(\*Electronic mail: david.grier@nyu.edu)

We present a novel immersed boundary method that implements acoustic perturbation theory to model an acoustically levitated droplet. Instead of resolving sound waves numerically, our hybrid method solves acoustic scattering semianalytically and models the corresponding time-averaged acoustic forces on the droplet. This framework allows the droplet to be simulated on inertial timescales of interest, and thereby admit a much larger time resolution than traditional compressible flow solvers. To benchmark this technique and demonstrate its utility, we implement the hybrid IBM for a single droplet in a standing wave. Simulated droplet shape deformations and streaming profile agree with theoretical predictions. Our simulations also yield new insights on the streaming profiles for elliptical droplets, for which a comprehensive analytic solution does not exist.

## I. INTRODUCTION

Acoustic manipulation uses the forces exerted by sound waves to lift objects against gravity and to move them along planned trajectories in three dimensions<sup>1-5</sup>. The theory of acoustic manipulation is well-developed for solid objects in inviscid fluids<sup>6</sup>. The behavior of deformable objects, however, poses more of a challenge. Acoustic scattering and sound-mediated shape changes occur on dramatically different time scales, making their interplay difficult to model selfconsistently<sup>7,8</sup>. The standard formulation of sound-mediated forces and flows is based on second-order perturbation theory. The first-order pressure and velocity fields,  $p_1(\mathbf{r},t)$  and  $\mathbf{u}_1(\mathbf{r},t)$ , respectively, describe incident sound waves together with waves scattered by particles. These first-order fields oscillate harmonically at the acoustic frequency,  $\omega$ , and vanish on average. Their interference, however, gives rise to steady acoustic radiation forces (ARF)<sup>9</sup> and streaming flows<sup>10-14</sup> at second order in the amplitude of the sound wave. This wavematter interaction has been formulated analytically for highly symmetric scatterers<sup>6,14–17</sup> and semi-analytically for scatterers of fixed arbitrary shape<sup>18</sup>. Even numerical solutions are challenging, however, for scatterers whose shape can change.

Here, we introduce an efficient computational framework based on the Immersed Boundary Method (IBM)<sup>19,20</sup> that accurately predicts the dynamics and shape evolution of fluid droplets in acoustic force landscapes, as well as the streaming flows around them. The IBM naturally accommodates the moving boundary of a deformable droplet and couples it to flows in the fluid medium. We then couple this dynamical system semi-analytically to an acoustic pressure wave by projecting the time-averaged acoustic force at the deformed droplet's surface onto the incompressible flow around an equivalent sphere. This framework models acoustic levitation substantially more efficiently than existing compressible-flow solvers by inherently accommodating both fast and slow processes. We validate this hybrid numerical framework by studying shape deformations and flow fields around fluid droplets in an acoustic levitator. This study identifies a dynamical transition between dipolar and quadrupolar streaming flows that may explain anomalous collective phenomena in experimen-

FIG. 1. Schematic overview of the immersed boundary method applied to a fluid droplet driven by an acoustic pressure field.

tal studies of acoustically levitated droplets<sup>5</sup> and can be useful for designing microfluidic devices<sup>21</sup>.

Section II reviews the standard IBM<sup>20</sup> along with extensions that incorporate the mass and surface tension of a fluid droplet. Acoustic forces and streaming flows are derived in Sec. III from acoustic perturbation theory. Section IV then The outcome compares well with results of the best available multiscale computational studies at a fraction of the computational cost.

## II. IMMERSED BOUNDARY METHOD

The Immersed Boundary Method was first introduced in 1972 to study blood flow in the heart<sup>19</sup>, and has since evolved into a general method for solving fluid-structure interaction problems<sup>20</sup>. Modeling fluid droplets requires a variant of this technique called the penalty Immersed Boundary Method that incorporates the droplets' mass and surface tension<sup>22,23</sup>. The present work further extends pentalty IBM by further incorporating the forces exerted by an acoustic wave propagating

through the fluid medium.

## A. The standard IBM

The standard formulation of the IBM<sup>20</sup> applies to a droplet embedded in a homogeneous incompressible fluid of density  $\rho$  and dynamic viscosity  $\eta$ . The droplet's surface,  $\mathbf{X}(\mathbf{q})$ , is parameterized by curvilinear coordinates,  $\mathbf{q}$ , and is discretized into a set of markers, { $\mathbf{X}_i$ }, at fixed material points along the boundary, as shown schematically in Fig. 1.

The fluid flow,  $\mathbf{u}(\mathbf{x}_j)$ , and pressure,  $p(\mathbf{x}_j)$ , are defined on a Cartesian grid,  $\mathbf{x}_j$ , with uniform spacing *h*, and are governed by the viscous, incompressible Navier-Stokes equations,

$$\boldsymbol{\rho} \left( \partial_t + \mathbf{u} \cdot \boldsymbol{\nabla} \right) \mathbf{u} = -\boldsymbol{\nabla} p + \boldsymbol{\eta} \nabla^2 \mathbf{u} + \mathbf{f}$$
(1a)

$$\boldsymbol{\nabla} \cdot \mathbf{u} = 0. \tag{1b}$$

By Newton's third law, the force on the fluid element at  $\mathbf{x}_i$ ,

$$\mathbf{f}(\mathbf{x}_{j},t) = -\int \mathbf{F}(\mathbf{q},t) \,\delta_{h}(\|\mathbf{x}_{j} - \mathbf{X}(\mathbf{q},t)\|) \,d\mathbf{q}, \qquad (2)$$

is equal and opposite to the local force on the boundary,  $\mathbf{F}(\mathbf{q},t)$ , due to surface tension and the influence of external fields. The kernel,  $\delta_h$ , interpolates over the markers,  $\mathbf{X}_i$ , in the neighborhood of a discrete gridpoint,  $\mathbf{x}_j$ . Likewise, each massless boundary marker is advected by the fluid at a velocity

$$\mathbf{U}_{i} = \int \mathbf{u}(\mathbf{x}_{j}, t) \,\delta_{h}(\|\mathbf{x}_{j} - \mathbf{X}_{i}\|) d\mathbf{x}_{j}$$
(3)

that is interpolated from the computational grid.

