate that our novelty-sparsity approach leads to exponentially lower memory requirements while achieving robust predictive performance.

4.2 Continual Learning

We perform CI-CL experiments, where the goal is to incrementally learn new semantic classes while at the same time automatically inferring the given task. We employ two different CL scenarios: *2-2 (4) cat* and *13-1 (7) cl* [95]. At *2-2 (4) cat*, data at every CL step comprises labels for all classes of different categories: D_1 : *void & flat*, D_2 : *construction & object*, D_3 : *nature & sky*, and D_4 : *human & vehicle*. For memory-based methods REPLAY, GDUMB, and PARMESAN, we update samples in M with labels from the current CL step while keeping the stored inputs. REPLAY and GDUMB utilize M for training θ , whereas

Table 1: Results for ablation studies, demonstrating the capabilities of PARMESAN. For semantic segmentation, we report performance for classes ($mIoU_{cl}$) and categories ($mIoU_{cat}$). “ θ pre-train” and “ θ train” indicate the usage of a pre-trained feature extractor F and if any additional training of learnable parameters θ is required. τ_l is the average wall-clock time for learning a sample.

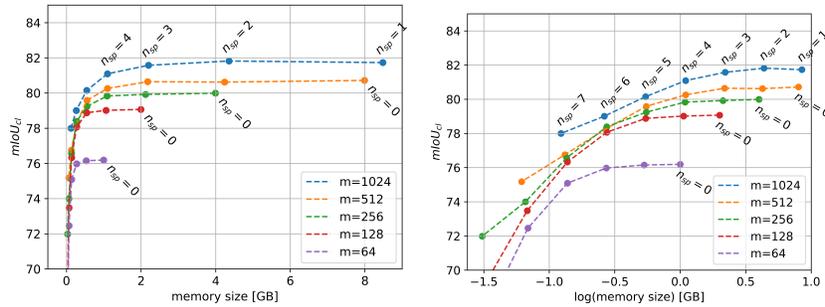

Fig. 4: Performance w.r.t. memory size on CITY. We control memory size by introducing sparse levels, leading to exponentially lower memory requirements and stable performance. Relevant contents are retained using local novelty search.

PARMESAN uses M for transduction. We summarize our results in Table 2, Table 3, Fig. 3, and provide additional information in Appendix B.3.

FT (B1, B12) and JOINT (B0, B11) behave as expected with strong forgetting and superior performance w.r.t. other methods, respectively. For same memory sizes, PARMESAN is on par with other CL baselines while enhancing flexibility, allowing simple learning and unlearning of individual examples, and boosting learning speed between 3-4 orders of magnitude. We further demonstrate that our method has stable knowledge retention properties (see Table 3). This effect can be attributed to our shift towards memory-induced forgetting, where we explicitly state what to learn (new classes), what to retain (old classes), and what to forget (background).

Table 2: Results for CL experiments on CITY fine, including size of M and learning times τ_l . Performance is measured on all classes after the final CL step.

5 Conclusion

Summary: We propose PARMESAN, a flexible, parameter-free transduction approach for dense prediction tasks. We also propose a message passing approach to take advantage of intra-query correlations, as well as a novelty-sparsity approach to retain memory efficiency and diversity. Our method is capable of performing CL in an easy and intuitive manner without any continuous training of learnable parameters. Our approach was demonstrated to learn substantially faster than common baselines while achieving competitive predictive performance and showing stable knowledge retention properties.

Limitations: Depending on hyperparameters like m , ϕ , and n_{sp} , PARMESAN can require more computational resources than learned task-heads. Moreover, choosing a suitable feature extractor requires taking a trade-off between a general-purpose model versus a data- and task-specific model.

Open Problems: Possible research opportunities include leveraging self-supervised feature extractors, studying explainability aspects, as well as investigating memory-related topics such as dataset distillation for memory consolidation. Inference

speed and memory requirements might be further improved, e.g., by using specialized libraries. Finally, PARMESAN can be beneficial to other fields such as domain adaptation, transfer learning, and few-shot learning, where flexibility and fast learning are often important.

