# Performance, Knowledge Acquisition and Satisfaction in Self-selected Groups: Evidence from a Classroom Field Experiment

Julius Düker<sup>\*</sup> Alexander Rieber<sup>†</sup>

#### Abstract

We investigate how to efficiently set up work groups to boost group productivity, individual satisfaction, and learning. Therefore, we conduct a natural field experiment in a compulsory undergraduate course and study differences between self-selected and randomly assigned groups. We find that self-selected groups perform significantly worse on group assignments. Yet, students in self-selected groups learn more and are more satisfied than those in randomly assigned groups. The effect of allowing students to pick group members dominates the effect of different group compositions in selfselected groups: When controlling for the skill, gender, and home region composition of groups, the differences between self-selected and randomly formed groups persist almost unaltered. The distribution of GitHub commits per group reveals that the better average performance of randomly assigned groups is mainly driven by highly skilled individuals distributed over more groups due to the assignment mechanism. Moreover, these highly skilled individuals contribute more to the group in randomly formed groups. We argue that this mechanism explains why self-selected groups perform worse on the projects but acquire more knowledge than randomly formed groups. These findings are relevant for setting up workgroups in academic, business, and governmental organizations when tasks are not constrained to the skill set of specific individuals.

# Introduction

Many economic and social activities require teamwork. How well a team performs depends not only on the individual characteristics and skills of its members but also on how they interact and cooperate with each other.<sup>1</sup> One factor that may influence team cooperation is how the team is formed. If team members can choose their partners, they may behave more altruistically or reciprocally than if they are randomly assigned to a team.<sup>2</sup> We find in a classroom field experiment, that self-selected groups perform significantly worse on group assignments. Still, students in these groups learn more and are more satisfied than those in randomly assigned groups.

This paper examines how the process of group formation affects the outcomes of teams and individuals in a cognitively demanding task. We conduct a classroom field experiment in a data analysis course involving group work and individual assessment. We assign students to either self-select their teammates or be randomly matched with other students to form groups of three. We follow the same students for two consecutive semesters, switching the group formation method between semesters. We complement our experimental data with administrative data on student characteristics, which allows us to isolate the effects of group composition and group formation on group performance, individual learning, and satisfaction.

<sup>&</sup>lt;sup>2</sup>See, e.g., Coricelli, Fehr, and Fellner (2004)

We measure group performance with the grades from the three data science projects each group completes during a semester. These projects account for 70% of the final grade and require groups to analyze real economic or corporate data, visualize data, and interpret results. We obtain our measure of individual learning from the final exam at the end of the semester, which accounts for 30% of the final grade. We compute satisfaction levels from surveys we require students to complete after each project. Further, we include administrative data on students' high school GPA as a proxy for individual ability and the place where a student went to high school as a proxy for their geographic origin. Additionally, we track individual contributions to the group projects using time-stamped commits in (private) GitHub repositories.

We find that self-selected groups perform significantly worse on group projects than randomly formed groups, but students in self-selected groups learn more and are more satisfied than those in randomly formed groups. We compare the effects of group composition and group formation on group performance, individual learning, and satisfaction. Group formation has a stronger impact than group composition on all three outcome variables. Allowing students to choose their group members increases their learning and satisfaction but reduces their performance, holding group composition constant. However, self-selected groups also have a different composition than randomly formed groups, which tends to lower their performance, learning, and satisfaction. Self-selected groups are more homogeneous in terms of GPA, gender, and geographic origin. These findings are consistent with the literature on homophily in group formation, e.g., McPherson, Smith-Lovin, and Cook (2001), Carrell, Sacerdote, and West (2013), or Charroin, Fortin, and Villeval (2022).

Combining both effects, we find that self-selected groups perform about 5.1 percentage points worse on group projects than randomly formed groups. Moreover, the performance of self-selected groups is more dispersed, reflecting the distribution of high school GPAs among groups. However, individuals in self-selected groups learn more, scoring 3.3 percentage points higher on the individual exam. They also perceive their group as more effective and report higher overall satisfaction with their group, by 12.4 percentage points, than those in randomly formed groups. To understand why self-selected groups perform worse on group projects but better on individual exams, we examine the distribution of work and skills within groups using GitHub data.

Using GitHub allows us to analyze the mechanisms behind these average effects based on individual contributions to each project.<sup>3</sup> Our analysis reveals that high-skilled students (high GPA) contribute most of the code and text in randomly formed groups. Self-selected groups, in contrast, distribute the workload more evenly across skill levels.<sup>4</sup> High-skilled and low-skilled students tend to cluster in self-selected groups, while they are mixed in randomly formed groups. As a result, randomly formed groups perform better in group projects because high-skilled students do more work. However, this work distribution also encourages low-skilled students to free-ride in randomly formed groups, which impedes their individual learning. Furthermore, the higher workload of high-contributing students in randomly formed groups leads to lower satisfaction rates among these students, which we cannot observe for self-selected groups.<sup>5</sup>

This paper adds to the literature on group formation and performance by conducting a field experiment in a data analysis course that involved high-stakes and cognitively challenging tasks. The most related studies to ours are from Fischer, Rilke, and Yurtoglu (2023), Fenoll and Zaccagni (2022), and Kiessling, Radbruch, and Schaube (2022), who also conduct classroom field experiments to compare the performance of self-selected and

<sup>&</sup>lt;sup>3</sup>Isomöttönen and Cochez (2014) and Haaranen and Lehtinen (2015) present case studies on how to use GitHub and GitLab in classroom settings and examine whether a project-based course such as ours can teach students to use the platform correctly. See also Feliciano, Storey, and Zagalsky (2016) and Lu et al. (2017) for a review on how to use GitHub in the classroom.

 $<sup>^4</sup>$  Note, self-selected and randomly formed groups do not differ significantly in how equally they distribute work.

 $<sup>{}^{5}</sup>$ Knez and Simester (2001), Bandiera, Barankay, and Rasul (2013) and De Paola, Gioia, and Scoppa (2019) argue that workers internalize the effects of their effort on coworkers when they feel socially connected to coworkers, which could result in less free riding and better performance.

randomly formed groups.<sup>6</sup> Fischer, Rilke, and Yurtoglu (2023) examine how the group formation process affects the skill composition and performance of groups. They find that self-selected groups are more assortatively matched and perform similarly or worse than randomly assigned groups in different tasks. Their task was low-stakes (15% of student grade) for a team of two, while ours was high-stakes (70% of final grade) for a group of three. While Fischer, Rilke, and Yurtoglu (2023) find evidence that self-selected groups perform worse in a classroom setting, Fenoll and Zaccagni (2022) and Kiessling, Radbruch, and Schaube (2022) find evidence that the opposite is the case.<sup>7</sup> In Fenoll and Zaccagni (2022), high school students are randomly or self-selected into groups of six students during a mathematics summer camp. They find that self-selected groups perform significantly better than randomly formed groups in a competition. Kiessling, Radbruch, and Schaube (2022) show that students perform significantly better in a running task when they can self-select their running partner. They show that the group formation process itself affects running performance, i.e., individuals increase effort if they can choose their teammates. Kiessling, Radbruch, and Schaube (2022) provide evidence for a positive formation effect in self-selected groups and evidence that working with a friend or a similar performer improves productivity.

We extend these studies in four ways: First, we examine a collaborative, high-stakes task for a group of three students. This allows us to study group dynamics that may differ from those in smaller groups. Second, we measure not only group performance but also individual learning and satisfaction, which we consider essential for a successful and lasting collaboration in a group. Third, we combine our experimental data with administrative data on student characteristics, which enables us to separate the effects of group composition and group formation on the outcomes. Fourth, we analyze individual contributions to the group, which helps us to understand how groups allocate work among their members.

The rest of the paper is organized as follows: In section two, we describe our experimental setup, develop our hypothesis in section three, and detail our empirical strategy in section four. In section five, we describe our data and provide some descriptive statistics. In section six, we present our main results on project performance, individual knowledge gain, and satisfaction in self-selected and randomly formed groups. In section seven, we explore the mechanisms behind our results using our GitHub data on individual commits. In section eight, we check the robustness of our main results. In the last section, we conclude.

# **Classroom Field Experiment**

#### Background

We conduct a field experiment in a classroom setting. The participants are undergraduate students in management and economics at a German university. They enroll in a compulsory data science course that covers data analysis, reproducibility, R programming, statistical inference and causality. The course lasts two semesters and students take it in their second year. They get a separate grade for each semester and they need to pass the first part to continue to the second part. The course structure is as follows:

• *Lectures:* In the first four weeks of each semester, the instructor introduces theoretical concepts on data science methods. The winter semester focuses on descriptive analysis

 $<sup>^6\</sup>mathrm{See}$  also Boss et al. (2021) and Chen and Gong (2018) for more classroom field experiments with self-selected groups

<sup>&</sup>lt;sup>7</sup>Also Chen and Gong (2018) and Boss et al. (2021) find evidence that self-selected groups outperform randomly formed groups, but do not control for skill composition.

and the summer semester on causal inference. The course materials are the same every year.  $^8$ 

- *Projects:* In the next 11 weeks of each semester, the students work in groups of three on three projects.<sup>9</sup>
- *Grades:* In each semester, the students can earn up to 100 points for their final grade. They get 10 points from a test project, 30 points from each of the two main projects, and 30 points from a final exam with 30 multiple-choice questions. The test projects are identical for both cohorts and most of their content is covered in class. The main projects change every semester.

