We investigate the signatures of fractionalization in quantum spin liquids by studying different phases of the Kitaev honeycomb model in the presence of an out-of-plane magnetic field through which the model becomes non-integrable. Using the infinite Projected Entangled Pair States (iPEPS) ansatz, along with analytical calculations and exact diagonalization, we calculate dynamical signatures of fractionalized particles through spin-spin and dimer-dimer correlations. Our analysis demonstrates the ability of these correlations to discern distinct fractionalized quantum sectors, namely Majorana fermions and the emergent Z_2 fluxes, in both the chiral spin liquid (CSL) phase under weak field and the emergent intermediate gapless phase (IGP) under moderate field. Importantly, our calculation reveals the nature of IGP observed at moderate fields, a region of ongoing debate, indicating that this phase is a Majorana metal induced by strong flux fluctuations.

Fractionalization can arise from strong frustration between localized spins, representing a hallmark of quantum emergent phenomena [1–4]. A classic illustration of this is found in two-dimensional Mott insulators where spins become frustrated due to the spin-orbit coupling. In this scenario, each spin experiences conflicting exchange interactions from its neighboring spins [5], preventing the formation of conventional spontaneous symmetry-breaking order. The ground state thus exhibits a quantum spin liquid (QSL) phase characterized by fractionalized degrees of freedom, with other intriguing properties such as braiding statistics and long-range entanglement [6–15]. Despite significant efforts dedicated to finding candidate QSL materials such as α - RuCl_3 [16–24], the quest to explicate fractionalization and its observable consequences, especially when the system is outside the scope of exact solution of integrable models [8, 9], remains one of the most formidable challenges in both theory and experiment.

In this Letter, we propose experimentally testable signatures of fractionalization through dynamical higher-order spin correlations. Specifically, we focus on the Kitaev honeycomb model [8] in a magnetic field applied out of the plane. In experiments on QSL candidate materials, often an external magnetic field is required to suppress magnetic order at low temperatures due to non-Kitaev exchange interactions [21, 23, 25–29]. We implement the infinite Projected Entangled Pair States (iPEPS) ansatz [30–35] to investigate both single-spin flip or spin-spin dynamical correlation function $S_1(\mathbf{k}, \omega)$ and two-spin flips or dimer-dimer correlation function $S_2(\mathbf{k}, \omega)$. Our main results are the sharp signatures of fractionalization that form our main predictions for Inelastic Neutron Scattering (INS) and Resonant Inelastic X-ray Scattering (RIXS) experiments [36, 37]. We demonstrate that dynamical dimer-dimer correlations $S_2(\mathbf{k}, \omega)$ show more definitive signatures of fractionalization compared to $S_1(\mathbf{k}, \omega)$.

In the CSL phase we find (i) whereas single spin flip spectra mixes features of Majorana fermions and fluxes and shows fuzzy features [38], the two spin-flip spectra can separate out the fractionalized quantum sectors of free Majorana fermions from the emergent Z_2 fluxes. (ii) The dimer-dimer spectra along certain axis shows definitive dispersive modes, attributable to the Majorana sector. Our iPEPS spectra agree with analytical calculations within perturbation theory.

In the heavily debated intermediate gapless phase (IGP) under moderate field [39–57], we find (i) both $S_1(\mathbf{k}, \omega)$ and $S_2(\mathbf{k}, \omega)$ obtained by iPEPS confirm its gapless spectrum down to the very low energy scale which is lower than all putative gaps obtained by previous parton mean field theories [52, 53]. (ii) Signatures of fractionalization are seen in $S_1(\mathbf{k}, \omega)$ which yields a very broad continuum signal. (iii) $S_2(\mathbf{k}, \omega)$ though also broad consistent with fractionalization, remarkably shows, in addition, considerably sharper features at low energies. (iv) Supported by data from iPEPS and exact diagonalization (ED), we present arguments that this IGP is a gapless Majorana metal phase induced by fluctuations of the Z_2 gauge field, which exhibits a log divergence in the Majorana density of states at low energy.

Phase diagram by iPEPS. — The Kitaev honeycomb model under an out-of-plane field along the [111] direction is depicted by the Hamiltonian:

$$H = \sum_{\langle ij \rangle, \alpha} K_\alpha \sigma_i^\alpha \sigma_j^\alpha - h \sum_{i, \alpha} \sigma_i^\alpha, \quad (1)$$

where $\alpha = x, y, z$ refers to the three bonds of the honeycomb lattice. In this letter, we focus on the isotropic antiferromagnetic compass exchange and set $K_\alpha = 1$. We employ iPEPS as the variational ansatz for the eigenstates of Eq. (1) and obtain the phase diagram. The ground state is obtained by minimizing the energy on the

FIG. 1. Phase diagram measured by (a) ground-state magnetization M , (b) Expectation of flux W_p , and their derivatives with respect to the field h perpendicular to the plane. Kinks at $h_{c1} \simeq 0.45$ and $h_{c2} \simeq 0.70$ marks the transition from the chiral spin liquid (CSL) to the intermediate gapless phase (IGP), and from IGP to the polarized phase (PP). All data are obtained by iPEPS with bond dimension $D = 5$.

effective square Bravais lattice through automatic differentiation techniques [58]. Excited states are obtained using the variational ansatz in the momentum representation $|\Psi_{\mathbf{k}}\rangle = \sum_{\mathbf{r}} e^{i\mathbf{k}\mathbf{r}} |\Psi_{\mathbf{r}}\rangle$, where $|\Psi_{\mathbf{r}}\rangle$ is the state with site \mathbf{r} being excited (See details of iPEPS in Supplemental Materials [59]). We fix the bond dimension to $D = 5$ and the boundary bond dimension to $\lambda = 100$. The phase diagram is illustrated in Fig. 1. We utilize the total magnetization M and the flux operator $W_p = \sigma_1^x \sigma_2^y \sigma_3^z \sigma_4^x \sigma_5^y \sigma_6^z$ to characterize the phase transition. The magnetization can be optimized down to 10^{-4} and W_p up to 0.99 for the pure Kitaev model, in agreement with known results [58, 60–63]. The magnetic susceptibility χ and the derivative of W_p diverge at $h_{c1} \simeq 0.45$ and $h_{c2} \simeq 0.70$, indicating two phase transitions, one between CSL and IGP, and the other between IGP and the polarized phase (PP). Specifically, upon applying a small magnetic field, the Majorana fermions develop a gap and acquire a non-zero Chern number, and meanwhile, the gauge fluctuation reduces W_p . When $h_{c1} < h < h_{c2}$, the perturbative picture breaks down due to the strong gauge fluctuations, and W_p shows a sharp decrease, marking the system’s entry into the IGP. Eventually, when $h > h_{c2}$, the system becomes polarized. The critical points at h_{c1} and h_{c2} are in close agreement with those reported in previous studies based on finite-size numerics [44, 46–48].

Dynamical Spectra in CSL. — In this section we describe and analyse iPEPS results for the single- and two-

spin flip structure factors in the low-field case. The single-spin flip structure factor is defined by

$$S_1^\alpha(\mathbf{k}, \omega) = \sum_{m \neq 0} \langle 0 | \sigma_{\mathbf{k}}^\alpha | m \rangle \langle m | \sigma_{-\mathbf{k}}^\alpha | 0 \rangle \delta(\omega - E_m + E_0) \quad (2)$$

where $\alpha \in \{x, y, z\}$, E_m stands for the energy of the m -th excited state $|m\rangle$; and, by a similar token, the two-spin flip structure factor is defined by

$$S_2^\alpha(\mathbf{k}, \omega) = \sum_{m \neq 0} \langle 0 | \mathcal{D}_{\mathbf{k}}^\alpha | m \rangle \langle m | \mathcal{D}_{-\mathbf{k}}^\alpha | 0 \rangle \delta(\omega - E_m + E_0) \quad (3)$$

where we introduce the notation $\mathcal{D}_j^\alpha \equiv \sigma_j^\alpha \sigma_{j+z}^\alpha$ for the two-spin dimer operators, and $\mathcal{D}_{\mathbf{k}}^\alpha$ is the \mathcal{D}_j^α transformed into momentum space. These are useful probes for studying Kitaev materials via INS and RIXS experiments, with the latter able to capture high-order processes like two-spin-flip, i.e., four-spinon excitations [36, 37]. One of our important results computed by the state-of-the-art iPEPS algorithm is that in the CSL phase $S_2(\mathbf{k}, \omega)$ distinctly isolates Majorana fermion features that can be separated from the flux excitations. Our results are obtained by iPEPS, with insights from analytical calculations.

The behavior of $S_1(\mathbf{k}, \omega) = \sum_{\alpha} S_1^\alpha(\mathbf{k}, \omega)$ in the CSL phase obtained by the iPEPS ansatz is shown in Fig. 2(a), where the fuzzy continuum signature reflects the fractionalized nature of the CSL, and the gap ~ 0.2 (measured in the unit of Kitaev exchange $K_\alpha \equiv 1$) corresponds to the energy gap induced by the two-flux excitation. Note that upon adding h the model is no longer exactly solvable, however, data obtained by iPEPS still are consistent with the leading order perturbative calculation of [38].