A Method

Initialization: We now describe the initialization of G in more detail. First, we need to initialize hyperparameters such as the number of data dimensions dim , the number of memory samples m and the resolutions $(res)^l$ for all levels. We then define connectivity kernels between nodes of different levels, which remain fixed for all samples. Each node in level l has a parent node in level $l + 1$. For the highest level $l = n$, all nodes have a single root node as their parent. Each node in level l typically has several child nodes in level $l - 1$, e.g., $n_{ch} = 2^{dim}$. Leaf nodes in level $l = 0$ refer to memory labels z_j . We assume that resolutions of h^1 , x , and z match, implying that each node in level $l = 1$ has exactly one child node in $l = 0$. We initialize parent indices $i_{k,par}$ such that hierarchical search has access to the full memory content. We initialize parent similarity scores $s_{k,par}$ with a value of 1.0 for all nodes.

Some neural architectures may not provide desired feature pyramids in the sense that resolutions are halved at every level or that bottlenecks have small resolutions. In these cases, connectivity kernels can either be adjusted accordingly, or missing representations can be inserted by interpolation or extrapolation of neighboring representations.

Technical Aspects: In order to avoid increasingly exhaustive search due to a rapidly growing number of nodes, we set ϕ such that hardware memory requirements remain quasi-constant across levels. For example, $\phi = 0.5$ for 2D data in combination with doubling the channel dimension in each level yields quasi-constant hardware memory usage. The same is true for 3D data and $\phi = 0.25$. This is especially relevant in case of high-dimensional data and high resolutions, where available hardware often imposes hard limits on the choice of hyperparameters. Naturally, smaller m allow for larger ϕ . For depth estimation with PARMESAN, we ignore invalid labels in M by manually setting their respective similarity scores $s_{k,par} = -100.0$ before applying the *softmax* operation.

We implemented all methods and experiments using the PyTorch framework [58]. We apply the exact same pre and postprocessing to retain comparability. We conduct all experiments on a single NVIDIA GeForce RTX 3090 (24 GB) graphics card. PARMESAN has inference times in the order of 1 second per image for $m = 256$, $\phi = 0.5$, and an input resolution of 512×1024 pixels. By default, we store memory content on RAM and transfer representations to GPU when needed for hierarchical search. In case of small GPU RAM, the hierarchical search can be chunked into smaller pieces via windowing and performed sequentially without compromising performance. For MP, all operations can be done on GPU.

B Experimental Setup and Additional Experiments

In this section, we provide more details regarding our overall experimental setup and perform some additional experiments.

B.1 Datasets

From the Cityscapes semantic segmentation benchmark dataset (CITY) [8], we use the 5000 images with fine semantic and disparity annotations, and the 19998 images with coarse semantic annotations (see Fig. 1). We use the official splits for training and validation with 2975 and 500 samples, respectively. Since labels for the 1525 test samples are not publicly available, we report best performances achieved on the validation split. For JSRT [76], a 80:10:10 split is applied, resulting in 199, 24, and 24 samples for training, validation, and testing, respectively. For CITY, we use 34 semantic classes with 8 categories for training and the official 19 classes for evaluation. For JSRT, we use 6 classes for training and evaluation: background, left lung, right lung, heart, left clavicle, and right clavicle. We rescale all samples to a resolution of 512×1024 pixels for CITY and 512×512 pixels for JSRT. For CITY disparity maps, we observe that some pixels near image borders are labeled incorrectly. We manually mask out these erroneous labels and treat them as invalid measurements.