#### **Group Projects**

The group projects involve various types of economic analysis. The first step is to acquire data from different sources, such as APIs, databases, or web scraping. The following steps are to wrangle, describe, and visualize the data. The projects in the second semester include regression analysis and causal inference. Along with each project, the groups must submit a short screencast presenting their main results, accounting for 30% of the project points. The projects are managed and submitted through Github, which allows us to track the frequency, content, and timing of each student's contribution.<sup>10</sup> After the deadline, we download the projects, pseudonymize them, and randomly assign them to one of the instructors for grading.<sup>11</sup> The instructors use a detailed rubric for each question to ensure objectivity and consistency. We inform the groups about their project points in the last week of the semester and at least five days before the final exam.

We also ask student assistants to grade the final submissions of both projects each semester on a 7-point Likert scale and provide feedback on improving the projects. We give the student assistants instructions on how to rate the projects and blind them to the group names and their tutorial assignments.<sup>12</sup> The groups receive feedback on improving their projects from the student assistants a week after submitting their projects.

#### Intervention

We want to compare the outcomes of self-selected and randomly formed groups in a compulsory data science course. We conduct a natural field experiment with two cohorts of students who take the course in two consecutive years, cohort 2020 and cohort 2021. At the start of the course, we ask students to consent to share their data on various measures, such as GitHub commits, grades, high school grade point average (GPA), quiz and online lab answers, project descriptions, and feedback reports. We do not tell students about the experiment, but only that we use their data to improve the course. The course

 $<sup>^{8}{\</sup>rm The}$  (German) website of the course with all the material covered can be found here: https://projek tkurs-data-science-ulm2021.netlify.app/

<sup>&</sup>lt;sup>9</sup>Besides the group projects, each student has to complete and pass six individual assignments in each semester: three interactive problem sets, an online test exam, and two review reports on other groups' projects. They need to score at least 80% on each problem set and 30% on the test exam to join a group. They need to write review reports to take the final exam. The students rank the review reports they receive from other groups and the instructors evaluate their quality (clearly structured, at least one point suggested for improvement, constructive). During the experiment, two students failed the test exam and we excluded them from our analysis. All other students passed these requirements and were admitted to the final exam.

<sup>&</sup>lt;sup>10</sup>A potential challenge for this course is free-riding in groups. Students may need help dealing with non-cooperative group members. We present three escalation levels for resolving group conflicts at the beginning of each semester. The first level involves a meeting with the auxiliary lecturer, where group members voice their concerns, receive advice, and make verbal commitments. The second level involves a meeting with both instructors, where we assign specific tasks to the uncooperative group member and monitor their progress. The third level involves splitting the group and requiring individual work for the remaining projects. We only reveal this option in the final meeting, not earlier. In our two-year experiment, only one group reached the third level, two groups reached the second level, and three groups reached the first level.

 $<sup>^{11}\</sup>mathrm{Note}$  that pseudonyms vary for each group throughout a semester.

 $<sup>^{12}</sup>$ Appendix A presents the instructions to student assistants before rating the projects. All student assistants have completed both parts of the course in previous years with a top quartile grade.

grade mainly depends on group work, which differs from previous studies using low-stakes tasks.<sup>13</sup> Wise and DeMars (2005) and Ofek-Shanny (2020) show that students provide significantly less effort with low stakes than high stakes tasks.

Figure 1 shows the timeline and assignments for each cohort and each course part. We explain them below.

Figure 1: Timeline

We compare two ways of forming groups of three students for the group projects: self-select and random. In the self-select specification, students have three weeks to create their groups using an online learning platform. On the platform, they can observe the members of the already formed groups at any time. We randomly assign the remaining students to groups at the end of the third week. In the random specification, we ask students if they want to participate in the group projects and then randomly assign them to groups. We inform students about their group members in week three.<sup>14</sup>

We survey students after each project via GitHub on their satisfaction and perception of group collaboration.<sup>15</sup> We assure students that their answers are confidential and have no consequences on the course. We also include two questions from the university course evaluation form to check the validity and seriousness of our survey.<sup>16</sup>

We use a within-subjects design where all cohort students have the same treatment during one semester. Table 1 shows how we distribute treatments across cohorts and semesters. Students in cohort 2020 self-select groups in the winter term and are randomly assigned in the summer term. Students in cohort 2021 are randomly assigned in the winter term and self-select groups in the summer term. We registered a pre-analysis plan in the American

 $<sup>^{13}</sup>$  E.g., Kiessling, Radbruch, and Schaube (2022), Fenoll and Zaccagni (2022), Fischer, Rilke, and Yurtoglu (2023), and Boss et al. (2021) use tasks accounting up to 15% of the final grade.

<sup>&</sup>lt;sup>14</sup>When the number of participants does not allow for groups of three only, we form one, respectively two groups of two. We exclude these groups of two students from our analysis. Moreover, we exclude groups from the self-selection treatment that were formed by us, because their members failed to find a group.

<sup>&</sup>lt;sup>15</sup>See Appendix B for survey questions.

 $<sup>^{16}</sup>$ The answers are consistent, e.g., for the question "In this course, I learn things that fill me with enthusiasm," we receive an average of 3.71 in our survey and an average of 3.79 in the university evaluation.

Cohort	Term	Group Formation	Participants	In Group of Three	Declared Consent	Comply with Treatment
2020	winter	Self- Selected	78	78	72	69
2020	summer	Random	63	63	57	57
2021	winter	Random	77	69	67	67
2021	summer	Self- Selected	73	66	57	52

 Table 1: Participants in Each Semester

Economic Association RCT registry and obtained IRB approval before the intervention.<sup>17</sup>

The Corona pandemic forced the university to switch to online teaching from April 2020 to August 2021, covering the period of the field experiment for cohort 2020. The pandemic affected the field experiment in two ways: First, we delivered lectures and tutorials online for both cohorts, using video tutorials and live streams. Second, students had less inperson contact with each other, which could influence their group formation. We account for this by implementing the self-select treatments when students still knew each other from previous semesters or had the opportunity to meet in person the semester before. Additionally, we ask students in the surveys about their previous relationships with their team members to analyze whether the pandemic affected the formation of self-selected groups.

# Hypotheses Development

Several factors play a role in determining individual learning and satisfaction within a group, as well as group performance. These factors can lead to significant performance differences between self-selected groups and those formed randomly. In this paper, we aim to untangle the effects that arise from the group formation process itself (referred to as the "formation effect") from those that occur due to differences in the group's composition (referred to as the "composition effect"). We pre-registered all our hypothesis in a pre-analysi plan before the start of the experiment in November 2020.<sup>18</sup>

We conclude from the literature that group formation affects performance positively in self-selected groups. Previous studies have shown that self-selected groups exert more effort than randomly formed groups, which could improve their performance (Kiessling, Radbruch, and Schaube (2022), Coricelli, Fehr, and Fellner (2004)).

But, following the literature, group composition affects performance in more nuanced ways. First, members in self-selected groups are more similar to each other than in random groups in many dimensions (e.g., McPherson, Smith-Lovin, and Cook (2001), Charroin, Fortin, and Villeval (2022), Fischer, Rilke, and Yurtoglu (2023)). This similarity can increase group identity and coordination, as well as the internalization of effort externalities (Bandiera, Barankay, and Rasul (2005), De Paola, Gioia, and Scoppa (2019), Ai et al. (2023)). Second, self-selected groups are more homogeneous regarding skill as individuals choose teammates with similar backgrounds and preferences (e.g., Charroin, Fortin, and Villeval (2022) and Ruef, Aldrich, and Carter (2003)). Fischer, Rilke, and Yurtoglu (2023) also finds such a selection of group members with comparable skill sets in an undergraduate

 $<sup>^{17}{\</sup>rm See}$  https://doi.org/10.1257/rct.6726-1.0

 $<sup>^{18}</sup>$ See AEA RCT Registry: https://doi.org/10.1257/rct.6726-1.0. In the pre-analysis plan, we use the terms endogenous and exogenous instead of self-selected and random. From now on, we refer to endogenously formed groups as self-selected groups and exogenously formed groups as randomly formed groups to stress the group formation process. Compared to the pre-analysis plan we switch hypotheses 3 and 4.

classroom setting. However, this homogeneity can reduce skill spillovers within a group and, therefore, lower performance (e.g., Page (2007), Mas and Moretti (2009), or Hamilton, Nickerson, and Owan (2003)). The type of task also matters for group performance, especially for more vs. less cooperative tasks (e.g., Fischer, Rilke, and Yurtoglu (2023)). Following Fischer, Rilke, and Yurtoglu (2023), we assume skill spillovers outweigh effort externality internalization and higher group identity in homogeneous groups. Therefore, we expect that group composition affects performance negatively in self-selected groups.