Having validated the iPEPS algorithm using S_1 , now we focus our attention on the total dimer-dimer correlations $S_2(\mathbf{k}, \omega) = \sum_{\alpha} S_2^\alpha(\mathbf{k}, \omega)$ and its z component $S_2^z(\mathbf{k}, \omega)$ shown in Fig. 2(b,c), which are relevant for high-order processes such as two-spin-flip [36, 37]. The most notable feature of $S_2(\mathbf{k}, \omega)$ in Fig. 2(b) is the sharp flat intensity at $\omega \sim 0.52$ which spans the whole Brillouin zone. This resembles that of the flux dynamics in the Abelian phase of the Kitaev model, where the lowest-lying peak is attributed to gapped flux excitations [38]. Indeed, as we will elaborate later, the low-energy peak Fig. 2(b) is attributed to the four-flux excitation. In contrast to the total $S_2(\mathbf{k}, \omega)$, the z component of the dimer dynamics $S_2^z(\mathbf{k}, \omega)$ exhibits a fractional continuum covering the entire Brillouin zone, as shown in Fig. 2(c). This continuum is marked by prominent intensity peaks at the K point, particularly around $\omega \simeq 7$, as marked in the black dashed circle in Fig. 2(c), which is also visible in the total $S_2(\mathbf{k}, \omega)$ shown in Fig. 2(b); and the discernible dome-like region at lower energies, as marked by black dashed curve in Fig. 2(c) where the intensity of $S_2^z(\mathbf{k}, \omega)$ becomes weak within the two dome-like envelopes. The marked contrast between $S_2^z(\mathbf{k}, \omega)$ and $S_2(\mathbf{k}, \omega)$ in the CSL arises because, while the contribution from $S_2^{x(y)}(\mathbf{k}, \omega)$ to $S_2(\mathbf{k}, \omega)$ contains flux excitations, the z component $S_2^z(\mathbf{k}, \omega)$, as will be

discussed in detail later, is virtually only sensitive to the fractionalized Majorana fermions under weak magnetic field, *separating out the fractionalized matter sector from the gauge sector*. Therefore, we note that these discernible features, including the dichotomy between $S_2^z(\mathbf{k}, \omega)$ and $S_2(\mathbf{k}, \omega)$, serve as definitive signatures of the CSL of the Kitaev model accessible in scattering experiments.

Given the aforementioned data accessed by our iPEPS calculation, we are now able to give an analytical account for the dimer-dimer spectra which can be computed exactly within perturbation theory. Despite the model losing its integrability at a finite h , significant insights can still be extracted from iPEPS through perturbative approximations. To the leading order perturbation, the dynamical behaviors of $\mathcal{D}_j^{x(y)}$ and \mathcal{D}_j^z in the CSL phase are distinct. Under the perturbation picture in [8], we can formally separate the ground state into its gauge sector where excitations are Z_2 fluxes, and the Majorana sector that is equivalent to a $p + ip$ superconductor (SC) [64, 65]. Specifically, $\mathcal{D}_j^{x(y)}$ induces four fluxes accompanied by the creation of a local Majorana pair $c_j c_{j+z}$ [59]:

$$\mathcal{D}_j^{x(y)} \left| M_0; \begin{array}{c} \text{hexagon} \\ \text{hexagon} \\ \text{hexagon} \end{array} \right\rangle = ic_j c_{j+z} \left| M_0; \begin{array}{c} \text{hexagon} \\ \text{hexagon} \\ \text{hexagon} \end{array} \right\rangle \quad (4)$$

The ket combines information about the Majorana and the gauge sector; the free Majorana sector M_0 is conditioned on a zero-flux configuration in the gauge sector, the white (gray) plaquette denotes the absence (presence) of a π flux, and the z bond is denoted by the horizontal link.

Given that these fluxes are static excitations in zero or a perturbative magnetic field aligned in the [111] direction, the resultant spectrum is characterized by a flat band of static flux composites. The strongest signal appears at an energy approximately equal to 0.52, corresponding to the energy gap induced by the excitation of four fluxes. Consequently, as illustrated in Fig. 2(b), the composite dimer-dimer dynamics $S_2(\mathbf{k}, \omega) = \sum_{\alpha} S_2^{\alpha}(\mathbf{k}, \omega)$ combines the flat bands attributable to four-flux excitations, with the fractional continuum emanating from amplitude modes in the free Majorana sector [59].

In contrast, \mathcal{D}_j^z does not excite flux, thus the dynamics are solely governed by the Majorana sector:

$$\mathcal{D}_j^z \left| M_0; \begin{array}{c} \text{hexagon} \\ \text{hexagon} \\ \text{hexagon} \end{array} \right\rangle = ic_j c_{j+z} \left| M_0; \begin{array}{c} \text{hexagon} \\ \text{hexagon} \\ \text{hexagon} \end{array} \right\rangle \quad (5)$$

This is true in both the non-Abelian (weak pairing) and the Abelian (strong pairing) phases of the Kitaev honeycomb model. The z -component of the dimer-dimer correlation $S_2^z(\mathbf{k}, \omega)$, being exclusively associated with the Majorana sector and independent of the gauge component, allows for an analytical computation within the framework of a non-interacting $p + ip$ superconducting model within leading order perturbation theory. Focusing on the zero-flux sector, the spectrum of S_2^z can be readily

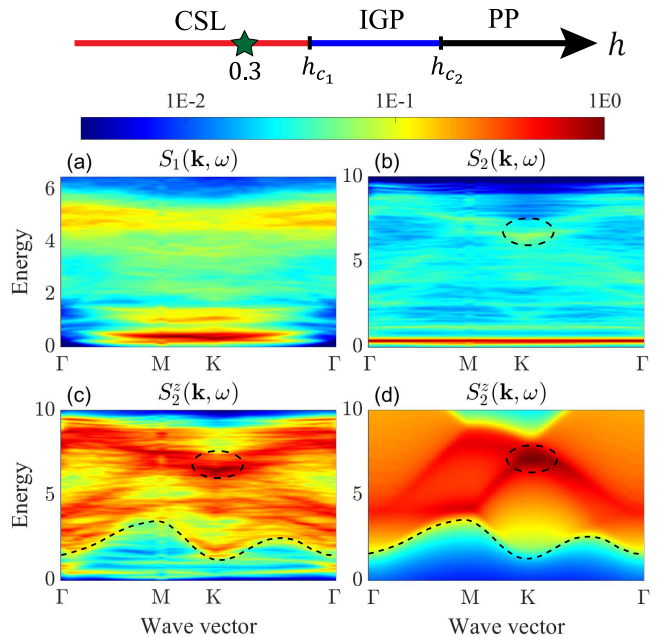

FIG. 2. Dynamical structure factors of the antiferromagnetic Kitaev model in the weak-field-induced CSL phase. (a) Total spin-spin spectrum $S_1(\mathbf{k}, \omega) = \sum_{\alpha} S_1^{\alpha}(\mathbf{k}, \omega)$, (b) total dimer-dimer spectrum $S_2(\mathbf{k}, \omega) = \sum_{\alpha} S_2^{\alpha}(\mathbf{k}, \omega)$, and (c) the dimer-dimer spectrum along z axis $S_2^z(\mathbf{k}, \omega)$. Spectra are obtained using iPEPS with the bond dimension $D = 5$ and a Lorentzian broadening factor $\eta = 0.05$. (d) Analytical result obtained by the leading order time-reversal-breaking perturbation $g = 0.08$, as defined in $Q_{\mathbf{k}}$ after Eq. (7). The black dashed curves in (c,d) and the black dashed circles in (b-d) are eye-guiding lines for the well-defined lower-bounded envelope of $S_2^z(\mathbf{k}, \omega)$ continuum and the sharpest peak around $\omega \simeq 7$. The momentum cut connects high-symmetry points Γ, M, K, Γ , see also [59]. All data are normalized by their maximum value.

calculated in the Lehmann representation [59]:

$$S_2^z(\mathbf{k}, \omega) = \frac{\sqrt{3}}{16\pi^2} \int_{\text{BZ}} G(\mathbf{k} - \mathbf{q}) \delta(\omega - \varepsilon_{\mathbf{k}, \mathbf{q}}) d^2 \mathbf{q} \quad (6)$$

where the energy of a complex-fermion pair is given by $\varepsilon_{\mathbf{k}, \mathbf{q}} \equiv E_{\mathbf{k}-\mathbf{q}} + E_{\mathbf{q}}$, and the spectral weight $G(\mathbf{k} - \mathbf{q})$ is calculated analytically:

$$G(\mathbf{k} - \mathbf{q}) = \frac{1}{4} \frac{E_{\mathbf{k}-\mathbf{q}}^2}{E_{\mathbf{k}-\mathbf{q}}^2 - Q_{\mathbf{k}-\mathbf{q}}^2} \quad (7)$$

We used $E_{\mathbf{k}}$ to denote the positive fermion band in the flux-free Hamiltonian, and $Q_{\mathbf{k}} \equiv 4g[\sin(\mathbf{k} \cdot \mathbf{n}_2) - \sin(\mathbf{k} \cdot \mathbf{n}_1) - \sin(\mathbf{k} \cdot (\mathbf{n}_2 - \mathbf{n}_1))]$ is due to the next nearest neighbor hopping amplitude g , i.e. the leading order time-reversal (TR)-breaking perturbation in the zero-flux sector [8]. Our analytical results are shown in Fig. 2(d), which agrees qualitatively with the iPEPS result in Fig. 2(c). Specifically, the sharp spot at $\omega \simeq 7$ and the low-energy envelop in $S_2^z(\mathbf{k}, \omega)$ directly reflect the band structure of itinerant Majorana fermions, hence can be particularly

useful in the RIXS for singling out the fractionalized Majorana degree of freedom in relevant candidate materials. Also note that the weak iPEPS signals below the dashed black curves in Fig. 2(c), which is absent in the analytical result in Fig. 2(d). This is due to induced fluxes for weak fields that are ignored within perturbation theory, where only majoranas are responsible for the dynamics.