The IBM defined by Eqs. (1)-(3) generally proceeds in a cycle, as depicted in Fig. 2. Given an initial droplet shape,  $\{\mathbf{X}_i\}$ , the forces,  $\{\mathbf{F}_i\}$ , on the boundary markers are calculated from the combined influences of surface tension and external forces. The complementary force field acting on the fluid,  $\mathbf{f}(\mathbf{x}_j,t)$ , is then computed with Eq. (2). The Navier-Stokes equations, Eq. (1), then are solved numerically<sup>19,20</sup> to obtain the updated fluid velocity,  $\mathbf{u}(\mathbf{x}_j,t)$ . Finally, Eq. (3) is used to determine the no-slip motion of the boundary,  $\partial_t \mathbf{X} = \mathbf{U}$ , and the procedure is repeated for the updated boundary configuration,  $\{\mathbf{X}_j\}$ .

In this work, we implement the same numerical scheme first introduced by Peskin<sup>19</sup>, using the spacial and temporal discretizations and four-point discrete delta function described in Sections 4-7 of Ref.<sup>20</sup>. To improve volume conservation, we calculate the fluid fields on a staggered, marker-and-cell grid<sup>24</sup>.

## B. Penalty IBM for Massive Droplets

The standard IBM cannot account for multiphase flows where properties of the droplet, such as density and viscoelasticity, differ from those of the surrounding medium<sup>24</sup>. For simplicity, we focus on the droplet's density contrast relative

FIG. 2. Immersed Boundary Method for acoustic manipulation of deformable objects.

to the medium. To incorporate the droplet's excess mass, we implement an extension of the IBM based on the penalty Immersed Boundary Method<sup>22,25</sup>.

The penalty IBM models the density of the droplet interior by introducing a a set of massless tracer particles at locations  $\{\mathbf{X}_i^m\}$  whose trajectories trivially satisfy Eqs. (1)-(3). As shown in Fig. 1, each of these fluid markers is coupled to a corresponding *mass marker* at position  $\mathbf{Y}_i^m$  by a spring of stiffness  $K_P$ . The *i*-th fluid marker experiences a force,

$$\mathbf{F}_{i}^{m} = K_{P} \left( \mathbf{Y}_{i}^{m} - \mathbf{X}_{i}^{m} \right), \tag{4}$$

that accelerates it according to Newton's second law,

$$M \partial_t^2 \mathbf{Y}_m = -\mathbf{F}_i^m - Mg\hat{z},\tag{5}$$

where *M* is the marker's mass and *g* is the acceleration due to gravity.

In theory, the fluid markers and mass markers ought to coincide in the limit of large  $K_P$ . In practice, however, numerical instability arises when  $K_P$  is too large. Consequently,  $K_P$  is chosen phenomenologically to maintain pair separations smaller than the computational grid size, typically at h/10.

#### C. Surface Tension

The internal boundary stress on a marker at  $\mathbf{X}_i$  is often formulated as a restoring force,  $\mathbf{F}_i = -\delta_{\mathbf{X}_j} E$ , that minimizes the interfacial energy,  $E[\{\mathbf{X}_j\}]$ . When this approach is used to model surface tension, the interfacial energy is proportional to the droplet's total surface area. In two dimensions, it is proportional to the length of the interface,

$$E[\{\mathbf{X}_j\}] = \sigma A = \sigma \sum_{j=1}^{N_{ib}-1} \|\boldsymbol{\ell}_j\|, \tag{6}$$

where  $\ell_j \equiv \mathbf{X}_{j+1} - \mathbf{X}_j$ , and  $\sigma$  is the interfacial tension. The force of surface tension acting on the marker is then

$$\mathbf{F}_{i}^{\sigma}\left(\sigma\sum_{j=1}^{N_{ib}-1}||\boldsymbol{\ell}_{j}||\right) = -\sigma(\hat{\ell}_{i}-\hat{\ell}_{i-1}). \tag{7}$$

FIG. 3. Streamlines within and around a  $4 \,\mu m$  droplet falling through an unbounded fluid at its terminal velocity,  $\approx 20 \,\mu m \, s^{-1}$ . We compare the analytic stream function from Happel and Brenner<sup>26</sup> (left) to simulations using a penalty immersed boundary method for the droplet's excess mass (right).

Equation (7) correctly models surface tension if the boundary markers are uniformly distributed around the droplet's boundary. To this end, the markers are redistributed tangentially along the boundary at each time step.

Surface tension exerts a normal on the droplet surface to minimize local curvature. Consequently, Eq. (7) also defines the surface normal,  $\hat{\mathbf{n}}_i = \mathbf{F}_i^{\sigma} / \|\mathbf{F}_i^{\sigma}\|$ .

#### D. Benchmark: Sedimenting Droplet

To demonstrate and benchmark our implementation of the IBM, we model the sedimentation of a droplet in an unbounded fluid<sup>23</sup>. Figure 3 presents a cross-section of the flow around and within a droplet of radius  $R = 4 \mu m$  and buoyant density  $\rho_p - \rho_0 = 0.18 \text{ g cm}^{-3}$ , which corresponds to silicone oil sedimenting in water<sup>5</sup>. For simplicity, we assume the fluid droplet has the same viscosity as the surrounding medium. The plot shows streamlines of the flow in the co-moving frame and is colored by the local flow speed. The data in Fig. 3(a) are computed with the IBM in a 20  $\mu m \times 20 \mu m$  periodic domain. They are compared side-by-side with the analytic result for a spherical droplet<sup>26</sup> in Fig. 3(b). This solution for the two-phase flow is reproduced in Appendix A.