We do not know which effect is stronger: group formation or group composition. Group formation implies that self-selected groups perform better, while group composition implies that randomly formed groups perform better. Therefore, our first hypothesis is undirected:

H1: On average self-selected and randomly formed groups do not differ in terms of project points.

We also want to measure the formation and composition effects separately. We use the following hypothesis to test if there is a formation effect in favor of self-selected groups<sup>19</sup>:

H1a: Groups with similar skill composition perform better under self-selection treatment compared to random formation treatment

Group composition also affects individual learning in a group. We conjecture that skill spillovers are the primary driver of group learning (See also Page (2007), Mas and Moretti (2009), or Hamilton, Nickerson, and Owan (2003)). The more skill-diverse a group is, the more skill spillovers occur between group members and the more they learn. This might be offset by other dimensions of similarity (e.g., age, gender, or home region) in self-selected groups, but we find no evidence for that in the literature. Therefore, we expect that group composition affects knowledge acquisition negatively in self-selected groups.

The formation effect might positively affect learning in self-selected groups because group members provide more effort. However, we expect this effect to be smaller than the composition effect from skill spillovers. We, therefore, hypothesize that the overall effect of self-selected group formation on knowledge acquisition is negative and state the following hypothesis:

H2: On average the knowledge gain throughout a semester is larger for randomly formed groups.

We use the following hypothesis to test the formation effect on knowledge acquisition:

H2a: Members of groups with similar skill composition learn more under self-selection treatment compared to random formation treatment

Moreover, we want to analyze individuals' satisfaction with the team. We think high individual satisfaction with the team is essential for long-lasting, efficient collaboration, as an individual's low satisfaction can disperse and harm collaboration. Individual satisfaction may be influenced by group formation and group composition. We argue that individuals value being able to form groups themselves and are more satisfied due to the formation effect in the self-selection treatment.

We typically enjoy spending time with someone we can relate to more than with strangers. Moreover, individuals prefer working with others of their own kind, and we expect higher group identity and satisfaction in homogenous groups than in heterogeneous groups. Since individuals tend to form groups with others with similar skills and preferences (McPherson, Smith-Lovin, and Cook (2001), Carrell, Sacerdote, and West (2013), and Charroin, Fortin, and Villeval (2022)), we expect the composition effect of self-selection on satisfaction, as well as the overall effect on satisfaction to be positive. Thus, we state hypotheses H3 and 3a as follows:

 $<sup>^{19}</sup>$ We also pre-registered sub-hypotheses for each main hypothesis where we wanted to analyze the impact of heterogeneity within groups. But because of insufficient statistical power we can not test hypotheses H1b, H2b, H3b, and H4b from the pre-analysis plan and thus do not include them in this section.

H3: Members of self-selected groups are more satisfied with the group composition than those from randomly formed groups.

H3a: Members of groups with similar skill composition are more satisfied under selfselection treatment compared to random formation treatment

We argue above that self-selected groups are more homogenous, internalize the externalities of their own effort provision, and identify themselves stronger with the group. For this reason, group members might contribute more to the group, particularly those who would otherwise contribute little. Low contributors might increase their effort provision to a larger extent, because it is easier for them coming from a low effort level. Therefore, we assume that self-selected groups distribute work more equally due to the composition effect.

Similar to the hypotheses above, we expect the formation effect to be in favor of selfselected groups. Individuals provide more effort when they can choose who to work with. This might induce a more equal distribution of work, as it is easier for low contributors to increase their effort provision. Hence, when taking composition and formation effect together, we also expect that self-selected groups distribute work more equally. This is in line with (Hamilton, Nickerson, and Owan (2003)). Thus, we state the following two hypothesis:

H4: Members of self-selected groups contribute more equally to the project.

*H4a:* Members of groups with similar skill composition contribute more equally under self-selection treatment compared to random formation treatment

# **Empirical Strategy**

We define the composition effect as the differences in group performance, individual knowledge acquisition, and satisfaction between self-selected and randomly formed groups, which we can explain with home region, skill, or gender composition. In contrast, the formation effect describes the differences between self-selected and randomly formed groups, which we cannot attribute to a distinct home region, skill, or gender composition.<sup>20</sup>

We estimate the effect of the formation mechanism on group performance using the following specification:

$$y_{jp} = \beta_1 S_{ct} + \beta_2 X_j + \gamma_p + \delta_t + \epsilon_{jp} \tag{1}$$

where  $y_{jp}$  is the performance of group j on project p,  $S_{ct}$  is an indicator variable for self-select group formation in cohort c and term t.  $X_j$  is a vector of group covariates, including skill composition, geographic origin composition, and gender of group members.  $\gamma_p$  represent project fixed effects,  $\delta_t$  are term fixed effects, and  $\epsilon_{jp}$  is the error term. The coefficient  $\beta_1$  captures the causal effect of self-select group formation on group performance. We cluster standard errors at the group level to account for within-group correlation.

In our regression specification, the composition effect is the difference in  $S_{ct}$  between the baseline model, not including any control variables, to the full model with all control variables  $X_{j}$ .

We measure group performance with the student assistant grades from the group projects. Student assistants are unaware of the experiment and anonymously grade group projects on a 1 to 7 scale. We tell student assistants that their grading has no impact on the final

 $<sup>^{20}</sup>$ We cannot distinguish whether the formation effect arises from giving students the choice to select their group members or from working with someone they have a connection with. This is a difficult question to answer, since self-selected groups tend to consist of friends or acquaintances, while randomly formed groups do not. Even when random groups include friends, they are likely to be less close than self-selected groups. This is also true in real-world settings, where self-selection often implies some degree of social ties.

grade of the groups they rate and remunerate them to evaluate the projects. Additionally, for the student assistant grading, we pseudonymize group names.<sup>21</sup> We linearly transform these grades to a 0 to 100 scale for better interpretability and comparability. Our main proxy for prior skill is the high school GPA of a student. For our skill composition covariates, we compute the difference between the group members with the best and the worst high school GPAs of a group and take the high school GPAs of the best and the second-best members of a group. To determine the geographic origin of students, we use the county where they graduated from high school. In our regression analysis, we include a dummy variable to indicate whether at least two group members originate from the same or neighboring counties. We ascertain students' genders from their first names.

We estimate the effect of the formation mechanism on individual knowledge acquisition and satisfaction using the following specification:

$$a_{itc} = \beta_1 S_{ct} + \beta_2 X_j + \delta_t + \epsilon_{itc} \tag{2}$$

where the dependent variable  $a_{itc}$  is knowledge acquisition of individual *i* from cohort *c* in term t. We measure knowledge acquisition as the share of correct answers in the final multiple-choice exam at the end of each semester, concentrated on the 15 questions about the projects. We use the same specification to estimate the effect of group formation on satisfaction. We obtain satisfaction levels from the surveys after each project on a scale from 1 to 5. We average the satisfaction measure regarding the two group projects of each semester for each student and then transform them to a scale from 0 to 100.

We estimate the effect of the formation mechanism on the distribution of individual contributions within a project using the following specification:

$$g_{ip} = \beta_1 S_{ct} + \beta_2 X_j + \delta_t + \epsilon_{ip} \tag{3}$$

where  $g_{ip}$  is the individual contribution of student *i* on project *p*. To assess an individual's contribution to a project, we first calculate the total number of words of code and text contributed by that individual and the total number of words of code and text contributed by the entire group to the project. The share of words an individual contributes to the total amount of words contributed to a project then gives us our measure for individual contribution. Since we are interested in how groups distribute work, we calculate the standard deviation of the share of words contributed for each group and project. We then use this standard deviation as the dependent variable for the regression above.

### Data and Descriptives

Our data includes information about group performance, individual contributions to projects, satisfaction, and knowledge acquisition over time. We track individual contributions on GitHub through commits made by each student. These commits allow us a) to compute how many words a student committed to a project, b) if they committed code and text to the project, and c) which questions they answered with that commit. Further, we implemented a survey after each project, which allows us to measure individual satisfaction and perceived contributions on a 5-point likert-scale.<sup>22</sup> We can measure individual knowledge acquisition using the exam results administered at the end of each semester.

All students from cohorts 2020 and 2021 who took part in the compulsory data science course described in the "Background" section are eligible to take part in our field experiment, given they participated in the project phase. We exclude all student groups consisting of two or four members from our analysis.<sup>23</sup> We also exclude individuals who do not consent

<sup>&</sup>lt;sup>21</sup>Student assistants grade projects and screencast separately. For our analysis, we calculate a weighted mean from these two grades. We use the same 70/30 weights we use for the lecturer grades. <sup>22</sup>In Appendix B, we provide all questions we asked in this survey.

 $<sup>^{23}</sup>$ Some groups have two or four members if the number of students in a term is not divisible by three.