Correlations in IGP.— The most notable findings in IGP at the intermediate field are illustrated in Fig. 3. Two essential signatures of IGP in the single-spin-flip dynamics are observed in Fig. 3(a,b). Noticeably, the spectrum immediately above zero energy is very broad, reflecting its highly fractionalized nature in contrast to those of CSL and PP [59]. At low energy, the spectrum is gapless at the M point at a lower field ($h = 0.5$), and with increasing field at both M and K points with K having a stronger signal ($h = 0.6$). Such shifting of gapless modes in IGP by h is qualitatively consistent with the previous investigation by classical-shadow tomography where a tunable Friedel-type oscillation was found in the same phase [51], reflecting its gapless fermionic nature.

The dimer dynamics shown in Fig. 3(c,d) further reveal distinguishable gapless signals at low energy, located primarily at Γ , with noticeable but weaker signal at K, and weak or negligible signal near M. This is in sharp contrast to the single-flip dynamics of IGP, as well as to the dimer dynamics in the CSL phase. These observations provide robust evidence for the gapless nature of the IGP. Notably, the data derived from iPEPS are free from the constraints of finite size, a limitation often encountered in previous studies utilizing ED and DMRG methods [46–48]. This advantage effectively eliminates the concern of spurious gaplessness that might arise in finite-geometry clusters.

IGP induced by flux fluctuations.— Given the iPEPS evidence for IGP, we next want to understand the mechanism for its emergence. We argue that the gapless spectrum in the IGP have to be accompanied by fluctuations of fluxes which close the gap of itinerant Majorana fermions, as evidenced in the iPEPS results. As a test, we first validate its contrapositional statement: that if flux fluctuations are energetically suppressed, IGP would be consequently removed. We therefore modify the original Hamiltonian to include an additional energy penalty for flux excitations: $H' = \sum_{\langle ij \rangle, \alpha} K_{\alpha} \sigma_i^{\alpha} \sigma_j^{\alpha} - \mu \sum_p W_p - h \sum_{i, \alpha} \sigma_i^{\alpha}$. In this formulation, the term $-\mu \sum_p W_p$ with $\mu > 0$ renders flux excitations energetically unfavorable. The summation $\sum_p W_p$ commutes with the pure Kitaev honeycomb model, consequently, it penalizes flux excitations without influencing the dynamics of the itinerant Majorana fermions. This allows for a direct examination of the role of flux fluctuations in the emergence and characteristics of IGP. Figure 4 shows the magnetic susceptibility of H' obtained by 24-site ED under PBC. For $\mu \simeq 0$ obtained by ED, the intermediate phase, corresponding to IGP [47] emerges under a finite magnetic field and persists for a finite range of h before the confinement

FIG. 3. Single- and two-spin flip spectra in IGP presented on a logarithmic color scale along the momentum path $\Gamma\text{MK}\Gamma$. (a) Total spin-spin spectrum $S_1(\mathbf{k}, \omega)$ at $h = 0.5$. (b) $S_1(\mathbf{k}, \omega)$ at $h = 0.6$. (c) Total dimer-dimer spectrum $S_2(\mathbf{k}, \omega)$ at $h = 0.5$. (d) $S_2(\mathbf{k}, \omega)$ at $h = 0.6$. Data are obtained by iPEPS with bond dimension $D = 5$ and a broadening factor $\eta = 0.05$.

transition into PP. However, as demonstrated in Fig. 4, at larger μ whereby the flux fluctuation is suppressed, the IGP spans a smaller range of h until vanishing at $\mu \gtrsim 0.6$. This showcases the important role played by the finite flux density in the formation of IGP; and suggests that a faithful effective theory thereof must consist of two dominant fields: itinerant Majorana fermions and localized fluxes, which cannot be captured by solving quadratic parton self-consistent equations [52, 53], since a flux excitation is a many-body entangled state of the Z_2 field, or equivalently, of the bond fermions [66, 67].

To further establish the connection of the IGP and Majoranas, we note that the Majorana fermion sector of the Kitaev model is depicted as a Majorana-hopping model of class D, which are known to have three phases: a topological insulator, a trivial insulator, and a gapless metal phase [68–71]. In the Kitaev model under a magnetic field, the topological insulator phase corresponds to CSL, and the gapless metal phase can arise from the fluctuating flux configurations induced by magnetic field [72].

We propose that the IGP is such a Majorana metal phase in a mean-field picture, which exhibits a $\log E$ scaling of density of states (DOS) near zero [68, 70]. At the microscopic level, such scaling of DOS can be tested by the spectrum of $S_1(\omega)$, whose low-energy dynamics are primarily attributed to metallic Majorana fermions. This is because fluxes are virtually unseen by the two-point correlation, i.e. that the two local flips of flux do not sig-

FIG. 4. (a) The role of proliferating fluxes in the emergence of the Majorana metal, as evidenced by susceptibility measurements $\chi(\mu, h) = N^{-1} \partial^2 E_0 / \partial h^2$. The IGP gradually disappears as flux excitation becomes more energetically penalized. Data was obtained by exactly diagonalizing H' in a 24-site cluster (3×4 unit cells) under PBC. (b) C_1 and C_2 cuts in (a). (c) The normalized integrated spectra $S_1(\omega) = \int_{\text{BZ}} d\mathbf{k} S_1(\mathbf{k}, \omega) / \int_{\text{BZ}} d\mathbf{k} \int_0^\infty d\omega S_1(\mathbf{k}, \omega)$ obtained by iPEPS with varying broadening factor η across the second Brillouin zone at $h = 0.6$.

nificantly affect the averaged Majorana band conditioned on an exponentially large ensemble of proliferating flux configurations. Interestingly, such a scaling behavior is robustly validated by iPEPS results in Fig. 4(c). The low-energy data exhibits a $\log E$ scaling despite variations in the broadening factor η . Notably, with the smallest η we still find no observable gap nor the trend of opening a gap in $S_1(\omega)$ at the energy scale 0.01, which is comparable to or lower than previous putative gaps obtained by parton mean field theories [52, 53]. Furthermore, the oscillation pattern under the finest energy resolution (smallest η) shown in Fig. 4(c), and the plateau at the lowest energies, are in good agreement with the metal phase of the class D predicted by random matrix theory [70, 73], supporting the emergence of a Majorana metal under moderate fields.

Conclusion and Outlook. — In this work, we have elucidated the signatures of fractionalization in Kitaev QSLs as a function of a [111] magnetic field with a focus on the chiral spin liquid (CSL) and the intermediate gapless Majorana metal phase (IGP). Utilizing iPEPS and analytical methods, we have identified dynamical signatures of fractionalized quasi-particles through spin-spin and dimer-dimer correlations. As the community awaits definitive fingerprints of QSLs, there is a need to develop new classes of experiments closely guided by theory. We believe our

predictions here can provide the necessary impetus for measuring higher-order dynamical spin correlations using INS, RIXS and pump-probe spectroscopy.

S1. IPEPS ALGORITHM

Tensor Network serves as a highly effective numerical tool for investigating strongly correlated systems, evolving from the well-known density matrix renormalization group (DMRG) algorithm [1]. Over the past decades, various ground state ansatz have been proposed, including Matrix Product State (MPS) [2], Projected Entangled Pair States (PEPS) [3], and projected entangled simplex states (PESS) [4]. The first and latter two ansatz adhere to the area law of entanglement in one and two dimensions [5], respectively. Beyond the description of ground state properties, numerous algorithms based on tensor networks have been developed to explore dynamical information. The fundamental approach for calculating the dynamical spectrum involves time evolution, employing methods such as Time-Evolving Block Decimation (TEBD) [6–8] or Time-Dependent Variational Principle (TDVP) [9–14]. However, real-time evolution often faces challenges associated with the volume law, limiting the duration of evolution and resulting in the loss of low-frequency information. Other algorithms, such as Lanczos and Chebyshev methods [15–19], directly address this issue in the frequency domain. These approaches rely on multiple DMRG calculations and typically perform well for finite systems. However, the the strong finite size effects thereof can give rise to spurious modes which vanish in the infinite limit.

In addition to the aforementioned approach, an alternative method involves adopting the single-mode approximation [20], which is originally proposed to elucidate the low-lying excitations of superfluids. Ostlund and Rommer [2, 21] introduced this ansatz within the matrix product state framework, and Vanderstraeten *et al.* [22] extended it to the PEPS context in tensor network methods. This method can be applied to infinite system and has been proven to be highly effective in computing the dynamical spectrum both in magnetic order [23–26] and spin liquid systems [27].

The Kitaev model discussed in the main text is defined on the honeycomb lattice with different interactions on three bonds, as illustrated in Fig. S1 (a). There are two sites and three bonds in one unit cell. To facilitate network contraction, we initially merge the A and B sites, transforming the lattice into a square lattice. Subsequently, we define the local tensor of iPEPS on the square lattice, as depicted in Fig. S1 (c). This allows us to implement the corner transfer matrix renormalization group (CTMRG) method for network contraction and measurement of observables. We employ the fixed-point approach for the implementation of CTMRG [25, 28], avoiding the need for singular value decomposition (SVD) and enabling acceleration on GPU. The maximum bond dimension of the environment is controlled by λ . The iPEPS ansatz is initially optimized using the simple update method [29], followed by further optimization through energy minimization using automatic differentiation techniques [28].