Slight differences between the two flow fields can be attributed to the influence of periodic boundary conditions on the simulations and to the implicit assumption of infinite surface tension in the analytic model.

## III. ACOUSTICS

The standard IBM relies on the incompressible Navier-Stokes equations, Eq. (1), and therefore does not accommodate sound waves. Describing the fields within an acoustic levitator requires the compressible Navier-Stokes equations,

$$\partial_t \boldsymbol{\rho} = -\boldsymbol{\nabla} \cdot (\boldsymbol{\rho} \mathbf{u}) \tag{8a}$$

$$\rho\left(\partial_t + \mathbf{u} \cdot \boldsymbol{\nabla}\right) \mathbf{u} = -\boldsymbol{\nabla}p + \eta \, \nabla^2 \mathbf{u} + \beta \eta \, \boldsymbol{\nabla}(\boldsymbol{\nabla} \cdot \mathbf{u}), \quad (8b)$$

where  $\beta = \xi/\eta + 1/3$  incorporates the fluid's volume viscosity,  $\xi^{14,27}$ .

In the absence of sound waves, the fluid medium is quiescent,  $\mathbf{u} = 0$ , and has uniform pressure  $p_0$ , and uniform density,  $\rho_0$ . An acoustic levitator projects a time-harmonic pressure wave,  $p_{inc}(\mathbf{x},t) = p_{inc}(\mathbf{x}) \exp(-i\omega t)$ , into the fluid. The droplet scatters a portion of  $p_{inc}$  to create a scattered wave,  $p_{scat}(\mathbf{x},t) = p_{scat}(\mathbf{x}, \{\mathbf{X}_j\}) \exp(-i\omega t)$ , that depends on the position and shape of the droplet. The incident and scattered waves together cause small pressure fluctuations,  $p_1(\mathbf{x}) = p_{inc}(\mathbf{x}) + p_{scat}(\mathbf{x})$ , about  $p_0$ . This first-order pressure wave is associated with a first-order density wave,  $\rho_1(\mathbf{x})$ , and a first-order velocity field,  $\mathbf{u}_1(\mathbf{x})$ , that are obtained by expanding Eq. (8) to first order in the fields.

Acoustic levitators typically operate at such high frequencies that the period of  $p_1(\mathbf{x},t)$  is much shorter than the viscous and inertial time scales that govern droplet dynamics and streaming flows. Those comparatively slow processes emerge as averages over multiple acoustic cycles. Because the firstorder fields are harmonic and therefore vanish on average, standard acoustic perturbation theory<sup>9</sup> expands the density, pressure and velocity fields to second order:

$$\boldsymbol{\rho} = \boldsymbol{\rho}_0 + \boldsymbol{\rho}_1 + \boldsymbol{\rho}_2 \tag{9a}$$

$$p = p_0 + p_1 + p_2$$
 (9b)

$$\mathbf{u} = \mathbf{u}_1 + \mathbf{u}_2. \tag{9c}$$

The second-order fields,  $\rho_2$ ,  $p_2$  and  $\mathbf{u}_2$ , do not vanish on average, and therefore describe steady dynamics that persist on hydrodynamic timescales and therefore account for the droplet's macroscopic behavior.

We extend the IBM to incorporate sound waves by identifying the time-averaged acoustic radiation force on each element of the droplet surface<sup>6,7,9,28,29</sup>:

$$\mathbf{F}_{i}^{ARF}(t) = -\langle p_{2} \rangle \, \hat{\mathbf{n}} - \rho_{0} \langle (\mathbf{u}_{1} \cdot \hat{\mathbf{n}}) \, \mathbf{u}_{1} \rangle \,, \tag{10}$$

where the continuous fields are evaluated at  $\mathbf{x} = \mathbf{X}_i$  and angle brackets represent an average over one acoustic cycle. The first term on the right-hand side of Eq. (10) describes acoustic radiation pressure, and the second term arises from advection of fluid by the droplet's oscillating boundary<sup>7,28</sup>.

The net force on the boundary marker at  $X_i$ ,

$$\mathbf{F}_{i}(t) = \mathbf{F}_{i}^{ST}(t) + \mathbf{F}_{i}^{ARF}(t), \qquad (11)$$

is the sum of the surface tension from Eq. (7) and the timeaveraged acoustic force from Eq. (10). The interfacial force drives streaming flows,  $\langle \mathbf{u}(\mathbf{x}_j,t) \rangle = \mathbf{u}_2(\mathbf{x},t)$ , and shape deformations,  $\partial_t \mathbf{X}_i = \mathbf{U}_i$ , through the cycle depicted in Fig. 2. This extension to the incompressible IBM is one of the principal contributions of the present work. Its implementation requires expressions for the first- and second-order fields.