Table 2: Summary Statistics of Main Variables

Variable	Obs. Unit	Mean	Ν	SD	Min	Median	Max
Gender: Female	Student	0.35	138		0.00	0.00	1.0
High School GPA	Student	2.33	138	0.63	1.00	2.30	3.6
Two group members neighboring county	Student Term	0.51	245	0.5	0.00	1.00	1.0
Exam Points	Student Term	19.79	241	4.45	5.00	20.00	29.0
Exam Points Related to Projects	Student Term	8.84	241	2.43	2.00	9.00	14.0
Satisfaction with Team	Student Term	4.09	241	1.01	1.00	4.00	5.0

to have their data used. Additionally, we exclude groups that were under the self-select treatment formed by us randomly and consist of students who did not manage to form a group themselves. Using these exclusion restrictions, we arrive at a total of 138 students in our data. Most students received both treatments: 121 participated in the self-select treatment and 124 in the random formation treatment. Table 1 depicts the number of students participating in our field experiment each semester. Albeit we implement a within-subjects design, there are differences in the number of students in each term within a cohort. We observe attrition in our sample when people leave the program after the first part of the course or because students quit during a semester due to personal reasons. This could also result in a higher or lower number of groups with two or four members, which we exclude from our analysis. We show in Appendix C, with a balance table for the subject-specific covariates, that there are no significant pre-experimental differences between students in self-selected and randomly-formed groups.

Table 2 presents descriptive statistics on the main dependent and independent variables. The student assistants rated the projects on a 7-point Likert scale, averaging 5.64 points (SD=1.09). The students also took a final exam worth 30 points and scored an average of 19.79 points (SD=4.45), with a wide dispersion. In the exam questions related to the projects, students scored an average of 8.84 points (SD=2.43). The students reported their satisfaction with their teams on a 5-point Likert scale, averaging 4.10 (SD=1.01). They also reported their (perceived) contributions to the project, with an average of 0.38 (SD=.11), indicating a relatively equal work distribution among team members. We measured the actual contributions by the number of words each student committed to the project on GitHub, with an average of 2362 words (SD=1874), but with considerable variation across team members. We also collected administrative data on the high school grade point average (GPA) for all 138 participating students. The German GPA ranges from 4.0 (the worst) to 1.0 (the best) and is the main criterion for university admission in Germany and a good proxy for the general skill level of students (e.g., Fischer and Kampkötter (2017)). The average GPA in our sample is 2.33 (SD=.63). Finally, table 2 shows that 56% (SD=0.50) of the group members came from neighboring counties.

# Results

In this section, we will shed light on how the group-forming mechanism affects group composition, individual and group performance, satisfaction, and knowledge acquisition. We aim to rule out the effect of group composition on group performance, satisfaction, and knowledge acquisition.

# **Group Composition**

To be able to rule out the effect of group composition on individual and group outcomes, we first need to examine whether and to which extent self-selected and randomly formed groups differ in group composition.

Notes: We calculate the difference in high school GPA in a group between the members with the best and the worst high school GPA. Home counties correspond to the county in which a student graduated from high school. We gather information on initial relationships with the first survey. All panels but panel C show group numbers; in panel C, each observation is an individual.

Figure 2 shows the differences in four dimensions: skill, friendship, home county, and gender. We use high school GPA as a proxy for skill and the county where the student attended high school as a proxy for the home county. In the first survey, we asked the students about their friendship status at the beginning of the semester. We get the gender of the students from their first names. In panel A of figure 2, each dot represents a group in a semester, and the cross marks the mean of the distribution. We also plot a boxplot and a kernel density distribution in panel A. Figure 2 reveals that self-selected groups are more homogenous in skill, more likely to come from the same or neighboring counties, more likely to be of the same gender, and more likely to include at least one friend than randomly formed groups. This is consistent with the literature on homophily and the nature of random sampling.

#### **Project Performance**

We are interested in how group performance is affected by self-selection and by the characteristics of the group members. Figure 3 visualizes differences in group performance between self-selected and randomly formed groups.

Figure 3: Relationship between Group Performance and Treatment

Notes: Each dot represents a group and a project. We mark the mean with a cross. Further, we plot a kernel density and a boxplot. We measure project performance on a linear scale from 1 to 7, where 7 refers to the best performance. For our analysis, we transform this project performance measure to a 0 - 100 scale.\* indicates that the p-value for the difference in means is below .1.

Table 3: Effect of group-forming mechanism on productivity

\*p<0.1; \*\*p<0.05; \*\*\*p<0.01

Notes: Standard errors reported in parentheses are clustered at the group level. In the regressions, a group and a project define an observation. The dependent variable is the points awarded to the groups by the student assistants transformed to a 0 to 100 scale. Best Group GPA is a control variable for the best high school GPA in a group, and Second Best Group GPA for the second best high school GPA in a group. German high school GPAs range from 1 to 4, where 1 refers to the best grade and 4 to the worst. Max GPA Difference is a control variable for the difference in high school GPA between the member of the group with the best GPA and the one with the worst GPA. Two members same region is 1 if two members of a group graduated from high school in the same or neighboring counties, otherwise it is 0.

Figure 3 suggests that randomly formed groups outperform self-selected groups on the projects, with a smaller dispersion of project grades, and contribute more to the projects. To receive an unbiased estimate of this relationship and to be able to control for confounders, we run four OLS regressions in table 3 on the effect of self-selected group formation on group performance in the projects. The first regression in table 3 (column 1) gives us an overall effect: We compare the average performance of self-selected and random groups without controlling for group characteristics. To disentangle the formation and composition effects, we add controls for the skill composition of a group in column 2. A higher project performance could result from knowledge spillovers within the group, where the most skilled member instructs the other group members on how to perform the task, or from one skilled group member completing most of the project alone. Thus, in column 2, we control for the skill level of the most skilled member of a group using their high school GPA.<sup>24</sup> and for skill heterogeneity within a group using the difference between the group's highest and lowest high school GPA. Group identity may also affect collaboration within a group. Ai et al. (2023) shows that individuals with a high hometown similarity exert higher effort in their groups. Therefore, we add in column 3 covariates on gender composition and the home region of group members. Our pre-analysis plan pre-registered one regression to study the formation and composition effect on group productivity. We present the results in column 4. Unlike in columns 2 and 3, we proxy individual skill levels with percentage points scored by a student in the test exam.<sup>25</sup>

The first row of table 3 shows our main variable of interest (*Self-selection*) concerning the formation effect. We define the difference in the estimate of *Self-selection* between columns 1 and 3 as the composition effect. Table 3 reveals that in terms of group performance, the formation effect is larger than the composition effect. We estimate a formation effect of -4.2 percentage points, corresponding to about .3 standard deviations of the project performance distribution. Self-selected groups perform 4.2 percentage points worse on the projects than randomly formed groups due to the formation effect. The composition effect is -.9 percentage points in magnitude, indicating that self-selected groups have a detrimental skill, gender, and home region composition for productivity.<sup>26</sup> From table 3, we cannot reject the null in favor of hypothesis 1a or 1b.

As we see from columns 2 and 3, most of the composition effect stems from a different skill composition in self-selected groups, e.g., self-selected groups are more skill homogeneous. A higher skill homogeneity reduces the likelihood of having someone with a solid high school GPA in one's group, which hurts group performance. The better the best group member, measured by her high school GPA, the better the group performance.<sup>27</sup> Similarly, the individual with the second best high school GPA affects group performance positively, but with half of the magnitude. The difference in high school GPA between the individual with a group's highest and lowest GPA explains little of the variation in group performance. Note that groups with a large maximum within-group GPA difference also have a higher probability of holding a member with a low GPA, which presumably does not contribute to a better group performance. Having a highly skilled individual in a group enhances group performance. Such better group performance might occur through knowledge spillovers, but more likely because the highly skilled individual solves the most difficult tasks of a project. Suppose those skill spillovers and the distribution of work are similar in self-selected and randomly formed groups. In that case, skill composition explains about

 $<sup>^{24}</sup>$ Note that German GPA is a linear scale, with 1.0 being the best grade and 4.0 the worst among students who receive a university entry certificate.

 $<sup>^{25}</sup>$ We deviate in columns 2 and 3 from the pre-registered regressions by using high-school GPA minima and within-group differences for two reasons: First, when submitting the pre-analysis plan, it was not clear that we would obtain administrative data on high-school GPAs. Second, we were forced to let students do the test exam online during the Corona lockdown. In the online test exams, we observe high degrees of collaboration during the test exam, which is why we restrained from using test exam scores as a proxy for individual skill.

 $<sup>^{26}</sup>$ The composition effect is not statistically significant. By conducting a test, as suggested by Yan, Aseltine, and Harel (2013), to compare the estimators for self-selection in the two regressions with and without controls, we receive a p-value of .47.

<sup>&</sup>lt;sup>27</sup>Keep in mind that good grades correspond to a low GPA.

15% of the performance loss in self-selected groups. We also ran a regression using the exact specification that we pre-registered before collecting the data in column 5. Using this specification, we find larger estimates than in the specifications from columns 2 and 3, where we included project fixed effects. However, because the two projects within a semester are slightly different, we prefer to include these project-fixed effects.