To characterize the excited states, we employ the single-mode approximation [20], which is originally proposed to elucidate the low-lying excitations of superfluids, yields a variational ansatz for the excited state

$$|\Psi_{\mathbf{k}}\rangle = \sum_{\mathbf{r}} e^{-i\mathbf{k}\cdot\mathbf{r}} |\Psi_{\mathbf{r}}\rangle \quad (\text{S1})$$

where \mathbf{k} denotes momentum and $|\Psi_{\mathbf{r}}\rangle$ is the state with an excitation at site \mathbf{r} . In these methods, \mathbf{r} is represented by substituting the local tensor A of the ground state at site \mathbf{r} with a pertubated local tensor B . The single-mode ansatz is illustrated in Fig. S1(d).

The excited states must fulfill the orthogonality constraint concerning the ground state $|\psi_0\rangle$:

$$\langle\psi_0|\Psi_{\mathbf{k}}(B)\rangle = 0$$

For $k = 0$, the constraint is automatically satisfied due

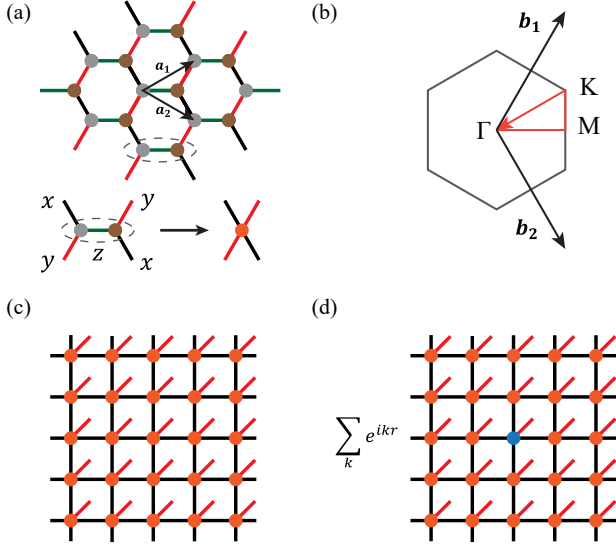

FIG. S1. (a) Kitaev model on honeycomb lattice and transformation to the square lattice by merging two sites. (b) The first Brillouin zone and the momentum path Γ -M-K- Γ . (c) Ground state iPEPS Ansatz defined on the square lattice, the local physical bond dimension is 4. (d) Excited state Ansatz.

to momentum conservation. However, when $k \neq 0$, the variational space should exclude the ground state:

$$\langle \psi_0 | \Psi_{k=0} \rangle = N \langle \psi_0 | \Psi_r \rangle = M \cdot B = 0 \quad (\text{S2})$$

where M denotes the contracted tensor of the entire tensor network excluding the B tensor, obtained through the CTMRG method. In this context, the overlap can be expressed as the contraction of two layers of the tensor network. Importantly, B must be confined within the tangent space of M . By converting it into a vector, we can derive dD^4 basis solutions from the linear equations, later denoted as B_α .

In addition to the aforementioned constraint, it is imperative to establish a fixed gauge for the PEPS. The excited state ansatz exhibits invariance under the gauge transformation:

$$B \rightarrow B + e^{-ik} AX - XA$$

This transformation is visually depicted as We define

FIG. S2. Gauge transformation along the x and y axis.

$B_X = e^{ik_x} AX - XA$ and $B_Y = e^{ik_y} AX - XA$. If we were to set $B = B_X$ or B_Y , this would yield a null state.

Therefore, to ensure physically viable states, we must confine the variational space to exclude the B_X and B_Y tensor spaces. Combining these restrictions, the physical allowed B tensors must satisfy

$$(M, B_X, B_Y) \cdot B = 0 \quad (\text{S3})$$

It is worth noting that the rank of both B_X and B_Y is D^2 . Consequently, the overall rank of the matrix is at most $2D^2 + 1$. As a result, there exist at most $2D^2 + 1$ linearly independent vectorized B tensors that need to be excluded in the tangent space. Given that the dimension of B is dD^4 , we can infer that there are at least $dD^4 - 2D^2 - 1$ solutions, denoted as \hat{B}_n ($n = 1, \dots, N_B$).

FIG. S3. Graphical representation of the orthogonality conditions. C and E are corner and edge tensor in CTMRG algorithm respectively.

To target excited states, we need to minimize the cost function

$$L = \frac{\langle \Psi_{\mathbf{k}}(B) | H - E_{\text{gs}} | \Psi_{\mathbf{k}}(B) \rangle}{\langle \Psi_{\mathbf{k}}(B) | \Psi_{\mathbf{k}}(B) \rangle} \quad (\text{S4})$$

to obtain B tensor. The minimization equals to solving the equation

$$\frac{\partial}{\partial B} \langle \Psi_{\mathbf{k}}(B) | H - E_{\text{gs}} | \Psi_{\mathbf{k}}(B) \rangle = E_{\mathbf{k}} \frac{\partial}{\partial B} \langle \Psi_{\mathbf{k}}(B) | \Psi_{\mathbf{k}}(B) \rangle \quad (\text{S5})$$

where $E_{\mathbf{k}}$ is the excitation energy. The dimension of B tensor is dD^4 . We can parameterize B with the vectorized basis obtained above

$$B = \sum_n b_n \hat{B}_n \quad (n = 1, \dots, N_B) \quad (\text{S6})$$

Then we define the effective Hamiltonian and the norm matrix

$$\begin{aligned} \langle \Psi_{\mathbf{k}}(B) | H | \Psi_{\mathbf{k}}(B) \rangle &= B^\dagger H_{\mathbf{k}} B \\ \langle \Psi_{\mathbf{k}}(B) | \Psi_{\mathbf{k}}(B) \rangle &= B^\dagger N_{\mathbf{k}} B \end{aligned} \quad (\text{S7})$$

Substituting into Eq. (S5), the equation becomes

$$H_{\mathbf{k}} b = E_{\mathbf{k}} N_{\mathbf{k}} b \quad (\text{S8})$$

where $b = (b_1, \dots, b_{N_B})^T$. By solving this general eigen equation, the local tensor B can be determined.

The zero-temperature dynamical spectral function is defined as

$$\begin{aligned} S^{\alpha\beta}(\mathbf{k}, \omega) &= \langle \psi_0 | O_{\mathbf{k}}^\alpha \delta(\omega - H + E_{\text{gs}}) O_{-\mathbf{k}}^\beta | \psi_0 \rangle \\ &= \sum_m \langle \psi_0 | O_{\mathbf{k}}^\alpha | \Psi_{\mathbf{k}}^m \rangle \langle \Psi_{\mathbf{k}}^m | O_{-\mathbf{k}}^\beta | \psi_0 \rangle \delta(\omega - E_{\mathbf{k}}^m + E_{\text{gs}}) \end{aligned} \quad (\text{S9})$$

where $\alpha, \beta = x, y, z$. $|\psi_m\rangle$ denotes the eigenstate of hamiltonian H with energy E_m . The corresponding spectral weight can be obtained by contracting the double layer tensor

$$\langle \Psi_{\mathbf{k}}^m | O_{\mathbf{k}}^\alpha | \psi_0 \rangle = \frac{1}{\sqrt{N}} \sum_{\mathbf{r}\mathbf{r}'} e^{-i\mathbf{k}\cdot(\mathbf{r}-\mathbf{r}')} \langle \Psi_{\mathbf{r}'}^m | O_{\mathbf{r}}^\alpha | \psi_0 \rangle. \quad (\text{S10})$$

The contraction can be obtained using the CTM summation. The delta function in Eq. (S9) can be approximated using the Lorentzian expansion with a broadening factor η .

In the main text, we have focused on the spectrum of two kinds excitations: one spin flip σ_i^α and two spin flip $\sigma_i^\alpha \sigma_{i+z}^\alpha$ ($\alpha = x, y, z$). We calculated the spectrum function in momentum space

$$\begin{aligned} S_1^\alpha(\mathbf{k}, \omega) &= \frac{1}{N} \sum_{ij} e^{-i\mathbf{k}\cdot(\mathbf{R}_i - \mathbf{R}_j)} [S_{aa}^\alpha(i, j, \omega) + S_{bb}^\alpha(i, j, \omega) \\ &\quad + e^{-i\mathbf{k}\mathbf{r}_{\text{ab}}} S_{ab}^\alpha(i, j, \omega) + e^{i\mathbf{k}\mathbf{r}_{\text{ab}}} S_{ba}^\alpha(i, j, \omega)] \\ S_2^\alpha(\mathbf{k}, \omega) &= \frac{1}{N} \sum_{ij} e^{-i\mathbf{k}\cdot(\mathbf{R}_i - \mathbf{R}_j)} S_2^\alpha(i, j, \omega) \end{aligned} \quad (\text{S11})$$

where \mathbf{R}_i and \mathbf{R}_j represent the sites of unit cells, and \mathbf{r}_{ab} is the distance between sites a and b within one unit cell. $S_{a/b, a/b}^\alpha(i, j, \omega)$ and $S_2^\alpha(i, j, \omega)$ denote the spectral function in real space. In the Lehmann representation, we have:

$$\begin{aligned} S_{a/b, a/b}^\alpha(i, j, \omega) &= \sum_m \langle \psi_0 | \hat{\sigma}_{i, a/b}^\alpha | \Psi_{\mathbf{k}}^m \rangle \langle \Psi_{\mathbf{k}}^m | \hat{\sigma}_{j, a/b}^\alpha | \psi_0 \rangle \\ &\quad \times \delta(\omega - E_{\mathbf{k}}^m + E_{\text{gs}}) \end{aligned} \quad (\text{S12})$$

and

$$\begin{aligned} S_2^\alpha(i, j, \omega) &= \sum_m \langle \psi_0 | \hat{\sigma}_{i, a}^\alpha \hat{\sigma}_{i, b}^\alpha | \Psi_{\mathbf{k}}^m \rangle \langle \Psi_{\mathbf{k}}^m | \hat{\sigma}_{j, a}^\alpha \hat{\sigma}_{j, b}^\alpha | \psi_0 \rangle \\ &\quad \times \delta(\omega - E_{\mathbf{k}}^m + E_{\text{gs}}) \end{aligned} \quad (\text{S13})$$

where $\hat{\sigma}_{i, a/b}^\alpha = \sigma_{i, a/b}^\alpha - \langle \psi_0 | \sigma_{i, a/b}^\alpha | \psi_0 \rangle$ and $\hat{\sigma}_{i, a}^\alpha \hat{\sigma}_{i, b}^\alpha = \sigma_{i, a}^\alpha \sigma_{i, b}^\alpha - \langle \psi_0 | \sigma_{i, a}^\alpha \sigma_{i, b}^\alpha | \psi_0 \rangle$. By representing the excited state as a summation, we can utilize CTM summation to calculate spectral weight as discussed in Eq. (S10).

S2. SPIN-SPIN CORRELATION

The spin-spin correlation in the pure Kitaev QSL or CSL under perturbation can be made explicit if we separate an eigenstate into gauge and matter sectors [30, 31]. For a fixed gauge configuration, the ground state wavefunction can be written as $|\psi\rangle = |M_{\mathcal{G}}, \mathcal{G}\rangle$ with \mathcal{G} denoting the Z_2 gauge configuration and $M_{\mathcal{G}}$ the matter majorana fermions on the gauge background. In such representation spin are fractionalized into majoranas $\sigma_j^a = ic_j b_j^a$, and the Hamiltonian in a particular $|\mathcal{G}\rangle$ sector becomes quadratic and integrable as $H = i \sum_{\langle ij \rangle_a} J_a u_{\langle ij \rangle_a} c_i c_j$, where $u_{\langle ij \rangle_a} = \pm 1$ are good quantum numbers that determine $|\mathcal{G}\rangle$ by pinning down a particular configuration of gauge fluxes $W_p = \pm 1$. In order to explicate useful properties of correlation between spins, we define bond fermions $\eta_{\langle ij \rangle_a} = \frac{1}{2}(b_i^a + ib_j^a)$ for $i \in A$ and $j \in B$ sublattice respectively, such that

$$\sigma_i^a = ic_i(\eta_{\langle ij \rangle_a} + \eta_{\langle ij \rangle_a}^\dagger), \quad \sigma_j^a = c_j(\eta_{\langle ij \rangle_a} - \eta_{\langle ij \rangle_a}^\dagger) \quad (\text{S14})$$

Local spin operators involve only two-point pauli matrices that share a link, each of which can be written as $\sigma_j^a \propto c_j \hat{\pi}_{1, \langle jk \rangle_a} \hat{\pi}_{2, \langle jk \rangle_a}$ using bond fermions representation defined in Eq. (S14), where $\hat{\pi}_{1, \langle jk \rangle_a}$ and $\hat{\pi}_{2, \langle jk \rangle_a}$ flip a pair of adjacent fluxes, denoted by subscripts 1, 2, that share the same link $\langle jk \rangle_a$. It is then readily to see that Pauli spin operators change the matter and gauge sectors of an eigen state $|n\rangle$ according to:

$$\sigma_j^x \left| M_0; \langle \text{hexagons} \rangle \right\rangle \propto c_j \left| M_0; \langle \text{flipped hexagons} \rangle \right\rangle \quad (\text{S15})$$

$$\sigma_j^y \left| M_0; \langle \text{hexagons} \rangle \right\rangle \propto c_j \left| M_0; \langle \text{flipped hexagons} \rangle \right\rangle \quad (\text{S16})$$

$$\sigma_j^z \left| M_0; \langle \text{hexagons} \rangle \right\rangle \propto c_j \left| M_0; \langle \text{hexagons} \rangle \right\rangle \quad (\text{S17})$$

where we have separated the majorana fermion c_j from the Z_2 gauge field. Here M_0 denotes the free Majorana sector conditioned on the zero-flux gauge sector. In the gauge sector, flipped fluxes $\Delta\pi = -1$ are denoted by hexagons in light gray, in contrast to the rest of hexagons in white that denote the original flux configuration of $|n\rangle$, and Bravais lattice label j denotes the primitive cell on the central horizontal link. By the orthogonality between flux configurations, it become readily to see that the two-point correlation in the ground state sector of the isotropic Kitaev model is determined by $\langle \sigma_j^\alpha \sigma_{j+\beta}^\alpha \rangle \delta_{\alpha, \beta} \simeq -0.52$ [31, 32]. This remains true for all flux bias μ defined in the main text, since the magnitude of the two-spin correlation only involves the Majorana sector which remains untouched by μW_p .

S3. DIMER-DIMER CORRELATION

Here we use the Majorana formalism to calculate the correlation between two z-dimers in the pure Kitaev QSL

or the CSL phase of the Kitaev honeycomb model. In the flux-free sector we write the pure Majorana Hamiltonian:

$$H_0 = \frac{1}{2} \sum_{\mathbf{q}} (a_{-\mathbf{q}} \ b_{-\mathbf{q}}) \begin{pmatrix} Q(\mathbf{q}) & if(\mathbf{q}) \\ -if^*(\mathbf{q}) & -Q(\mathbf{q}) \end{pmatrix} \begin{pmatrix} a_{\mathbf{q}} \\ b_{\mathbf{q}} \end{pmatrix} \quad (\text{S18})$$

where a and b are momentum representation of Majorana operators $c_{i,A(B)}$ on sublattice $A(B)$:

$$a_{\mathbf{q}} = \sum_j e^{-i\mathbf{k}\cdot\mathbf{r}_j} c_{j,A}, \quad b_{\mathbf{q}} = \sum_j e^{-i\mathbf{k}\cdot\mathbf{r}_j} c_{j,B} \quad (\text{S19})$$

The time-reversal (TR) symmetry is broken due to

$$Q(\mathbf{k}) = 4g[\sin(\mathbf{k}\cdot\mathbf{n}_2) - \sin(\mathbf{k}\cdot\mathbf{n}_1) - \sin(\mathbf{k}\cdot\mathbf{n}_3)] \quad (\text{S20})$$

where $\mathbf{n}_3 = \mathbf{n}_2 - \mathbf{n}_1$. The off-diagonal elements for each mode is related to $f(\mathbf{q}) = K_x e^{i\mathbf{q}\cdot\mathbf{n}_1} + K_y e^{i\mathbf{q}\cdot\mathbf{n}_2} + K_z \equiv K_x e^{iq_x} + K_y e^{iq_y} + K_z$ where we've defined $q_x \equiv \mathbf{q}\cdot\mathbf{n}_1$ and $q_y \equiv \mathbf{q}\cdot\mathbf{n}_2$. For the convenience of derivation, we split its real and imaginary parts into [32]:

$$f(\mathbf{q}) = E_{\mathbf{q}} + i\Delta_{\mathbf{q}} \quad (\text{S21})$$

$$E_{\mathbf{q}} = 2(K_x \cos q_x + K_y \cos q_y + K_z), \quad (\text{S22})$$

$$\Delta_{\mathbf{q}} = 2(K_x \sin q_x + K_y \sin q_y) \quad (\text{S23})$$

We investigate the dimer dynamics in the TR-breaking case. In the diagonal basis of the complex fermions C we have

$$H_0 = \sum_{\mathbf{k}} E_{\mathbf{k}} (C_{\mathbf{k},1}^\dagger C_{\mathbf{k},1} - C_{\mathbf{k},2}^\dagger C_{\mathbf{k},2}) \quad (\text{S24})$$

The energy is given by

$$E_{\mathbf{q}} = \pm \sqrt{Q_{\mathbf{q}}^2 + |f_{\mathbf{q}}|^2} = \pm \sqrt{Q_{\mathbf{q}}^2 + \Delta_{\mathbf{q}}^2 + E_{\mathbf{q}}^2} \quad (\text{S25})$$

with the ground state given by filling the negative band of C_2 fermion $|\text{gs}\rangle = \prod_{\mathbf{k}} C_{\mathbf{k},2}^\dagger |0\rangle$, where the complex fermion modes created by C_2^\dagger are related to majoranas by

$$a_{\mathbf{q}} = \frac{\Delta_{\mathbf{q}} - iE_{\mathbf{q}}}{\sqrt{2}(E_{\mathbf{q}} - Q_{\mathbf{q}})} (C_{\mathbf{q},2} - C_{-\mathbf{q},2}^\dagger), \quad (\text{S26})$$

$$b_{\mathbf{q}} = \frac{1}{\sqrt{2}} (C_{\mathbf{q},2} + C_{-\mathbf{q},2}^\dagger)$$