## A. First-Order Equations for the Acoustic Wave

The first-order Navier-Stokes equations,

$$\partial_t \rho_1 = -\rho_0 \, \boldsymbol{\nabla} \cdot \mathbf{u}_1 \tag{12a}$$
$$\rho_0 \, \partial_t \mathbf{u}_1 = -\boldsymbol{\nabla} p_1 + \eta \, (\boldsymbol{\beta} + 1) \, \boldsymbol{\nabla} (\boldsymbol{\nabla} \cdot \mathbf{u}_1)$$

$$-\eta \, \boldsymbol{\nabla} \times \boldsymbol{\nabla} \times \mathbf{u}_1, \tag{12b}$$

can be simplified to a pair of wave equations,

$$\nabla^2 \phi = -\frac{k^2}{\gamma} \phi \tag{13a}$$

$$\nabla \times \nabla \times \boldsymbol{\psi} = k_{\nu}^2 \boldsymbol{\psi}, \qquad (13b)$$

by introducing the Helmholtz decomposition,

$$\mathbf{u}_1(\mathbf{r}) = \boldsymbol{\nabla}\boldsymbol{\phi} + \boldsymbol{\nabla} \times \boldsymbol{\psi}, \qquad (14a)$$

$$p_1(\mathbf{r}) = \frac{i\omega\rho_0}{\gamma}\,\phi(\mathbf{r}),\tag{14b}$$

and noting that  $p_1(\mathbf{r}) = c_0^2 \rho_1(\mathbf{r})$  in an isentropic fluid medium with speed of sound  $c_0$ . Equation (13a) describes a scalar pressure wave that propagates with the acoustic wavenumber,  $k = \omega/c_0$ . Likewise, Eq. (13b) describes vortical waves that carry away the acoustic energy lost to viscous damping. The acoustic damping coefficient,

$$\gamma = 1 + (\beta + 1) \left(\frac{k}{k_{\nu}}\right)^2, \tag{15}$$

and the viscous wave number,

$$k_{\nu} = \frac{1+i}{\delta},\tag{16}$$

are both characterized by the thickness of the viscous boundary layer<sup>27</sup>,

$$\delta(\omega) = \sqrt{\frac{2\eta}{\rho_0}} \frac{1}{\omega}.$$
 (17)

Following conventional acoustic radiation theory<sup>5,27</sup>, we neglect viscosity in the first-order fields, so that  $\gamma \approx 1$  and  $\psi \approx 0$ . The solution to Eq. (13) can then be found by a multipole expansion of  $\phi(\mathbf{r})$  both inside and outside the droplet<sup>30</sup>,

$$\phi_{\mathbf{I}}(\mathbf{r}) = \phi_0 \sum_{\ell=0}^{\infty} \sum_{m=-\ell}^{\ell} b_{\ell}^m j_{\ell}(k_{\mathbf{I}}r) P_{\ell}^m(\cos\theta) \quad \text{and}$$
(18a)

$$\phi_{\rm O}(\mathbf{r}) = \phi_0 \sum_{\ell=0}^{\infty} \sum_{m=-\ell}^{\ell} a_{\ell}^m [j_{\ell}(kr) + s_{\ell}^m h_{\ell}(kr)] P_{\ell}^m(\cos\theta), \quad (18b)$$

respectively, where  $j_{\ell}$  and  $h_{\ell}$  are the spherical Bessel and Hankel functions, respectively, and  $P_{\ell}^m$  is the associated Legendre polynomial. Distances in Eq. (18a) are scaled by the wavenumber inside the droplet,  $k_{\rm I} = \omega/c_{\rm I}$ .

The beam-shape coefficients,  $a_{\ell}^m$ , depend on the structure of the incident sound wave, which typically is known *a priori*. The scattering coefficients,  $s_{\ell}^m$  and  $b_{\ell}^m$ , are obtained by satisfying boundary conditions at the droplet surface,

$$p_{\rm I} = p_{\rm O}$$
 and (19a)

$$\mathbf{u}_{\mathrm{I}} \cdot \hat{\mathbf{n}} = \mathbf{u}_{\mathrm{O}} \cdot \hat{\mathbf{n}}. \tag{19b}$$

For a spherical droplet of radius R, which is the simplest case, the scattering coefficients reduce to

$$b_{\ell}^{m} = \tilde{\rho} a_{\ell}^{m} \left[ \frac{j_{\ell}(kR)}{j_{\ell}(k_{I}R)} + s_{\ell}^{m} \frac{h_{\ell}(kR)}{j_{\ell}(k_{I}R)} \right] \quad \text{and}$$
(20a)

$$s_{\ell}^{m} = -\frac{\tilde{\rho}\tilde{c}\,j_{\ell}(kR)\,j_{\ell}'(k_{\rm I}R) - j_{\ell}(k_{\rm I}R)\,j_{\ell}'(kR)}{\tilde{\rho}\tilde{c}\,h_{\ell}(kR)\,j_{\ell}'(k_{\rm I}R) - j_{\ell}(k_{\rm I}R)\,h_{\ell}'(kR)},\tag{20b}$$

where  $\tilde{\rho} = \rho_{\rm O}/\rho_{\rm I}$  and  $\tilde{c} = k_{\rm I}/k = c_{\rm O}/c_{\rm I}$ , and primes denote derivatives with respect to the argument. In the special case  $\tilde{c} = 1$ , the scattering coefficients simplify further to

$$b_{\ell}^{m} = \tilde{\rho} a_{\ell}^{m} \left[ 1 + s_{\ell}^{m} \frac{h_{\ell}(kR)}{j_{\ell}(kR)} \right] \quad \text{and} \tag{21a}$$

$$s_{\ell}^{m} = -\frac{\rho - 1}{\tilde{\rho}\frac{h_{\ell}(kR)}{j_{\ell}(kR)} - \frac{h_{\ell}'(kR)}{j_{\ell}'(kR)}}.$$
(21b)

Equations (20) and (21) serve as a point of departure for describing scattering by aspherical droplets.