We conclude that in terms of productivity, the composition effect and the formation effect lead to lower productivity in self-selected groups. The formation effect in our setting is four times the size of the composition effect. The composition effect implies that self-selected groups have a productivity-harming group composition and/or interact less efficiently and use fewer personal characteristics and skills. The size and the direction of the estimate for the formation effect are unexpected and contradict Kiessling, Radbruch, and Schaube (2022) and Coricelli, Fehr, and Fellner (2004). We expect that allowing students to choose group members motivates them to exert more effort. An alternative explanation for our formation effect: We might overestimate the formation effect by defining it as the remaining effect of group formation after controlling for skill, gender, and home region composition. Although we control group composition's most relevant factors, we might miss elements of group composition uncorrelated with skill, gender, and home region, differently distributed among self-selected and random groups but crucial for group collaboration.

#### **Knowledge Acquisition**

Letting students form groups by themselves negatively affects group performance, but what about individual learning? Does choosing your teammates makes you learn more? In figure 4, we plot the knowledge acquisition in self-selected and randomly formed groups separately.

In figure 4 ,we show that individuals from self-selected groups seem to acquire slightly more knowledge during the group projects than those from randomly formed groups.<sup>28</sup> Although randomly formed groups outperform self-selected groups on group projects, this does not increase knowledge acquisition. Again, run similar regressions to those in table 3 with this data, deviating in two points: First, in these regressions, we observe individuals in one semester instead of groups in a project. Therefore, in all five regressions in table 4, a student in a semester denotes an observation. Second, as a consequence, we do not include project fixed effects.

As in table 3 above, we present in the first line of table 4 the estimate for the formation effect in column 3. Again, the difference between the estimators of columns 1 and 3 shows the composition effect. Table 4 reveals that the formation effect is larger than the composition effect in absolute value, meaning self-selection has a net positive effect on individual learning. The formation effect is positive in all regressions, meaning self-selection helps individual learning. It is economically meaningful with 5.5 percentage points (in column 4), corresponding to .3 standard deviations of the knowledge acquisition distribution. The difference between columns 1 and 3 shows the composition effect, which is the difference between self-selected and randomly formed groups due to their different compositions.<sup>29</sup> The composition effect is negative and 2.2 percentage points in size, meaning self-selection hurts individual learning by creating less diverse groups.

 $<sup>^{28}\</sup>mathrm{Note}$  that these two means are statistically not different from each other.

 $<sup>^{29}</sup>$ This difference is statistically not significant when conducting the test suggested in Yan, Aseltine, and Harel (2013), we receive a p-value of .13.

Figure 4: Relationship between Knowledge Acquisition and Treatment

Notes: Each dot represents a student and a semester. We mark the mean with a cross. Further, we plot a kernel density and a boxplot. We measure knowledge acquisition by the number of points a student achieves in the final exam on project-related multiple-choice questions. There are 15 questions related to the projects in the final exam, each awarded with one point. For our analysis, we transform this knowledge acquisition measure to a scale from 0 - 100. N.S. stands for no statistically significant difference.

We control for the skill level of individuals in a group with three different measures: The high school GPA of the best student in the group, the high school GPA of the second best student in the group, and the difference in high school GPA between the best and the worst student in the group. Having a highly skilled student in the group boosts individual learning, probably because of knowledge spillovers. The other two measures of skill composition (second-best GPA and Difference in GPA ) have no additional significant effect on individual learning, as shown in column 2. We also find that gender and home region diversity matter for individual learning. Students learn more when they work with teammates of different gender and home regions than with teammates of the same gender and home region, as shown in column 3 of table 4.

In column 4, we run our pre-registered regression on individual knowledge acquisition from our pre-analysis plan. Column 4 shows that we find larger estimates in the pre-registered specification than in the specifications from columns 2 and 3. However, because our proxy for ability (percentage points on the exam) is very noisy, as explained above, our preferred specification is the one in column 3, where we use student GPA and additionally control for other factors that affect group composition. Following our analysis in table 4, we reject the null in favor of hypothesis 2a but not in favor of 2b.

We conclude that the self-selection of groups has a complex impact on individual learning. Due to the formation effect, individuals learn more in self-selected groups. However, this positive effect is counteracted by a less diverse group composition, which hinders individual learning.

Table 4: Effect of group-forming mechanism on final exam points on project questions

\*p<0.1; \*\*p<0.05; \*\*\*p<0.01

Notes: Standard errors reported in parentheses are clustered at the group level. In the regressions, a student in a semester define an observation. The dependent variable is the number of correct answers on the 15 project-related questions in the final exam, transformed to a 0 to 100 scale. Best Group GPA is a control variable for the best high school GPA in a group, and Second Best Group GPA for the second best high school GPA in a group. German high school GPAs range from 1 to 4, where 1 refers to the best grade and 4 to the worst. Max GPA Difference is a control variable for the difference in high school GPA between the member of the group with the best GPA and the one with the worst GPA. Two members same region is 1 if two members of a group graduated from high school in the same or neighboring counties, otherwise it is 0.

We conjecture that self-selected groups interact differently with each other and probably also distribute work differently than gender and home region heterogeneous groups. This might positively affect group performance but affect knowledge acquisition negatively. In the next section, we provide evidence on how self-selected and randomly formed groups differ in collaboration by analyzing individual contributions to the group projects and knowledge acquisition.

#### Satisfaction

We have seen that self-selection affects group performance and individual learning through adverse group composition but mostly through the group-forming mechanism itself. We argue that a group-forming mechanism only achieves high group performances and high levels of knowledge gain in the long term if group members are content with their group and the collaboration within the group. Therefore, we examine in this section if choosing your teammates makes you happier.

Figure 5: Relationship between Satsifaction and Treatment

Notes: This figure shows the students' satisfaction with their team after each project. We elicit satisfaction in the surveys after each project on a linear 1 to 5 scale, where 5 refers to the highest satisfaction value. For our analysis, we transform this satisfaction measure to a scale from 0 - 100.

We look at student satisfaction with their groups from the surveys to answer this question. We summarize our findings graphically in figure 5 and with OLS regressions in table 5. Figure 5 shows a shift towards higher satisfaction levels for students in self-selected groups: Members of self-selected groups report much higher satisfaction with the teamwork than members of randomly formed groups. In table 5 we present four different OLS regressions that estimate the effect of self-selection on individual satisfaction. In these regressions, a student in a semester denotes one observation. All regressions include term fixed effects, and we cluster standard errors at the group level.

Table 5: Effect of group-forming mechanism on individual satisfaction

\*p<0.1; \*\*p<0.05; \*\*\*p<0.01

Notes: Standard errors reported in parentheses are clustered at the group level. In the regressions, a student and a project define an observation. The dependent variable is the students' satisfaction with the team from the survey after each project, transformed to a 0 to 100 scale. Best Group GPA is a control variable for the best high school GPA in a group, and Second Best Group GPA for the second best high school GPA in a group. German high school GPAs range from 1 to 4, where 1 refers to the best grade and 4 to the worst. Max GPA Difference is a control variable for the difference in high school GPA between the member of the group with the best GPA and the one with the worst GPA. Two members same region is 1 if two members of a group graduated from high school in the same or neighboring counties, otherwise it is 0.

In column 1 of table 5, we show the baseline regression that only includes self-selection as an explanatory variable. In column 2, we add skill composition variables. In column 3, we add gender and home region composition variables, and in column 4, we run the pre-registered regression from our pre-analysis plan.

Again, we show in the first line of table 5 the estimate for the formation effect in column 3. The difference of the variable *Self-selection* between columns 1 and 3 shows the composition effect. In terms of satisfaction, the formation effect dominates the composition effect. Our estimate for the formation effect is 13.8 percentage points (in column 3), corresponding to roughly 2/3 standard deviations of the satisfaction distribution. The composition effect is negative, meaning self-selection hurts individual satisfaction by creating less diverse and less optimal groups.<sup>30</sup> The formation effect is much larger than the composition effect in absolute value, meaning that self-selection has a net positive effect on individual satisfaction from our pre-analysis plan. We find smaller, but still sizeable, estimates in the preregistered specification than in the specifications from columns 2, 3, and 4. Following our analysis in table 5, we reject the null in favor of hypothesis 3a but not in favor of 3b.

Having a highly skilled student in the group ( *Best Group GPA* ) boosts individual satisfaction, probably because of higher expectations and confidence. We also find that gender and home region diversity do not significantly affect individual satisfaction. Students are equally happy or unhappy with their groups regardless of their teammates' genders and home regions. Self-selection has a simple and robust impact on individual satisfaction: It makes students happier with their groups.

# Mechanism

In the results section, we show that self-selected groups have lower group performance, acquire more knowledge, and are more satisfied with their groups. These effects remain large when controlling for skill and gender composition in groups. To examine the mechanisms behind these effects, we analyze high school GPAs, individual contributions via GitHub, and students' survey responses and relate them to group performance, knowledge acquisition, and satisfaction. In this section, we explore how groups allocate their work among their members depending on how they formed groups and how this affects their group project performance, knowledge acquisition, and satisfaction.