B.2 Models, Methods, Training and Evaluation

Models: We use a U-Net [69] variant with residual blocks [26] and instance normalization [87] as our default architecture, resulting in 9 levels (excluding the label-level $l = 0$) with respective feature map resolutions of $[512 \times 1024, 256 \times 512, 128 \times 256, 64 \times 128, 32 \times 64, 16 \times 32, 8 \times 16, 4 \times 8, 2 \times 4]$ pixels. The respective number of feature maps are $[6, 12, 24, 48, 96, 192, 384, 768, 1536]$, resulting in a total of 73.15m learnable parameters.

For some experiments, we use a ConvNeXt Tiny with pre-trained weights for feature extraction [45]. Pre-training was performed on ADE20K [99] for semantic segmentation. We use the publicly available, pre-trained weights provided by [45]. The ConvNeXt model comprises 4 levels with feature map resolutions of

Fig. 1: Annotations of Cityscapes dataset (original image, depth map, fine semantic map, coarse semantic map). While coarse annotations only outline the most prominent objects via polygons, pixel-exact fine annotations are regarded as the ground truth.

[128, 64, 32, 16] and corresponding number of feature maps [96, 192, 384, 786]. To be able to use it with our transduction module, we complete feature pyramids, i.e., add missing resolutions, via interpolation and extrapolation of neighboring representations. For ConvNeXt, we use the same number of feature maps at respective resolutions as for U-Net.

Method: For memory search, we set $n_{ch} = 4^{dim}$ for all levels. For MP, we set $\lambda = 1$, $k = 16$. Convergence is typically achieved within 32 MP steps. For test-time augmentation (TTA), we use 3 forward passes with down-scaled and reflection-padded variants of x_q . Registration of down-scaled variants with the original variant is achieved by up-scaling and center-cropping the respective predictions. We down-scale inputs by factors $s = \{0.8, 0.9, 1\}$, where $s = 1$ implies no transformation. A final prediction is obtained by averaging over all passes.

Training: Some of our experiments (baseline methods and pre-training for PARMESAN) require training of learnable parameters θ . We use the cross-entropy loss as the default loss function for semantic segmentation. For monocular depth estimation, we regress $d := \log(depth)$ and use the scale-invariant loss [13] with $\lambda = 0.5$. We mask out invalid labels both during training and evaluation. Training is performed via stochastic gradient descent [66], utilizing the backpropagation algorithm [33, 70] and the AdamW optimizer [34, 47] with default hyperparameters, a minibatch size of 8, a constant learning rate of 0.0001, and a weight decay of 0.00001. We apply gradient-norm clipping [57], allowing maximum gradient norms of 50. We train our models on randomly cropped patches of 512×512 pixels for CITY and on full images of 512×512 pixels for

Table 1: Size of M (samples stored on GPU), peak allocated GPU memory C at inference, inference speed τ_i , and predictive performance on CITY.

ID	Method & Setup	M [GB]	C [GB]	τ_i [s]	τ_l [s]	mIoU _{cl}	mIoU _{cat}
A0	JOINT	-	0.93	0.0068	3.72	82.5	87.4
A1	ours	6.40	11.0	1.43	0.012	82.1	87.0
A2	ours, no MP	6.40	10.9	0.25	0.012	81.4	86.4
A3	ours, no TTA	6.40	10.8	0.48	0.012	81.2	86.3
A14	ours, $m=4, \phi=1$	0.009	4.44	1.25	0.011	72.8	78.1
A15	ours, 75% channels	4.82	9.10	1.37	0.011	82.0	86.9
A16	ours, 50% channels	3.29	7.40	1.32	0.010	81.8	86.7

JSRT. For data augmentation during training, we use horizontal flips ($p = 0.5$, not for JSRT), vertical flips ($p = 0.5$, not for JSRT), rotations ($p = 0.5, \pm 25^\circ$), Gaussian noise ($p = 0.5, \sigma = 0.05$), as well as changes in brightness, saturation, and contrast.