#### B. Second-Order Equations for Time-Averaged Dynamics

The first-order incident and scattered sound waves together give rise to steady forces and flows at second order. The steady, time-averaged second-order Navier-Stokes equations,

$$-\boldsymbol{\nabla}\cdot\langle\boldsymbol{\rho}_{1}\boldsymbol{u}_{1}\rangle=\boldsymbol{\rho}_{0}\langle\boldsymbol{\nabla}\cdot\boldsymbol{u}_{2}\rangle \tag{22a}$$

$$\langle \boldsymbol{\rho}_1 \partial_t \mathbf{u}_1 + \boldsymbol{\rho}_0 (\mathbf{u}_1 \cdot \boldsymbol{\nabla}) \mathbf{u}_1 \rangle = -\boldsymbol{\nabla} \langle \boldsymbol{p}_2 \rangle + \boldsymbol{\eta} \boldsymbol{\nabla}^2 \langle \mathbf{u}_2 \rangle + \boldsymbol{\beta} \boldsymbol{\eta} \boldsymbol{\nabla} \langle \boldsymbol{\nabla} \cdot \mathbf{u}_2 \rangle,$$
 (22b)

reduce to

$$-\boldsymbol{\nabla}\langle p_2 \rangle + \boldsymbol{\eta} \, \boldsymbol{\nabla} \times \langle \boldsymbol{\nabla} \times \mathbf{u}_2 \rangle = \mathbf{f}_R \tag{23}$$

in the limit that the fluid is incompressible,  $\langle \nabla \cdot \mathbf{u}_2 \rangle = 0^{31}$ . The Reynolds stress that drives the flow,

$$\mathbf{f}_{R}(\mathbf{r}) \equiv \rho_{0} \boldsymbol{\nabla} \cdot \langle \mathbf{u}_{1} \mathbf{u}_{1} \rangle, \qquad (24)$$

is obtained from the first-order solution. The acoustic radiation pressure,  $\langle p_2 \rangle$ , and vortical acoustic streaming,  $\langle \nabla \times \mathbf{u}_2 \rangle$ , are given by the irrotational and solenoidal components of  $\mathbf{f}_R$ , respectively. The latter term vanishes because we neglect viscosity in the first-order fields, which means that  $\mathbf{u}_1(\mathbf{r}) = \nabla \phi$  and therefore that the Reynolds stress is irrotational. Consequently, the viscous flows described by the second term on the left-hand side of Eq. (23) vanish. From this, we conclude that the radiation pressure is<sup>9,16</sup>

$$\langle p_2 \rangle = \frac{1}{2} \rho_0 \langle u_1^2 \rangle - \frac{1}{2} \kappa_0 \langle p_1^2 \rangle, \qquad (25)$$

where  $\kappa_0 = (\rho_0 c_0^2)^{-1}$  is the isentropic compressibility of the fluid. The second-order pressure wave depends on the squares of the first-order fields and therefore does not vanish on an average over the acoustic period. It nevertheless can vary on inertial time scales.

When the boundary layer is thin,  $\delta(\omega) \ll R$ , Eq. (25) is a good approximation for  $\langle p_2 \rangle$  evaluated at the time-averaged position of the droplet surface, and therefore completes the description of the sound wave required to model the acoustic force acting on the droplet through Eq. (10). While we have neglected viscous streaming due to the Reynolds stress,  $\mathbf{f}_R(\mathbf{r})$ , in Eq. (24), our simulations still have acoustic streaming flows that are driven by the the momentum flux advected by the boundary, which is described by the second term on the right-hand side of Eq. (10).

## C. Acoustic Radiation Force on an Ellipsoid

Together, Eq. (10) and Eq. (25) express the second-order acoustic radiation force on the droplet in terms of first-order acoustic fields. Analytic solutions for these first-order fields are known for certain geometries with high symmetry. More generally, the scattering coefficients in Eq. (18) may be obtained via a variety of semi-analytic techniques. These include the T-matrix method, which has been extended to acoustics by Waterman<sup>18</sup>, the discrete dipole approximation<sup>32</sup>, and modal-matching methods<sup>17,33</sup>. Here, we introduce an alternative approximation scheme that leverages the exact spherical solution and consequently is more efficient when deformations are small.

#### 1. Approximate solutions for slightly aspherical droplets

To leading order, the fields scattered by a slightly aspherical droplet are approximated by the fields scattered by the minimally enclosing sphere. The simple spherical approximation, however, does not satisfy the appropriate boundary conditions for the fluid velocity at the droplet's surface,

$$[\mathbf{u}_O(\mathbf{r}_s) - \mathbf{u}_I(\mathbf{r}_s)] \cdot \hat{\mathbf{n}}(\mathbf{r}_s) = 0$$
(26a)

$$[\tilde{\rho} \mathbf{u}_O(\mathbf{r}_s) - \mathbf{u}_I(\mathbf{r}_s)] \cdot \hat{\mathbf{t}}(\mathbf{r}_s) = 0, \qquad (26b)$$

where  $\hat{\mathbf{t}}$  is the surface tangent unit vector, and  $\hat{\mathbf{t}} \times \hat{\mathbf{n}} = 0$ . Taking  $\mathbf{U}(\mathbf{r})$  to be the flow field that would be created by the enclosing sphere, the actual flow field at position  $\mathbf{r}_s$  on the surface of the distorted sphere can be approximated by

$$\mathbf{u}_I(\mathbf{r}_s) = \mathbf{U}_I(\mathbf{r}_s),\tag{27a}$$

$$\mathbf{u}_O(\mathbf{r}_s) = \mathbf{U}_O(\mathbf{r}_s) + \boldsymbol{\delta}(\mathbf{r}_s). \tag{27b}$$

FIG. 4. ARF profile from  $\theta \in [0, \pi]$  for ellipsoids of various eccentricities at a displacement from the node of  $z_0 = -0.6 \mu m$ . The ARF at the surface is calculated using the spherical fields from Eq. (21) (blue), the projection correction described in Eq. (26) (orange), and the exact analytic solution in spheroidal coordinates (green).

