

# Cognitively Biased Users Interacting with Algorithmically Biased Results in Whole-Session Search on Controversial Topics

BEN WANG and JIQUN LIU, The University of Oklahoma, USA

When interacting with information retrieval (IR) systems, users, affected by confirmation biases, tend to select search results that confirm their existing beliefs on socially significant contentious issues. To understand the judgments and attitude changes of users searching online, our study examined how *cognitively biased* users interact with *algorithmically biased* search engine result pages (SERPs). We designed three-query search sessions on debated topics under various bias conditions. We recruited 1,321 crowdsourcing participants and explored their attitude changes, search interactions, and the effects of confirmation bias. Three key findings emerged: 1) most attitude changes occur in the initial query of a search session; 2) confirmation bias and result presentation on SERPs affect search behaviors in the current query and perceived familiarity with clicked results in subsequent queries. The bias position also affect attitude changes of users with lower perceived openness to conflicting opinions; 3) Interactions in the first query and dwell time throughout the session are associated with users' attitude changes in different forms. Our study goes beyond traditional simulation-based evaluation settings and simulated rational users, sheds light on the mixed effects of human biases and algorithmic biases in controversial information retrieval tasks, and can inform the design of *bias-aware* user models, human-centered bias mitigation techniques, and socially responsible intelligent IR systems.

CCS Concepts: • **Information systems** → **Users and interactive retrieval**.

Additional Key Words and Phrases: confirmation bias, information retrieval, whole-session search, search evaluation, bias reinforcement and mitigation

Ben Wang and Jiqun Liu. 2024. Cognitively Biased Users Interacting with Algorithmically Biased Results in Whole-Session Search on Controversial Topics. 1, 1 (March 2024), 21 pages. <https://doi.org/10.1145/nnnnnnn.nnnnnnn>

## 1 INTRODUCTION

In contrast to the assumptions of most formal user models, information searchers are *boundedly rational* and their judgments and search behaviors are often affected by both *system biases* and their *cognitive biases* [39]. When encountering information involving multiple or contradicting perspectives, people tend to accept the information that is consistent with their own beliefs [73], leading to higher risks of opinion polarization and misinformation spreading [4, 44]. This preference for confirming existing opinions is called *confirmation bias* [48]. This bias was also observed in interactive information retrieval (IIR) research, with users frequently clicking attitude-confirmation results while avoiding attitude-disconfirming results [73–75]. Such interactions may reinforce users' existing opinions due to the *exposure effect*, depending on the amount of time and frequency of the interactions on a specific opinion [5, 19]. Consequently, this effect may lead to biased judgments and unfair decisions, and further generate biased training data for search systems, which may aggravate societal biases through personalized retrieval and recommendations [25, 53, 54].

1

However, most studies only considered human biases in ad hoc retrieval and isolated document evaluation contexts [e.g., 19, 57, 61, 75]. The single-query session considers each search as a standalone query but ignores users' interactions and cognitive changes in prolonged task-driven search sessions [43]. However, the effects of confirmation bias in *multi-query* sessions on users' attitudes or search interactions still remains understudied. In addition, as mainstream research tend to examine human bias and algorithmic bias *separately* (with human biases being studied in user studies, while algorithmic bias mainly being investigated in simulation-based experiments), it is not clear how cognitively biased users would react to and make judgments under biased SERPs.

Inspired by previous work on user attitudes and interactions in searching debated topics [19, 57], this study designed a simulated three-query search session under various *bias conditions*. The bias condition is represented by the result presentations on SERPs (i.e., manipulated ranks, amounts, or obfuscation of opinionated results on SERPs) and the combinations of SERP conditions in the three-query session. We conducted a crowdsourcing study and assigned participants to different bias conditions for between-subjects experiments. We investigated users' attitude changes, search interactions, and confirmation bias effects in multi-query search sessions.