We used $a_{-\mathbf{q}}$ and $b_{\mathbf{q}}$ are Majorana fermions modes of A and B sublattices. Working in the zero-flux sector, it

would be convenient to identify the effect of $\mathcal{D}_j^z \equiv \sigma_j^z \sigma_{j+z}^z$ on the pure Majorana sector. For clarity, we first apply Fourier transformation on $\mathcal{D}_j^z = \sigma_{i,A}^z \sigma_{i,B}^z$ without the parton decomposition, where we label σ_j^z and σ_{j+z}^z using their respective sublattice indices in the Bravais lattice,

$$\begin{aligned} \mathcal{D}_{\mathbf{k}}^z &= \text{F.T.}\{\sigma_{i,A}^z \sigma_{i,B}^z\} = \sum_i e^{-i\mathbf{k}\cdot\mathbf{r}_i} \sigma_{i,A}^z \sigma_{i,B}^z \\ &= \sum_{\mathbf{q}} \sigma_{\mathbf{k}-\mathbf{q},A}^z \sigma_{\mathbf{q},B}^z \end{aligned} \quad (\text{S27})$$

Furthermore, since $\mathcal{D}_{\mathbf{k}}^z$ does not affect the gauge sector, that is, as discussed in the main text

$$\mathcal{D}_j^z \left| M_0; \langle \text{hexagon lattice} \rangle \right\rangle = i c_{j,A} c_{j,B} \left| M_0; \langle \text{hexagon lattice} \rangle \right\rangle, \quad (\text{S28})$$

where the i attached to the Majorana bilinear comes from the definition in Eq. (S14). This leaves the gauge sector untouched, and its dynamical structure factor is completely determined by the Majorana sector. Therefore, we can define the $\tilde{\mathcal{D}}_{\mathbf{k}}^z$ operator that only describes the effect of $\mathcal{D}_{\mathbf{k}}^z$ on M_0 in a fixed uniform Z_2 gauge where all links are chosen to be +1. Hence, using the notation in Eq. (S19), we have

$$\tilde{\mathcal{D}}_{\mathbf{k}}^z = \text{F.T.}\{i c_j c_{j+z}\} = i \sum_{\mathbf{q}} a_{\mathbf{k}-\mathbf{q}} b_{\mathbf{q}} \quad (\text{S29})$$

which is in keeping with Eq. (S27). In order to calculate the dynamical spectrum, we write it in terms of $C_{\mathbf{q},2}$, which according to Eq. (S26) takes the form:

$$\tilde{\mathcal{D}}_{\mathbf{k}}^z = i \sum_{\mathbf{q}} F(\mathbf{k}-\mathbf{q}) (C_{\mathbf{k}-\mathbf{q},2} C_{\mathbf{q},2} + C_{-\mathbf{q},2}^\dagger C_{-\mathbf{k}+\mathbf{q},2}^\dagger) \quad (\text{S30})$$

where we have defined

$$F(\mathbf{k}-\mathbf{q}) \equiv \frac{1}{2} \frac{\Delta_{\mathbf{k}-\mathbf{q}} - iE_{\mathbf{k}-\mathbf{q}}}{E_{\mathbf{k}-\mathbf{q}} - Q_{\mathbf{k}-\mathbf{q}}} \quad (\text{S31})$$

and we have ignored terms like $C_{\mathbf{k}-\mathbf{q}} C_{-\mathbf{q}}^\dagger$ that do not contribute to dynamics (e.g. $C_{-\mathbf{q}}^\dagger |\text{gs}\rangle = 0$). Hence, using Eq. (S26) and Eq. (S29), the dynamical correlation becomes

$$\begin{aligned} S_2^z(k, \omega) &= \sum_{m \neq 0} \langle 0 | \mathcal{D}_{\mathbf{k}}^z | m \rangle \langle m | \mathcal{D}_{-\mathbf{k}}^z | 0 \rangle \delta(\omega - E_m + E_{\text{gs}}) = - \sum_{m \neq 0} \langle \text{gs} | \tilde{\mathcal{D}}_{\mathbf{k}}^z | m \rangle \langle m | \tilde{\mathcal{D}}_{-\mathbf{k}}^z | \text{gs} \rangle \delta(\omega - E_m + E_{\text{gs}}) \\ &= - \sum_{m \neq 0} \sum_{\mathbf{q}, \mathbf{p}} F(\mathbf{k}-\mathbf{q}) F(-\mathbf{k}-\mathbf{p}) \langle \text{gs} | C_{-\mathbf{q},2}^\dagger C_{-\mathbf{k}+\mathbf{q},2}^\dagger | m \rangle \langle m | C_{-\mathbf{k}-\mathbf{p},2} C_{\mathbf{p},2} | \text{gs} \rangle \delta(\omega - E_m + E_{\text{gs}}) \\ &= - \sum_{\mathbf{q}} F(\mathbf{k}-\mathbf{q}) F(-\mathbf{k}+\mathbf{q}) \delta[\omega - (E_{-\mathbf{k}+\mathbf{q}} + E_{-\mathbf{q}})] \equiv \sum_{\mathbf{q}} G(\mathbf{k}-\mathbf{q}) \delta[\omega - (E_{-\mathbf{k}+\mathbf{q}} + E_{-\mathbf{q}})] \end{aligned} \quad (\text{S32})$$

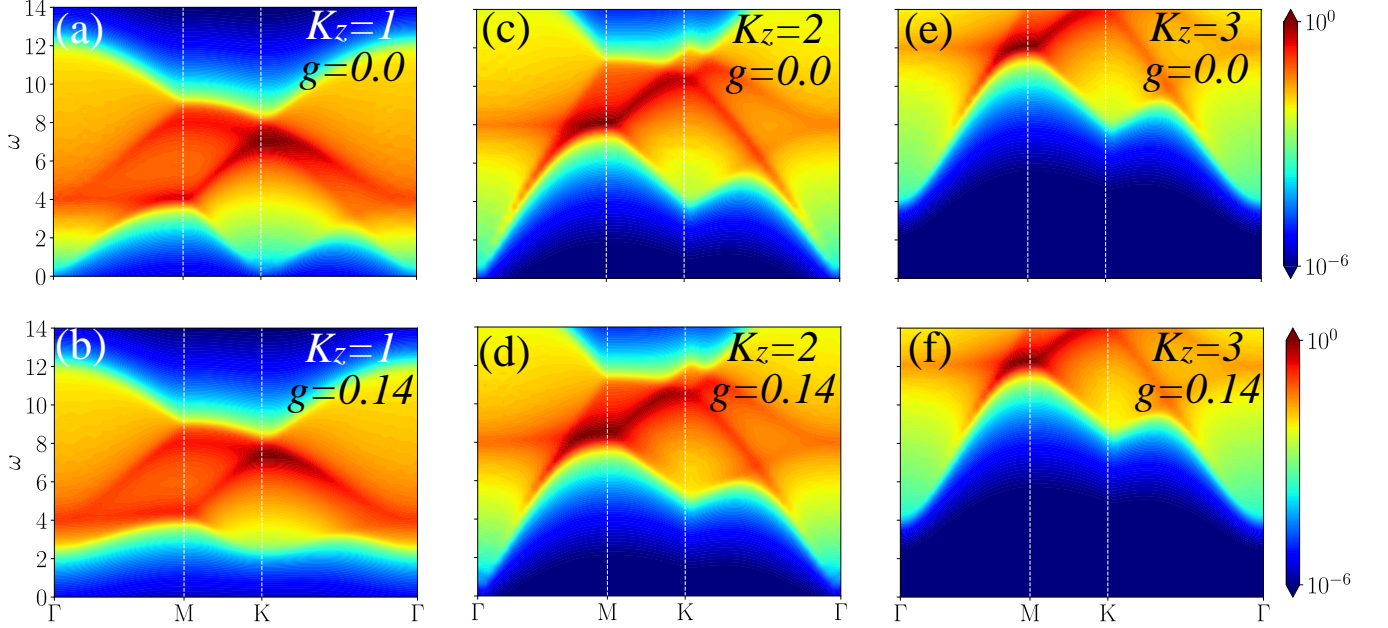

FIG. S4. $S_2^z(\mathbf{k}, \omega)$ of two spin flip for AFM Kitaev model under varying magnetic field h and different anisotropies. (a,b) Kitaev spin liquid at the isotropic limit, with and without the three-spin time-reversal-breaking perturbation g . (c,d) The same calculation done at the non-Abelian to Abelian transition $K_z/K = 2$, where $K \equiv K_x = K_y = 1$; and (e,f) inside the Abelian phase.