This flow field satisfies the boundary conditions in Eq. (26) if

$$\boldsymbol{\delta}(\mathbf{r}_s) \cdot \hat{\mathbf{r}} = n_{\theta}(\mathbf{r}_s) \left(1 - \frac{1}{\tilde{\rho}}\right) \mathbf{U}_I(\mathbf{r}_s) \cdot \hat{\mathbf{t}}(\mathbf{r}_s), \quad \text{and} \quad (28a)$$

$$\boldsymbol{\delta}(\mathbf{r}_{s}) \cdot \boldsymbol{\hat{\theta}} = n_{\boldsymbol{\theta}}(\mathbf{r}_{s}) \left(1 - \frac{1}{\tilde{\rho}}\right) \mathbf{U}_{I}(\mathbf{r}_{s}) \cdot \mathbf{\hat{n}}(\mathbf{r}_{s}), \quad (28b)$$

where  $n_{\theta} \equiv \mathbf{\hat{n}}(\mathbf{r}_s) \cdot \mathbf{\hat{\theta}}$ .

The velocity field obtained with Eq. (28) does not necessarily satisfy the Helmholtz equation, nor is it necessarily curl-free. Both of these conditions are *approximately* satisfied, however, so long as the droplet's distortions are small,  $n_{\theta} \ll 1$ . Moreover,  $\mathbf{u}(\mathbf{r})$  satisfies the boundary conditions from Eq. (19), and therefore should accurately represent the induced flow near the droplet's surface.

## 2. Comparison to analytic solution for an ellipsoid

We test this approximation scheme on the special case of spheroidal droplets, whose scattering coefficients can be expressed analytically in spheroidal coordinates<sup>30</sup>. The associated spheroidal wave functions are much more costly to evaluate than spherical harmonics, which limits the utility of the analytic solution for time-resolved simulations. Analytic solutions for spheroids are useful, nonetheless, for validating our computationally efficient approximation scheme.

Figure 4 compares analytic and approximated force profiles computed for spheroids of various eccentricities. Each spheroid is taken to be displaced by  $z_0 = -0.6 \mu m$  from the node of a standing wave; the influence of the droplet's displacement is discussed further in Appendix B. The spherical solution,  $\mathbf{u}_O(\mathbf{r}_s) = \mathbf{U}_O(\mathbf{r}_s)$ , plotted in blue, has qualitatively different behavior from the true solution, plotted in green, even at small deformations. By contrast, the corrected solutions,  $\mathbf{u}_O(\mathbf{r}_S) = \mathbf{U}_O(\mathbf{r}_S) + \boldsymbol{\delta}(\mathbf{r}_S)$ , plotted in orange, agrees with analytic radiation force for moderate deformations. The normal component of the computed force tracks the functional form of the exact solution up to a reasonably small multiplicative factor. This discrepancy should not significantly affect the shape or dynamics of the droplet, which is assumed to be incompressible. Agreement with the analytic solution is much better for the tangential forces, which are responsible for driving acoustic streaming flows in our simulations. The hybrid IBM therefore should predict the structure of streaming flows far more accurately than the simple spherical approximation, and far more efficiently than the analytic solution. A further discussion of limitations of Eq. (28) is provided in Appendix B.

## IV. RESULTS: DROPLET IN A STANDING PLANE WAVE

Section II introduces an IBM that models the dynamics of a droplet suspended in a fluid under the general influence of external forces. Section III explains how sound propagating through the fluid generates such forces. Purely analytic solutions to the sound-driven moving-boundary problem are not yet available. Any purely numerical description of the sound wave<sup>34,35</sup> would have to iterate through an enormous range of time scales to capture the moving droplet's steady dynamics. Our hybrid implementation describes the sound wave semianalytically and handles the moving-boundary problem numerically. The result is an accurate and exceptionally efficient implementation.

We demonstrate the efficacy of the hybrid IBM with an illustrative model system: a single droplet levitated in a planar acoustic standing wave. To set up the IBM for this system, we specify the standing wave's scalar potential,

$$\phi_i(\mathbf{r}) = \phi_0 \sin(kz), \tag{29}$$

with amplitude  $\phi_0$  and a nodal plane at z = 0. The associated beam-shape coefficients<sup>6</sup>,

$$a_{\ell}^{m} = (2\ell+1)\cos\left(kz + \frac{\ell\pi}{2}\right). \tag{30}$$

yield a compact expression for the the net ARF on the droplet:

$$\sum_{i=0}^{N_b} \mathbf{F}_i^{ARF} = \frac{1}{2} \rho_0 \phi_0^2 Q \sin(2kz) \,\hat{z},\tag{31}$$

where the radiation force efficiency, Q, is a dimensionless scattering coefficient that depends on droplet geometry and boundary conditions<sup>5,6</sup>. For a rigid sphere in a standing wave,  $Q = k^3 V_p / 5^6$ , and  $V_p$  is the volume of the particle. The scale of the acoustic force,  $\frac{1}{2}\rho_0\phi_0^2$ , is set by the driving voltage in experimental realizations<sup>5</sup>.

The simulations described in this section all start with a spherical droplet of radius  $R = 2\mu m$  and density  $\rho_I =$ 1.18 g cm<sup>-3</sup>, dispersed in water. The droplet is subject to a buoyant force,  $F_g = (\rho_I - \rho_0) V_p g \approx 60 \text{ pN}$ , that is balanced by acoustic forces. To model practical acoustic levitators for water-borne samples<sup>5</sup>, the driving frequency is set to 2 MHz. The dimensionless size parameter, kR = 0.034, is well within the Rayleigh limit,  $kR \ll 1$ . The droplet initially is released at the nodal plane, and then relaxes to its equilibrium position,  $z_0$ , and to its equilibrium shape.