Our study defined and investigated two types of *within-session* attitude changes, including the **accumulative attitude change**, defined as the absolute sum of the differences between *pre-* and *post-query* attitudes; and the **directional attitude change**, defined as the difference between preexisting and the most recent post-query attitudes, considering the preexisting attitude's direction. Initially, we explored the nature of within-session attitude changes, focusing on their relationships with user characteristics and query-wise attitude changes (i.e., differences between pre- and post-query attitudes). Subsequently, we examined how confirmation bias influences search interactions and attitude changes. We analyzed the effects of SERP conditions, including *within-query effects* (the immediate impact on the current query) and *between-query effects* (the extended impact of previous queries on a subsequent query) on search interactions. Additionally, we examined how bias levels and the sequence position of biased SERPs in the session affect attitude changes. Finally, we investigated the relationships between attitude changes and search contexts, and measured the feature importance in attitude change predictions. Our findings are threefold:

- Users' most attitude changes occur in the first query in a search session, while their search interactions in the second and third queries also affect their attitude changes in a nonlinear manner.
- Confirmation bias and algorithmically biased SERP presentation affect users' search interactions in the current query and their perceived familiarity with clicked results in subsequent queries. Users with lower perceived openness (i.e., a self-reported value about reactions to conflicting opinions) are more susceptible to directional attitude changes when influenced by the sequence position of biased queries.
- Users' attitude changes tend to be linearly correlated with their interactions in the first query, and tend to have a nonlienaar association with their time-based behaviors, suggesting different mechanisms of exposure effect.

Overall, these findings enhanced our knowledge about biases on both human and system sides at the session-level. Our study urges search system designers to consider user characteristics and result presentation to effectively intervene users' search behaviors and prevent bias reinforcement. Our study further underscores the need for responsible and transparent application of implementing bias mitigation strategies, emphasizing the importance of prioritizing users' well-being and providing accurate and unbiased information.

## 2 RELATED WORK

To solidify the justification for our work, this section introduces previous research on cognitive biases [e.g. 32, 66], especially confirmation bias, as well as algorithmic bias and mitigation in IR.

### 2.1 Confirmation Bias in IR

During the information searching process, human cognitive biases can significantly affect the quality of search results, making them less effective and accurate, and further affect the success of whole-session search tasks [5, 28, 29, 38, 46, 49, 59, 76]. IR researchers have investigated these biases to understand seemingly irrational decisions in users' search activities and perceptions of search results [e.g. 5, 20, 38]. Previous studies showed that certain cognitive biases, stemming from preexisting beliefs or ongoing search sessions, can influence user behaviors, perceptions of the relevance and usefulness of search results, and their whole-session satisfaction levels [40]. Some prominent biases include anchoring bias [11, 64], reference-dependent effects [10, 40], user expectations [42, 69, 70], and confirmation biases [73, 74].

*Confirmation bias* is one of the most common cognitive biases that users face, which refers to the tendency to search for, interpret, and remember information that confirms one's preexisting beliefs or attitudes [48]. This bias can occur in searches on debated or controversial topics and shape users' opinions and search behaviors [36, 73]. White and his colleagues [74, 75] have conducted several studies on belief dynamics and biases in web search, and their findings indicate that confirmation bias can persist even when users were presented with evidence that contradicts their beliefs. Pothirattanachaikul et al. [53] conducted a study to investigate the effects of document opinion and credibility on confirmation bias in IR. They found that users were more likely to click on search results that confirmed their preexisting beliefs and attitudes, and the document opinion and credibility also affected their beliefs. Draws et al. [19] designed different ranking conditions and analyzed confirmation bias in searching debated topics. They recruited participants with neutral opinions, examined their actively open-minded thinking, and explored whether user cognitive engagement (e.g., willingness, inclusiveness, tolerance) would increase their attitude changes, as reported in previous research [50, 68, 74]. Although their results did not reveal any differences in attitude changes among the ranking conditions or user groups, they suggested potential exposure effects on attitude changes. The exposure effect depends on the amount of time and frequency a user is exposed to a specific opinion, which may reinforce their attitudes toward that opinion [5].