### Project performance and knowledge acquisition

An unequal distribution of work may harm group performance and knowledge acquisition. We, therefore, want to know how groups distribute work within the group in randomly and self-selected groups. We use the within-group standard deviation of the share of words committed to a project on GitHub by each group member as a measure of work inequality. A higher standard deviation means more unequal work distribution. We run the pre-registered regression 3 from our empirical specification with standard deviation of individual contributions as the dependent variable. Each group in a project is one observation.

 $<sup>^{30}{\</sup>rm The}$  composition effect statistically not significant with a p-value of .62 when conducting the test suggested in Yan, Aseltine, and Harel (2013).

Table 6: Effect of group-forming mechanism on GitHub-Contributions

\*p<0.1; \*\*p<0.05; \*\*\*p<0.01

Notes: Standard errors reported in parentheses are clustered at the group level. In the regressions, a group and a project define an observation. For the dependent variable we calculate the share of words from the number of words of code and text a student has contributed via GitHub to the total amount of words of code and text of her or his group in a project. We then calculate for each group and project the standard deviation of the shares of words of the group members, which is our dependent variable in these regressions. Best Group GPA is a control variable for the best high school GPA in a group, and Second Best Group GPA for the second best high school GPA in a group. German high school GPAs range from 1 to 4, where 1 refers to the best grade and 4 to the worst. Max GPA Difference is a control variable for the difference in high school GPA between the member of the group with the best GPA and the one with the worst GPA. Two members same region is 1 if two members of a group graduated from high school in the same or neighboring counties, otherwise it is 0.

We find no evidence in table 6 that self-selected or randomly formed groups distribute the work within their groups more unequally. We also find no evidence that the group skill composition affects the work distribution, and therefore, we cannot reject the null in favor of hypothesis 4 or 4a. For robustness, we measure inequality in work distribution per group with the Herfindahl-index but find no significant differences between randomly and self-selected groups.<sup>31</sup>

Albeit groups distribute work not more or less inequally in one of the two treatments, they might distribute work to group members with particular characteristics (e.g. the more skilled group members). Moreover, social ties and communication in self-selected groups might change the impact of high-skilled individuals on group and individual outcomes.

From our main results we know that highly skilled students in groups enhance group performance significantly. This enhanced group performance could result from the fact that highly skilled students transfer their knowledge to other group members to achieve a higher performance as a team. Alternatively, the highly skilled group member could solve more tasks overall or more challenging tasks in a project by himself. To investigate this channel, we look at the individual contributions of each student to their GitHub projects. We compare self-selected and randomly formed groups to see if the best student in the group has a different role depending on how the group was formed. In table 7 we examine the individual contributions and outcomes of students in self-selected and randomly formed groups. We use two dummy variables to indicate whether a student has the best or the second-best high school GPA in their group. We look at the share of words committed by each student to their GitHub project (columns 1 to 4) and their knowledge acquisition, measured by the score in the final exam on project-related questions (columns 5 to 8). We control for the skill distribution, the home region, and the gender composition of each group.

Table 7: Effect of group-forming mechanism on final exam points on project questions for different GPAs

\*p<0.1; \*\*p<0.05; \*\*\*p<0.01

Notes: Standard errors reported in parentheses are clustered at the group level. In the regressions, a student in a semester define an observation. In colums 1 to 4, the dependent variable is the share of words contributed by a student to a project, and in columns 5 to 8, the number of correct answers on the 15 project-related questions in the final exam, transformed to a 0 to 100 scale. Own is Best Group GPA and Own is Second Best Group GPA indicate whether a student has the best or the second best high school GPA in their group. Best Group GPA is a control variable for the best high school GPA in a group, and Second Best Group GPA for the second best high school GPA in a group. German high school GPAs range from 1 to 4, where 1 refers to the best grade and 4 to the worst. Max GPA Difference is a control variable for the difference in high school GPA between the member of the group with the best GPA and the one with the worst GPA. Two members same region is 1 if two members of a group graduated from high school GPA in the same or neighboring counties, otherwise it is 0. Individual With Best GPA in Group is 1 if the corresponding student has the best high school GPA in the group, otherwise it is 0.

We show, in table 7, that the best student in a group contributes more than the second-best and the worst student in both self-selected and randomly formed groups. This is consistent with our findings above in table 6. The most skilled group member contributes roughly

 $<sup>^{31}\</sup>mathrm{We}$  present the results in Appendix D.

15 percentage points more than the lowest skilled group member in self-selected groups, whereas the most skilled group member contributes 22 percentage points more in randomly formed groups.<sup>32</sup>

We also find that the most skilled student in a self-selected group acquires not significantly more knowledge than their group members, even if we control for the skill distribution, the home region, and the gender composition in the group. This suggests that there are skill spillovers in self-selected groups. We do not find spillovers to the same extent in randomly formed groups, where the best student performs significantly better than the others.

Table 8: Effect of group-forming mechanism and contribution in project on knowledge aquisition

\*p<0.1; \*\*p<0.05; \*\*\*p<0.01

Notes: Standard errors reported in parentheses are clustered at the group level. In the regressions, a student in a semester define an observation. The dependent variable is the number of correct answers on the 15 project-related questions in the final exam, transformed to a 0 to 100 scale. Share of Github Contributions in Group ranges from 0 to 100 and indicates which share of a groups words of code and text committed to all of the groups projects throughout a semester is provided by the corresponding student.

Table 7 reveals, that the most skilled members of a group contribute more to the overall

 $<sup>^{32}\</sup>mathrm{In}$  Appendix E we show that the more skilled members of a group contribute not significantly more to the challenging tasks of a project.

project and acquire more knowledge, but only in randomly formed groups. In self-selected groups, both effects are less pronounced. In the next step, we examine whether contributing to a project is associated with higher knowledge acquisition or if the highly skilled members acquire knowledge well due to other reasons than contributing substantially to the projects. We, therefore, regress in table 8 knowledge acquisition on students' contributions to the projects of a group in a semester via GitHub and interact it with a group formation dummy variable. We show that contributing one percentage point more to the projects throughout a semester increases knowledge acquisition in self-selected groups by 0.11 percentage points on average and in randomly formed groups by 0.28. We conclude that in order to acquire knowledge, it is significantly more important for students from randomly formed groups to contribute to the projects than those from self-selected groups.<sup>33</sup>

So why do self-selected groups perform worse on the group projects, but individuals acquire more knowledge from the projects? Based on our findings in this section, we come up with the following explanation: In randomly formed groups, the most skilled student of a group contributes significantly more to the projects than in self-selected groups. Because in self-selected groups, students with low skills solve more project tasks, they perform worse on the group projects than randomly formed groups. However, we also see that in self-selected groups, the low-skilled members and those who contribute little to the projects acquire almost as much knowledge as the rest of the group. In contrast, in randomly formed groups, students with low prior skills and those who contribute little to the projects acquire only little knowledge from the projects.<sup>34</sup> We argue, that these differences between randomly and self-selected groups occur because of better communication and discussion in self-selected groups nourished by stronger social ties and higher group identity. This then results in higher knowledge acquisition for the entire group.

So far we find, that self-selected groups distribute work substantially differently than randomly formed groups. In the tables above we show how the different distribution of work in the two treatments explains the formation effect. In table 9 we examine whether distributing work to more or less skilled individuals works as a channel for explaining the composition effect. Thus, we add to the regressions from table 3 and 4 control variables for the share of GitHub contributions by the members with the highest and lowest skill levels in a group. We show in table 9 that the composition effect almost diminishes for group project performance but remains nearly unchanged for knowledge acquisition.<sup>35</sup> We conclude that how groups distribute work across skill levels explains the majority of the composition effect in group project performance. This means that the different group composition in self-selected groups affects project performance mostly because groups distribute work differently according to the skill levels of their members. The composition effect in knowledge acquisition seems to work differently: The effect of a different group composition in self-selected groups on knowledge acquisition occurs not because groups distribute work differently in self-selected groups. The skill level of an individual's group members seems to directly impact the knowledge acquisition of that individual. However, remember that we find above a much larger formation effect which affects, through a different work distribution in self-selected and randomly formed groups, group performance and knowledge acquisition.

 $<sup>^{33}</sup>$ In Appendix F, we show on the project-task level that contributing to a task of a project is associated with a higher probability of answering exam questions correctly, that relate to that question. This effect is less pronounced for self-selected groups.

 $<sup>^{34}</sup>$ Remember, the skill level rank of a student within a group and contribution to a group project is negatively correlated. This means the most skilled members of a group do most of the work.

 $<sup>^{35}</sup>$ Note that in table 9 the estimator for the effect of the contribution of the most skilled group member on project performance and the the estimator for the effect of the contribution of the least skilled group member on knowledge acquisition are negative. We argue that the effects are highly heterogeneous and that having high contributions of these students is correlated with a dysfunctional group.