## A. Separation of Timescales

Modelling a levitated droplet illustrates the advantages of our hybrid method relative to conventional numerical techniques. The acoustic IBM presented in Ref.<sup>8</sup>, for example, computes the influence of acoustic forces by directly solving the compressible Navier-Stokes equations using a 5thorder Weighted Essentially Non Oscillatory (WENO) scheme. When applied to a system that is comparable to ours<sup>34</sup>, the WENO scheme numerically resolves acoustic wave propagation with timestep  $dt \approx R/c \approx 1.33$  ns. By treating acousticscale processes semi-analytically, the hybrid IBM can resolve the droplet's dynamics with time steps of 15 µs, which represents an inherent ten-thousand-fold improvement in efficiency.

## B. Equilibrium Shape of a Levitated Droplet

The equilibrium shape of a droplet in an acoustic field is typically found analytically<sup>36,37</sup> by relating the surface curvature to acoustic stresses with the Young-Laplace formula. Working in two dimensions, the equilibrium shape of a slightly deformed droplet of radius R may be expanded in associated Legendre polynomials<sup>15</sup>,

$$r(\boldsymbol{\theta}) = R + \sum_{\ell=0}^{\infty} \sum_{m=-\ell}^{\ell} x_{\ell m} P_{\ell}^{m}(\cos \boldsymbol{\theta}).$$
(32)

When the droplet has the same viscosity as the medium, the normal force,  $F_n(\theta) = \mathbf{F}^{ARF} \cdot \hat{n}$ , determines the static shape deformation<sup>15,38</sup>,

$$x_{\ell m} = \frac{R^2}{(\ell+2)(\ell-1)\sigma} \int_{-1}^{1} F_n(\theta) P_\ell^m(\cos\theta) d\cos\theta.$$
(33)

In a standing wave, the primary deformation mode is described by  $x_{20}$ , which flattens the droplet into a roughly elliptical shape. Figure 7 compares the value for  $x_{20}$  observed in IBM simulations of a droplet of  $R = 2 \,\mu\text{m}$  with predictions of Eq. (33) over a range of values of surface tension,  $\sigma$ , and trap strength,  $\phi_0^2$ . The computed deformation agrees well for droplets close to the trapping plane, and deviates at larger displacements from the node. This is because our approximation for scattering, Sec. III C 1, begins to break down at larger displacements from the node.

FIG. 5. Streaming profiles for a droplet levitated in water with  $\sigma = 3.3 \text{ nN}\mu\text{m}^{-1}$  and  $R = 2\mu\text{m}$  at various trap strengths. (a) Gravity displaces the droplet downward from the nodal plane, favoring quadrupolar streaming in the weakest levitator. (b) Increasing trap strength induces a crossover to dipolar streaming. (c) Increasing trap strength further induces a second crossover to quadrupolar flow. The flow's vorticity is indicated by color.

FIG. 6. Streamlines of the streaming flow for a droplet of radius  $R = 2\mu m$  in a strong levitator,  $z_0 \approx -0.15\mu m$ . (a) Reducing the surface tension,  $\sigma$ , by half relative to Fig. 5 allows the droplet to deform while retaining quadrupolar flows. (b) Further reducing surface tension increases the droplet's distortion while significantly decreasing the vorticity in the streaming flow. (c) A highly deformable droplet induces dipolar streaming flows.

## C. Acoustic Streaming

Acoustic forces not only translate and deform the droplet, but also generate interior and exterior streaming flows. In the case of a spherical droplet, these flow fields can be described analytically. The streaming profiles for an acoustically levitated droplet are characterised by a transition from dipolar flow to quadrupolar flow depending on the relative magnitude of acoustically-driven pulsation and translation modes respectively<sup>14</sup>. The streaming behavior depends on properties of the droplet and surrounding fluid, and can also be manipulated directly by adjusting the sound intensity,  $\phi_0^2$ , of the trap to control the droplet's position relative to the node.

## 1. Spherical Droplet

The streaming profiles around a spherical droplet have been computed analytically by Baasch, Doinikov, and Dual in Ref.<sup>14</sup>. Their solution should be comparable to results of the hybrid IBM under conditions where shape deformations are small, *i.e.*  $\sigma R \gg \rho_0 \phi_0^2$ . The results in Fig. 5 are obtained by fixing the surface tension at a fairly large value,  $\sigma = 3.3 \text{ nN} \mu \text{m}^{-1}$ , and varying the trap strength,  $\phi_0^2$ . Because the droplet is more dense than its medium, it sinks below the nodal plane by a distance that is inversely proportional to the traps' strength and therefore samples different regions of the acoustic force landscape. This has consequences for the na-

FIG. 7. Dependence of a droplet's degree of deformation on the relative strength of the acoustic driving. Outliers represent droplets that were not stably trapped.

ture of the induced streaming flow.

Figure 5(a) shows the quadupolar streaming flow that is induced when the droplet is far below the nodal plane in a comparatively weak acoustic trap. Increasing  $\phi_0$  by a factor of 3 in Fig. 5(b) lifts the droplet toward the nodal plane and qualitatively transforms the streaming flow into a principally dipolar motif. This transition from quadrupolar to dipolar flow has been with increasing trap stiffness has been predicted analytically and is reported in Fig. 7 of Ref. [14]. Further increasing the trap stiffness in Fig. 5(c) lifts the particle still closer to the nodal plane and induces second transition back to quadrupolar streaming that appears not to have been reported previously.

## 2. Deformable Droplets

Both dynamical transitions reported in Fig. 5 occur for droplets that are stiff enough to remain substantially spherical while trapped. This is consistent with the assumption of sphericity that underlies the analysis in Ref.<sup>14</sup>. Figure 6 reveals yet another dynamical transition that occurs when a strongly-trapped droplet is soft enough to deform, a scenario that has not been considered in previous studies. The droplet in Fig. 6(a) is comparable to the droplet in Fig. 5(c), except that its surface tension is smaller by a factor of two. The droplet consequently deforms into an ellipsoid under the uniaxial stress of the acoustic levitator and settles at a slightly different height relative to the nodal plane. The induced streaming flow nevertheless retains its quadrupolar nature.