where $|m\rangle \equiv |m(\mathbf{k}, \mathbf{q})\rangle$ are excited states associated with quasi-particles with momentum \mathbf{k} and \mathbf{q} ; and we have defined G using Eq. (S31)

$$G(\mathbf{k} - \mathbf{q}) \equiv -F(\mathbf{k} - \mathbf{q})F(-\mathbf{k} + \mathbf{q}) = \frac{1}{4} \frac{E_{\mathbf{k}-\mathbf{q}}^2}{E_{\mathbf{k}-\mathbf{q}}^2 - Q_{\mathbf{k}-\mathbf{q}}^2} \quad (\text{S33})$$

which is even under inversion as expected. Setting it in the infinite-lattice limit $N \rightarrow \infty$ and choosing the unit vectors of the lattice to be $\mathbf{n}_1 = (\frac{1}{2}, \frac{\sqrt{3}}{2})$, $\mathbf{n}_2 = (-\frac{1}{2}, \frac{\sqrt{3}}{2})$, the continuous limit of Eq. (S32) thus takes on the form

$$S_2^z(\mathbf{k}, \omega) = \frac{\sqrt{3}}{16\pi^2} \int_{\text{BZ}} G(\mathbf{k} - \mathbf{q}) \delta(\omega - \varepsilon_{\mathbf{k}, \mathbf{q}}) d^2\mathbf{q} \quad (\text{S34})$$

where $\varepsilon_{\mathbf{k}, \mathbf{q}} \equiv E_{-\mathbf{k}+\mathbf{q}} + E_{-\mathbf{q}}$, as is used in the main text. At zero or infinitesimally small field, the distribution of $S_2^z(\mathbf{k}, \omega)$ is a direct consequence of two-particle density of states. Noting that, with zero or very small TR-breaking perturbation, $G(\mathbf{k})$ in Eq. (S33) would approximately become a constant $\simeq \frac{1}{4}$, and the distribution of S_2^z in \mathbf{k}, ω become determined only by the density of states of two-particle excitations. For example, $S_2^z(\mathbf{k} = \Gamma, \omega \simeq 4)$ is a bright peak for $\mathbf{k} = 0$ cut, as shown in Fig. S4. This is because, under zero or small perturbation, the largest two-particle density of states is at $\omega \simeq 2E_{\mathbf{k}=0}$, with $E_{\mathbf{k}=0} \simeq 2$. Hence for pure Kitaev QSL or CSL with very small perturbation, we expect a bright spot at $\mathbf{k} = \Gamma$, $\omega \simeq 4$, as consistent in the iPEPS result in Fig. 2 of the main text. Similar argument can be used for other

features. Importantly, as shown in Fig. S4(b,c) the bright spot at $(\omega \simeq 7, \mathbf{k} \simeq \text{K})$ persists despite the perturbation, making it a sharp and robust feature that reflects the fractionalized quantum sector of Majorana fermions.

Here in addition to the $S_2^z(\mathbf{k}, \omega)$ presented in the main text at the isotropic limit of Kitaev couplings, we now list $S_2^z(\mathbf{k}, \omega)$ for both the isotropic and anisotropic Kitaev coupling strengths, with and without the TR-breaking perturbation. Results are shown in Fig. S4. These includes both the non-Abelian (weak pairing) and the Abelian (strong pairing) phases as well as the topological phase transition at $K_z/K = 2$, $K \equiv K_x = K_y = 1$. We note that the $S_2^z(\mathbf{k}, \omega)$ of the pure Kitaev QSL at the isotropic limit is the most susceptible to the TR-breaking perturbation. As shown in Fig. S4(a,b), the signal immediately above K point is abruptly pushed to higher energy upon introducing the next-nearest-neighbor hopping perturbation; while for the Abelian phase ($K_z/K > 2$) and the topological phase transition point ($K_z/K = 2$), the next-nearest-neighbor hopping does not induce noticeable difference. This can be attributed to the fact that Majorana fermions are high gapped in the anisotropic Abelian phase of Kitaev honeycomb model; and the perturbation at the transition point does not gap out the Majorana fermion but simply alters the semi-Dirac point at M into a Dirac point at M [33], leaving no significant impact in energy levels of Majorana excitations.

FIG. S5. Dynamical structure factor $S_1(\mathbf{k}, \omega) = \sum_{\alpha} S_1^{\alpha}(\mathbf{k}, \omega)$ of two spin flip for AFM Kitaev model under varying magnetic field h . The spectra are presented on a logarithmic color scale along the momentum path $\Gamma\text{MK}\Gamma$ through the BZ.

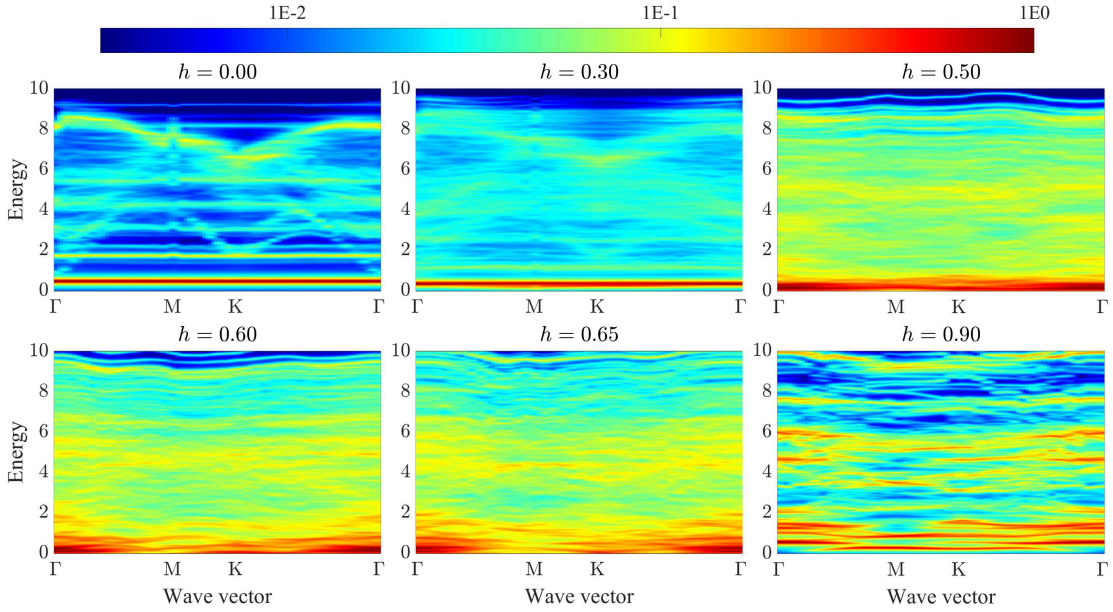

FIG. S6. Dynamical structure factor $S_2(\mathbf{k}, \omega) = \sum_{\alpha} S_2^{\alpha}(\mathbf{k}, \omega)$ of two spin flip for AFM Kitaev model under varying magnetic field h . The spectra are presented on a logarithmic color scale along the momentum path $\Gamma\text{MK}\Gamma$ through the BZ.

S4. ADDITIONAL RESULTS

Here we provide the spectra for additional parameters, as shown in Fig. S5 for the one-spin flip spectra $S_1(\mathbf{k}, \omega)$ and Fig. S6 for the two-spin flip spectra $S_2(\mathbf{k}, \omega)$. The spectra at the Γ , M, and K points are shown in Fig. S7 and Fig. S8. To demonstrate the intermediate phase is gapless, we show in Fig. S9 the approximate density of states (DOS) and integrated spectra along the $\Gamma\text{MK}\Gamma$

path, defined as follows:

$$\rho(\omega) = \frac{\int_{\Gamma\text{MK}\Gamma} d\mathbf{k} \sum_m \delta(\omega - E_{\mathbf{k}}^m + E_{\text{gs}})}{\int_0^{\infty} d\omega \int_{\Gamma\text{MK}\Gamma} d\mathbf{k} \sum_m \delta(\omega - E_{\mathbf{k}}^m + E_{\text{gs}})} \quad (\text{S35})$$

$$S_1(\omega) = \frac{\int_{\Gamma\text{MK}\Gamma} d\mathbf{k} S_1(\mathbf{k}, \omega)}{\int_0^{\infty} d\omega \int_{\Gamma\text{MK}\Gamma} d\mathbf{k} S_1(\mathbf{k}, \omega)} \quad (\text{S36})$$

$$S_2(\omega) = \frac{\int_{\Gamma\text{MK}\Gamma} d\mathbf{k} S_2(\mathbf{k}, \omega)}{\int_0^{\infty} d\omega \int_{\Gamma\text{MK}\Gamma} d\mathbf{k} S_2(\mathbf{k}, \omega)}. \quad (\text{S37})$$