 Table 9: Effect of group-forming mechanism on Group Performance and Knowledge

 Acquisition with Contribution controls

\*p<0.1; \*\*p<0.05; \*\*\*p<0.01

Notes: Standard errors reported in parentheses are clustered at the group level. In columns 1 and 2, a group and a project define an observation and the dependent variable is the performance on the group projects on a scale from 0 to 100. In columns 3 and 4, a student and a semester define an observation and the dependent variable is the performance on the 15 questions related to the projects in the final exam on a scale from 0 to 100. Contribution of Best and Contribution of Third-best indicate which share of the GitHub Commits was contributed by the group member with the highest high school GPA and which share by the group member with the lowest high school GPA in a group.

#### Satisfaction

Self-selected groups are more satisfied because of a formation effect. We come up with two possible explanations: First, individuals perceive the extent of their own contribution in self-selected groups more precisely and do not overestimate their contribution. Second, individuals internalize the external effects of their contributions in self-selected groups and are less dissatisfied with a higher perceived contribution in self-selected groups than in randomly formed groups. Figure 6 shows the relationship between perceived and actual contributions to the project on GitHub on the left and between perceived contribution and satisfaction on the right. We see that both self-selected and randomly formed groups report their contributions accurately. However, those who contribute and those who perceive to contribute more than average are much happier in self-selected groups than in randomly formed groups.

Figure 6: GitHub Contribution and Perceived Contribution in Semester

Notes: We calculate the share of words contributed from the number of words a student contributes via GitHub to the total amount of words of their group in a project. We here do not distinguish between words of code and words of text contributed. We elicit students' satisfaction with the team in the survey after each project on a scale from 1 to 5, where 5 refers to high satisfaction levels. In the same surveys, we ask students to indicate on a scale from 0 to 100 how much they think they contributed to the group project. Each observation corresponds to an individual and a project.

In table 10, we regress satisfaction on students' contributions to the projects of a group in a semester via GitHub. We show that contributing one percentage point more to the projects throughout a semester decreases satisfaction in self-selected groups by 0.148 percentage points and in randomly formed groups by 0.369 percentage points. We conjecture that students in self-selected groups are more satisfied when contributing a large share of the overall project because they internalize the benefits of their contribution and enjoy doing more work if they can pick their group members.

	Dependent variable:			
	Satisfaction			
Self-selection	4.896 (4.267)	5.585 (4.270)

Table 10: Effect of group-forming mechanism and contribution in project on satisfaction

\*p<0.1; \*\*p<0.05; \*\*\*p<0.01

Notes: Standard errors reported in parentheses are clustered at the group level. In the regressions, a student in a semester define an observation. The dependent variable is the average satisfaction level of a student in a semester from the surveys and ranges from 0 to 100. Share of Github Contributions in Group ranges from 0 to 100 and indicates which share of a groups words of code and text committed to all of the groups projects throughout a semester is provided by the corresponding student.

# Robustness

The regressions above on group performance analyze the effect of letting groups form themselves on the grades of the two projects in each semester and cohort. However, students might smooth their individual contributions over a semester, not a project. This could affect the individual effort a student assigns a project and the effort the whole group puts into a project. In Appendix G, we run the regressions from table 3 again and show that results remain unchanged if we aggregate observations on semester and group level. In the regression table in Appendix G each observation represents a group in a semester, whereas in table 3 one observation denotes a group in a project.

How well a group performs might also depend on the social preferences and social skills of its members.<sup>36</sup> We add dummy variables to our main regression from table 3 for whether there is a team player in a group, whether there is someone with altruistic social preferences

<sup>&</sup>lt;sup>36</sup>See, e.g. Weidmann and Deming (2021)

	Project 1	Project 2	Project 3	Project 4
Cohort 2021 compared to 2020	+ +			+

 Table 11: Comparison of Project Difficulty Levels

in a group, and whether there is someone with conditional cooperative social preferences in a group. We obtain these measures from an online lab experiment we conduct for each cohort at the end of the summer term. <sup>37</sup> In defining team players we follow Weidmann and Deming (2021): A team player performs one standard deviation or more above the mean in the RMET.<sup>38</sup> We show in Appendix H, that adding those additional covariates does not change our estimates from table 3. We do not include these variables in our main regression results because roughly 1/3 of the students did not participate in the experiment, and we assume that these students are systematically less involved with the course and have social preferences, deviating from the rest of the sample.

We change the projects each semester and cohort. As a result, we have for each of those projects only observations for one kind of group formation mechanism. We are aware of the problem that different levels of difficulty of the projects could drive our results on the effect of group formation on project points and individual perception of the course. We address this problem in two ways: First, even though we change the projects, we keep them similar in the way we ask questions and the skills required to work on them. Second, we hire a student assistant, skilled in data analysis, to evaluate and compare the difficulty levels of Project 1, 2, 3, and 4 in the two cohorts. We do not inform the student assistant about the experiment. Table 11 shows how the student assistant rates the difficulty levels of the project sfrom cohort 2021 compared to the projects from cohort 2020. "+" means, that the project was more difficult in cohort 2021 and "-" that it was easier in cohort 2021. The evaluation scale is linear and ranges from "- - " to "+ + +". Table 11 shows that taken both projects of a semester together, the projects of winter term 2020 have the same level of difficulty as those of summer term 2021.

 $<sup>^{37}</sup>$ We pay students 6 EUR to participate in the online experiment. The online experiment has three parts: an incentivized dictator game, a sequential prisoner's dilemma, and a shortened version of the modified Reading the Mind in the Eyes Test (RMET) to measure social preferences and cognitive empathy. We use the dictator game to control for altruistic behavior among the participants. In the dictator game, we ask participants to split 10 EUR between themselves and a charity of their choice. Each participant is a dictator and there are no receivers. We use the sequential prisoner's dilemma to classify participants into three prosocial types: altruists, conditional cooperators, and selfish. Our version of the prisoner's dilemma is the same as Esteves-Sorenson (2018): First, we show each participant how payoffs are determined in a prisoner's dilemma. Then, we present them with a prisoner's dilemma with potential payoffs between 0.00 and 5.63 EUR. In the first round, all participants are first movers and in the second round, all participants are second movers and decide how they would react to each of the two first mover choices. Then, we match students randomly and implement their strategies. We use the RMET to assess emotional intelligence, which is strongly related to team efficiency. In the modified RMET by Baron-Cohen et al. (2001), participants have to read emotions by looking at pairs of eyes. For each pair of eyes, the participant has four options and only one is correct. We use the shortened version from Weidmann and Deming (2021) with 26 pairs of eyes. We also provide students with synonyms for unclear expressions. After the dictator game, the sequential prisoner's dilemma, and the RMET, we randomly choose one of the three parts to pay each participant. Fehr and Schmidt (1999) showed that subjects do not behave differently with probabilistic payments compared to a certain amount of money. Note that the RMET is not incentivized, and therefore, participants receive no extra payment if this part of the experiment is randomly chosen for payoff. At the end of the online experiment, students have to fill in a short survey to provide us with the necessary information to pay participants and match data from the field experiment.

<sup>&</sup>lt;sup>38</sup>Note that RMET and high school GPA are not correlated, so we control for two covariates: Academic skill and cognitive empathy

# Conclusion

We conduct a natural field experiment in the classroom, where students work in groups of three on cognitively challenging projects. We investigate how the composition and formation effect drive differences in the project performance of groups, knowledge gained by individual group members, and individual satisfaction between self-selected and randomly formed groups. We find that the formation effect dominates the composition effect in all three dimensions: The formation effect is four times the size of the composition effect in terms of group performance, three times the size in terms of knowledge acquisition, and eleven times the size in terms of satisfaction.

The composition effect is negative for self-selected groups in all three observed dimensions. We conclude that self-selected groups have a productivity, knowledge acquisition, and satisfaction-harming group composition. This is the case because the elevated skill homogeneity in self-selected groups harms productivity and satisfaction, and together with the increased homogeneity in terms of gender and home region in self-selected groups, it also harms knowledge acquisition. In contrast, we associate the formation effect with lower group productivity but higher knowledge acquisition and satisfaction. We explain these adverse effects with differences in how groups distribute work across their members: Randomly formed groups distribute more work to the highly skilled group members, for whom the marginal effect of acquiring knowledge from contributing to the projects is smaller than for less skilled individuals. This explains why self-selected groups acquire more knowledge during the group projects, albeit performing worse on the projects than randomly formed groups. We further show that self-selected groups are more satisfied because high-contributors are less unsatisfied with contributing a lot when they can choose their group members.

If we take the formation and composition effect together, we find that self-selected groups perform 5.1 percentage points worse in their projects than randomly formed groups. This effect is statistically significant and economically meaningful as it composes 1/3 of a standard deviation in the project performance distribution.<sup>39</sup> Moreover, members of self-selected groups acquired 3.3 percentage points more knowledge and are 12.5 percentage points more satisfied than those in randomly formed groups. Our group performance results align with Fischer, Rilke, and Yurtoglu (2023) on group presentations and contradict Fenoll and Zaccagni (2022) and Kiessling, Radbruch, and Schaube (2022). Compared to our setting, the task in Kiessling, Radbruch, and Schaube (2022) is non-collaborative, and effort does not affect the public good.