Reducing the surface tension, in Fig. 6(b), increases the distortion and moves both the interior and exterior circulation closer to the droplet surface. Reducing the surface tension still further, in Fig. 6(c), suppresses the vortex structure entirely.

The streaming flow around the ellipsoid droplet is primarily dipolar. This deformation-induced dynamical transition also appears not to have been observed in prior studies. These observations illustrate the value of the hybrid IBM for probing the dynamical properties of insonated droplets.

## V. DISCUSSION

We have introduced a hybrid immersed boundary method that efficiently models the stresses on acoustically levitated droplets and the surrounding fluid. We have validated our method by simulating a single droplet in a plane standing wave, and comparing the results with the best available analytical and numerical solutions. Even in this minimal system, the hybrid IBM reveals transitions between dipolar and quadrupolar streaming under strong-driving conditions that have not been reported in previous studies. These observations offer new insights into the response of deformable droplets to the forces and torques created by acoustic landscapes.

Compared to traditional compressible flow simulations, our hybrid method cuts computational cost by utilizing semianalytic techniques to accommodate acoustic scattering in hydrodynamic simulations. The benefits are greatest when stress-induced deformations are small enough that analytic scattering calculations can be carried out rapidly. When the droplet shape is highly irregular and unpredictable, most known semi-analytic techniques converge slowly and may be prohibitively expensive. However, for droplets with small to moderate deformations, the hybrid IBM may be up to three orders of magnitude faster than compressible flow simulations. For the implementation presented here, the hybrid method efficiently and effectively models complex shape deformations and streaming profiles around a single droplet, and can easily be scaled up to study acoustohydrodynamic interactions among multiple particles.

The framework presented here is, by design, extremely flexible. If necessary, the accuracy of the hybrid IBM can be improved by introducing more advanced scattering solutions for Eq. (18), implementing viscous waves from Eq. (13b), or even adding additional pairwise acoustic forces, like the Bjerknes force<sup>5</sup>. Or, as in this work, inexpensive approximations can be used throughout to efficiently model qualitative behaviors.

We are grateful to professor Charles Peskin for extensive discussions on the formulation of the Immersed Boundary Method.

## DATA AVAILABILITY

The data that support the findings of this study are available from the corresponding author upon reasonable request.

FIG. 8. Normal and tangential components of the acoustic radiation force as a function of position,  $\theta$ , on the droplet surface for ellipsoids of various eccentricities. (a) moderate displacement:  $z_0 = -3.5 \,\mu\text{m}$ . (b) larger displacement:  $z_0 = -10.6 \,\mu\text{m}$ . The ARF at the surface is calculated using the spherical fields from Eq. (21) (blue), the projection correction described in Eq. (26) (orange), and the exact analytic solution in spheroidal coordinates (green).

#### Appendix A: Flows around a sedimenting spherical droplet

Analytic solutions are available for the viscous flow fields inside and around a spherical fluid droplet as it moves with with velocity  $\mathbf{v} = v\hat{z}$  through an immiscible fluid<sup>26</sup>. Assuming that the two fluids have the same viscosity, the stream functions inside and outside the droplet are

$$\boldsymbol{\psi}^{(i)}(\mathbf{r}) = \frac{1}{8} v r^2 \left(\frac{r^2}{a_p^2} - 1\right) \sin^2 \theta, \quad \text{and} \qquad (A1)$$

$$\Psi^{(o)}(\mathbf{r}) = \frac{1}{8} v \frac{a_p^3}{r} \left( 1 - 5 \frac{r^2}{a_p^2} \right) \sin^2 \theta,$$
 (A2)

respectively. The associated flow field is

$$\mathbf{u}(\mathbf{r}) = \boldsymbol{\nabla} \times (\boldsymbol{\psi}\hat{z}). \tag{A3}$$

# Appendix B: Applicability of the Scattering Approximation from Sec. III C

The approximation in Sec. III C is derived by assuming that the acoustic fields at the droplet surface,  $r = S(\theta)$ , are similar to that at a minimally enclosing sphere,  $r = R \equiv \max[S(\theta)]$ . The interior potential from Eq. (18a) can be rewritten by Taylor expanding the radial function to 1st order in S - R,

$$j_{\ell}(kS) = j_{\ell}(k_{\rm I}R) + (S-R)kj'_{\ell}(k_{\rm I}R) + \mathcal{O}\{(S-R)^2\}$$

In the long-wavelength limit,  $kR \ll 1$ , we can use the smallargument asymptotic form  $j_{\ell}(z) \propto x^{\ell}$ , and so we have

$$j_{\ell}(kS) = \left[1 + \ell\left(\frac{S}{R} - 1\right)\right] j_{\ell}(k_{\mathrm{I}}R) + \mathscr{O}\{(S - R)^2\}$$

so that  $\phi_I(R) \approx \phi_I(S)$  as long as

$$\left(\frac{S}{R}-1\right) \ll \frac{1}{\ell}$$

for all non-negligible modes. Likewise, repeating this procedure for the scattered field reveals that  $\phi_s(R) \approx \phi_s(S)$  when  $(\frac{S}{R}-1) \ll 1/(\ell+1)$ .

Because the error in the radial function is also proportional to  $\ell$ , higher modes are approximated more accurately than lower modes. Consequently, the applicability of this method also depends on the local structure of the acoustic field. In this work, we have shown in Fig. 4 that our approximation performs well even at moderately large deformations, when the droplet is close to the node. However, as illustrated by Fig. 8, the range of validity is restricted to smaller deformations when the droplet is farther away from the node.