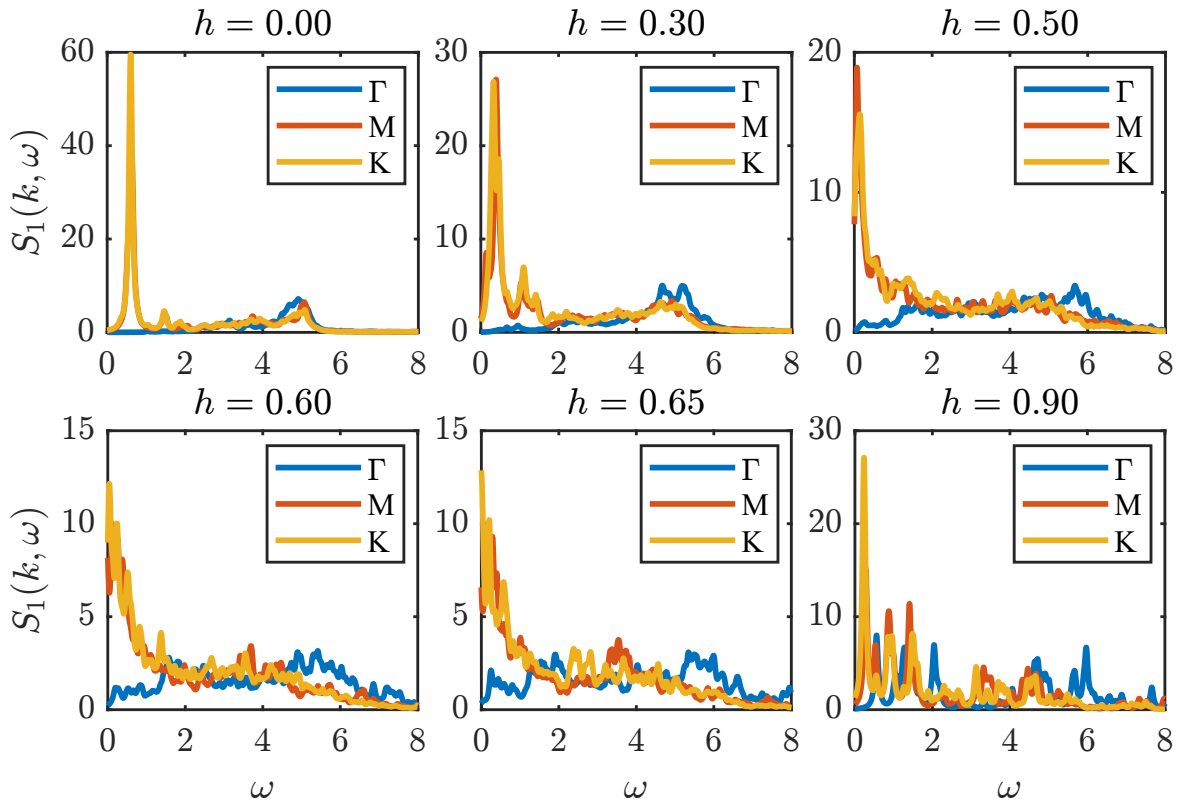

FIG. S7. $S_1(\mathbf{k}, \omega)$ at Γ, M, K points. The broadening factor is $\eta = 0.05$.

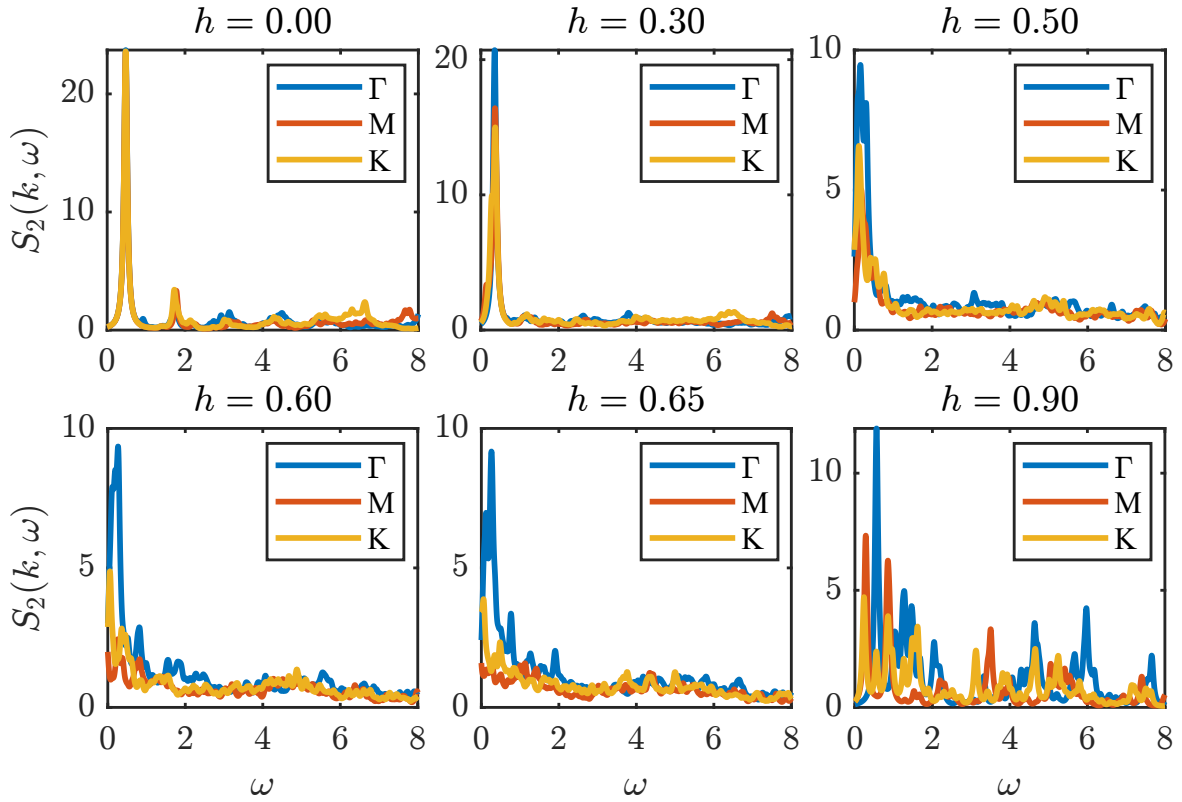

FIG. S8. $S_2(\mathbf{k}, \omega)$ at Γ, M, K points. The broadening factor is $\eta = 0.05$.

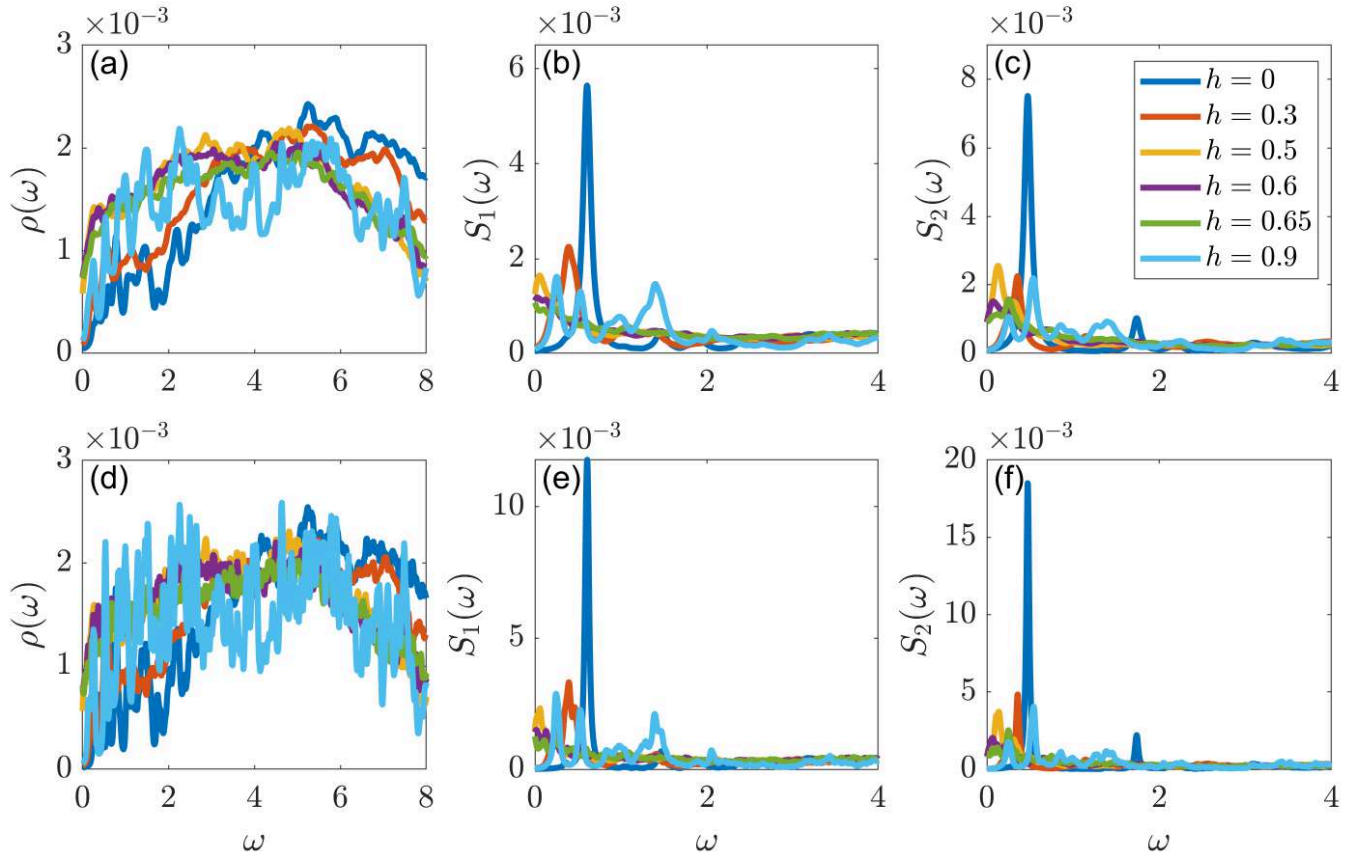

FIG. S9. iPEPS results for (a)(d) the density of states $\rho(\omega)$, (b)(e) the integrated single spin flip spectra $S_1(\omega)$, and (c)(f) the integrated single spin flip spectra $S_2(\omega)$. The broadening factor is $\eta = 0.05$ for the upper three figures and $\eta = 0.02$ for the lower three figures. Notably, at $\eta = 0.02$ (as well as $\eta = 0.01$ shown in Fig. 4(c) in the main text), we still find no observable gap nor the trend of opening a gap in $S_1(\omega)$, $S_2(\omega)$ and $\rho(\omega)$ at the lowest energies which are comparable to or lower than previous putative gaps, ranging from 0.01 to 0.05, obtained by parton mean field theories [34, 35]. This suggests that although quadratic parton mean-field theories are capable of qualitatively capturing phase transitions, the apparent gap in the non-perturbative regime can be spurious due to the missing many-body entanglement between bond fermions which nevertheless remains intact in iPEPS calculations.