Our results implicate that self-selection on cooperative high cognition tasks with exchangeable group members is performance-harming. However, self-selection comes at a higher satisfaction and a lower workload of highly skilled individuals compared to randomly formed groups. We advocate for teaching settings in which knowledge acquisition is essential to give individuals some choice in the group formation process. Moreover, in settings where individual well-being is of major interest, we recommend letting groups self-select.

 $<sup>^{39}</sup>$ See for instance Boss et al. (2021) with and effect size of .19 SD, Fenoll and Zaccagni (2022) with 0.38 SD, Fischer, Rilke, and Yurtoglu (2023) with 0.52 SD, and Kiessling, Radbruch, and Schaube (2022) with 0.15 SD.

# Appendix

# Appendix A

This repository has 4 (5 for some) folders, named somewhat oddly. These folders contain the project elaborations of the groups that have been assigned to you.

We always anonymize the group names for us, and you will also get the anonymized group names (naming of the folders) here. The anonymization is done according to a particular system and is done anew for each project.

Besides the project elaborations of the groups, a file with the ending "\_Loesung.html" is contained, which contains the sample solution for this project. You should use this sample solution as a basis for your evaluation of this project.

The focus of the evaluation is on the description of the tables and graphs and, where required, their interpretation. However, it is also important to scale graphics and tables sensibly and present them nicely in this assignment. For example, there would be a deduction if the code chunks in the group elaboration are visible in the HTML.

Please rate the written submissions and screencasts you receive on a scale of 1-7 in the file TutorRating.Rmd, which is contained in the respective folder per group, and knit the file afterward! Please continue to write down in bullet points what led to point deductions in your evaluation. These bullet points will then be played back to the group along with the students' reviews. This will give the group some more in-depth feedback and help them better categorize the reviews of their fellow students.

#### Appendix B

- 1.) In this course I learn things that fill me with enthusiasm (Likert Scale)
- 2.) I did understand the most important topics of this project. (Likert Scale)
- 3.) How satisfied are you with your team? (Likert Scale)
- 4.) How efficient was the teamwork in this project? (Likert Scale)
- 5.) How large do you think is your contribution to the project? (in %)
- 6.) How evenly was the work distributed in your team? (Likert Scale)
- 7.) Do you think it is fair to get one grade per team? (Only after last project)

8.) Which best describes your relationship to your group members? (Only after first project):

- $\Box$  I did not know my group members before
- $\Box$  I knew one or both of my group members before, but did not have much contact
- $\Box$  One of the group members is a friend
- $\Box$  Both group members are friends

# Appendix C

Variable	Ν	Mean	SD	Ν	Mean	SD	Test

Table 13: Effect of group-forming mechanism on GitHub-Contributions with Herfindahl-Index

\*p<0.1; \*\*p<0.05; \*\*\*p<0.01

Notes: Standard errors reported in parentheses are clustered at the group level. In the regressions, a group and a project define an observation. For the dependent variable we calculate the share of words from the number of words of code and text a student has contributed via GitHub to the total amount of words of code and text of her or his group in a project. We then calculate for each group and project the gini-coefficient of the shares of words of the group members, which is our dependent variable in these regressions. Best Group GPA is a control variable for the best high school GPA in a group, and Second Best arange from 1 to 4, where 1 refers to the best grade and 4 to the worst. Max GPA Difference is a control variable for the difference in high school GPA between the member of the group with the best GPA and the one with the worst GPA. Two members same region is 1 if two members of a group graduated from high school in the same or neighboring counties, otherwise it is 0.

#### Appendix E

	Dependent variable: Share of GitHub Contributions (Self-select)			
Own is Best Group GPA	0.101**	0.209***		
-	(0.045)	(0.052)		
Hard Question	0.013	-0.012		
	(0.033)	(0.029)		
Own is Second Best Group GPA	$0.089^{*}$	0.081**

Project FE	Х	Х		
Observations	2,117	2,332		
$\mathbb{R}^2$	0.052	0.084		
Adjusted $\mathbb{R}^2$	0.045	0.078		
Residual Std. Error	0.364	0.341		

Table 14: Effect of difficulty of task and relative skill level on contribution

\*p<0.1; \*\*p<0.05; \*\*\*p<0.01

Notes: Standard errors reported in parentheses are clustered at the group level. In the regressions, a student and the task of a project define an observation. The dependent variable is the share of words contributed by a student to a project task. Own is Best Group GPA and Own is Second Best Group GPA indicate whether a student has the best or the second best high school GPA in their group. Best Group GPA is a control variable for the best high school GPA in a group, and Second Best Group GPA for the second best high school GPA in a group. German high school GPAs range from 1 to 4, where 1 refers to the best grade and 4 to the worst. Max GPA Difference is a control variable for the difference in high school GPA between the member of the group with the best GPA and the one with the worst GPA. Two members same region is 1 if two members of a group graduated from high school in the same or neighboring counties, otherwise it is 0. Individual With Best GPA in Group is 1 if the corresponding student has the best high school GPA in the group, otherwise it is 0.

# Appendix F

Figure 7: Relationship between Skill, Effort Provision in Projects and Knowledge Gain Notes: In the graph we show how contributing to a project task via GitHub is correlated with the probability of answering an exam question correctly that directly relates to that task. Here an observation represents a student and a project task. The three panels show the averages and 95%-confidence intervals separately for students who have the worst, second best, and best high school GPA of their group.

# Appendix G

	Dependent variable:					
	Project Percentage Points Term					
	(1)	(2)	(3)	(4)	(5)	
Self-selection	$-5.990^{**}$ (2.822)	$-4.710^{*}$ (2.741)	$-5.115^{*}$ (2.705)	$-4.930^{*}$ (2.876)	$-8.132^{**}$ (3.454)	
Best Group GPA		$-10.220^{***}$ (3.287)	-7.744 (6.832)	-7.703 (7.443)		
Second Best Group GPA			-3.835 (4.887)	-3.450 (5.051)		
Max GPA Difference			-0.648 (4.466)	$0.380 \\ (4.896)$		
All Members Female				-0.082 (5.045)		
One Member Male				-0.342 (3.751)		
All Members Male				-3.039 (4.025)		
Two Members Same Region				0.428 (2.678)		
Group Mean Test Exam					$0.360^{**}$ (0.171)	
Self-selection:Summer Term					$3.833 \\ (5.761)$

Residual Std. Error	$0.052 \\ 13.207$	$0.165 \\ 12.393$	0.156 12.462	$0.122 \\ 12.706$	0.076 13.033	

Table 15: Effect of group-forming mechanism on term productivity

\*p<0.1; \*\*p<0.05; \*\*\*p<0.01

Notes: Standard errors reported in parentheses are clustered at the group level. In the regressions, a group and a semester define an observation. The dependent variable is the mean of points awarded to the groups throughout a semester by the student assistants transformed to a 0 to 100 scale. Best Group GPA is a control variable for the best high school GPA in a group, and Second Best Group GPA for the second best high school GPA in a group. German high school GPAs range from 1 to 4, where 1 refers to the best grade and 4 to the worst. Max GPA Difference is a control variable for the difference in high school GPA between the member of the group with the best GPA and the one with the worst GPA. Two members same region is 1 if two members of a group graduated from high school in the same or neighboring counties, otherwise it is 0.

### Appendix H

	Dependent variable:				
-	Project Percentage Points				
	(1)	(2)	(3)	(4)	
Self-selection	$ \begin{array}{c} -5.942^{**} \\ (2.881) \end{array} $	$ \begin{array}{c} -6.011^{**} \\ (2.806) \end{array} $	$-5.664^{*}$ (2.875)	$-7.318^{*}$ (3.801)

Table 16: Effect of group-forming mechanism on productivity with lab controls

\*p<0.1; \*\*p<0.05; \*\*\*p<0.01

Notes: Standard errors reported in parentheses are clustered at the group level. In the regressions, a group and a project define an observation. The dependent variable is the points awarded to the groups by the student assistants transformed to a 0 to 100 scale. Team Player in Group is a dummy variable indicating whether at least one group member scores 75 percent or more on the RMET. Member Giving in Dictator Game is a dummy variable, which is one when at least one group member is not keeping all the money in the dictator game. Altruist in Group and Conditional Cooperator in Group are two dummy variables computed from the prisoners dilemma, indicating whether there is at least one group member in a group, that cab be classified as altruist or conditional cooperator, respectively. Best Group GPA is a control variable for the best high school GPA in a group, and Second Best Group GPA for the second best high school GPA in a group. German high school GPAs range from 1 to 4, where 1 refers to the best grade and 4 to the worst. Max GPA Difference is a control variable for the difference in high school GPA between the member of the group with the best GPA and the one with the worst GPA. Two members same region is 1 if two members of a group graduated from high school in the same or neighboring counties, otherwise it is 0.