Evaluation: We use exponential moving average models [59, 71, 82] with a rate of 0.99 for evaluation. Early stopping [53] with a patience of 5 and a validation verbosity of 3000 update steps is used (400 for JSRT). Early stopping in CL experiments only depends on the performance on available classes at the respective CL step. Since classes are highly imbalanced in the *13-1 (7) cl* scenario, we apply early stopping using both old and current classes for JOINT and GDUMB.

We use the Intersection over Union (IoU) [30, 81] as evaluation metric for semantic segmentation, which is defined as the ratio between the size of the intersection and the size of the union of two finite sample sets, measuring their similarity. In this work, we use IoU to measure predictive performance of a model for the task of pixel-wise, multi-class classification, i.e., semantic segmentation. We employ the standard evaluation procedure as defined in [8]. Specifically, we apply the mean IoU (mIoU), where scores are calculated globally without favoring any class in particular. This variant is also referred to as “micro”-averaging.

Results: We show qualitative prediction results for all ablation studies and CL experiments in Fig. 2 and Fig. 3, respectively. Experiments A14, A15, and A16 are not mentioned in the main paper text. Results in Table 1 indicate moderate memory requirements for our method. Performance remains robust in case of low m (A14) or when using less channels (A15, A16). Iterative MP and sequentially executed TTA lead to higher τ_i w.r.t. our best setup (A1 / A2 / A3).

B.3 Continual Learning Setup

The goal in CL is learning a sequence of N tasks $\mathcal{T} = ((T_1, D_1), \dots, (T_N, D_N))$ on respective datasets $\mathcal{D} = (D_1, \dots, D_N)$. Old data D_j is inaccessible for CL step i for $j < i$. For memory-based CL methods, data from D_j can still be retained if it is stored in M . Given a task-solving model (“solver”) $S : X \rightarrow Z$ with inputs $x \in X$, predictions $y \in Z$, and labels $z \in Z$, the objective is

minimizing the unbiased sum of losses $\mathbb{E}_{x,z}[L(y,z)]_{\mathcal{T}}$ over all tasks on the entire data distribution.

We employ two different CL scenarios: *2-2 (4) cat* and *13-1 (7) cl*. At *2-2 (4) cat*, data at every CL step comprises labels for all classes of different categories: D_1 : *void & flat*, D_2 : *construction & object*, D_3 : *nature & sky*, and D_4 : *human & vehicle*. As proposed by Yang et al. [95], the *13-1 (7) cl* scenario starts with 13 classes at CL step $i = 1$ (i.e., *road, sidewalk, building, wall, fence, pole, traffic light, traffic sign, vegetation, terrain, sky, person, rider*) and adds one new class at every following CL step (i.e., *car, truck, bus, train, motorcycle, bicycle*).

In contrast to image classification, samples for semantic segmentation can contain classes that belong to different CL steps, which is referred to as overlapping labels. For the CI-CL scenario, this requires introducing a dedicated background class to avoid data-leakage between different CL steps. Therefore, non-available classes are re-labeled as background in each CL step. This implies that the background class is different for different CL steps. As proposed in recent work [5], we ignore background pixels for validation.

Our method supports any combination of the three CL scenarios TI, DI, and CI. Although we focus on studying the offline CL scenario in this paper, our method can also be used for online CL, where one does not have access to the entire dataset of a specific task in order to learn continually.

In order to keep labels consistent for REPLAY, we employ an adaptive masking approach. For samples of the current CL step i , we mask out all background pixels, i.e., pixels which do not belong to currently active classes. In contrast, for memory samples we mask out all pixels which belong to currently active classes, i.e., keeping pixels of old classes and the background. Training minibatches for REPLAY consist of standard samples in addition to replay samples, which we select randomly from M . For REPLAY, we observe that using 4 or more replay samples from M per update step leads to strong memory overfitting, which in turn leads to reduced validation performance. For $m = 940$, we achieve best results with minibatches composed of 3 replay samples and 8 standard samples.

For MiB and REPLAY baselines, the background class is learned in the first CL step. During successive CL steps, background is partially unlearned again depending on new classes.