### 2.2 Bias Reinforcement And Mitigation

The effect of confirmation bias in IR can have a complex process and significant consequences. Firstly, users might be exposed to biases in search results with algorithmic biases originated from the training data and retrieval algorithms (e.g., presenting results with ranking or diversity bias and information with unfairness and inequity) [23, 35, 65]. Then, users influenced by algorithmic biases or unfair results may form stereotypes and opinionated or polarized beliefs [9, 33, 72]. In addition, users' influenced search behaviors can further generate biased data for the search system, leading to more personalized and biased results. Ghenai et al. [27] conducted a think-aloud study and found that biased search engine results can significantly influence users' decisions based on the majority of the search results. Pogacar et al. [52] conducted an online survey and found that biased search results towards incorrect information can lead to incorrect decisions. Knobloch-Westerwick et al. [34] found that users preferred attitude-consistent messages and high-credibility sources. They also suggested exposure effects of diverse search results on reinforcing or mitigating attitude strength.

Search result diversity plays a vital role in promoting fairness by encompassing a variety of topics and perspectives [24, 26]. This diversity contributes to topical fairness as it ensures that users are exposed to a broad range of information items and viewpoints [71]. Fairness in IR can take different forms, such as demographic parity, which emphasizes equitable presentation of search results for various user groups [65]. In addition, fairness also involves a balanced overview of search results that represents different perspectives on a given topic [16]. Ensuring fairness may require ranking search results to present diverse perspectives in a just and equitable manner [24]. By combining diversity and fairness principles, IR systems can offer users more inclusive and unbiased search experiences.

The diversity becomes more important in multiple-query sessions, where users can interact with different perspectives and subtopics subsequently [55, 56]. In these sessions, a search topic often comprises multiple subtopics or diverse viewpoints, making it essential to promote result diversity. By encouraging exploratory search behaviors through multiple queries, users are potentially exposed to a varied range of information, facilitating more balanced or polarized opinions [8, 29, 30]. Multi-query sessions also provide complex conditions for user acceptance of diverse content [41].

By directly or indirectly manipulating the search result diversity, various strategies have been proposed to mitigate the strength of users' opinions and reduce confirmation bias. Rieger et al. [57] conducted an experiment on participants with moderate to strong preexisting attitudes toward debated topics. They utilized a result obfuscation on the SERP interface and reduced participants' clicks on attitude-confirming results. Draws et al. [18] and Gao and Shah [24] proposed diverse-viewpoint and fairness-aware ranking algorithms that take into account the diversity of search results to create a fairer ranking in search engine results. Pothirattanachaikul et al. [54] found that the "People Also Ask" feature can influence users' search behaviors and perceptions of search results, depending on the user's prior knowledge and attitudes toward the topic.

### 3 RESEARCH QUESTIONS

It is critical to understand and mitigate confirmation bias in IR to avoid negative consequences such as reinforcing polarized biases and perpetuating harmful stereotypes. Presenting diverse perspectives and using unbiased algorithms are potential mitigation strategies. However, there are still gaps in the current research about users' opinion or attitude changes on controversial topics and confirmation bias at the session level. To address this, we designed a three-query session on a simulated search interface about debated topics under various *SERP bias conditions* and conducted a *between-subjects* study with crowdsourcing participants. Specifically, this study aims to answer these research questions (RQs):

**RQ1** : How are users' within-session attitude changes associated with query-wise attitude changes and user characteristics?

**RQ2** : What are the effects of confirmation bias on users' search interactions and within-session attitude changes?

**RQ3** : To what extent are user characteristics and search interactions associated with their within-session attitude changes?

### 4 METHODOLOGY

Figure 1 shows the crowdsourcing study design and analysis for each research question. We designed a three-query search session with combinations of various biased SERP conditions (Tables 1 and 3). We recruited crowdsourcing participants, collected user demographics and characteristics, search interactions (Table 2), and pre- and post-query attitudes toward a debated topic. The rest of this section describes the details on this figure. Section 4.1 defines users'

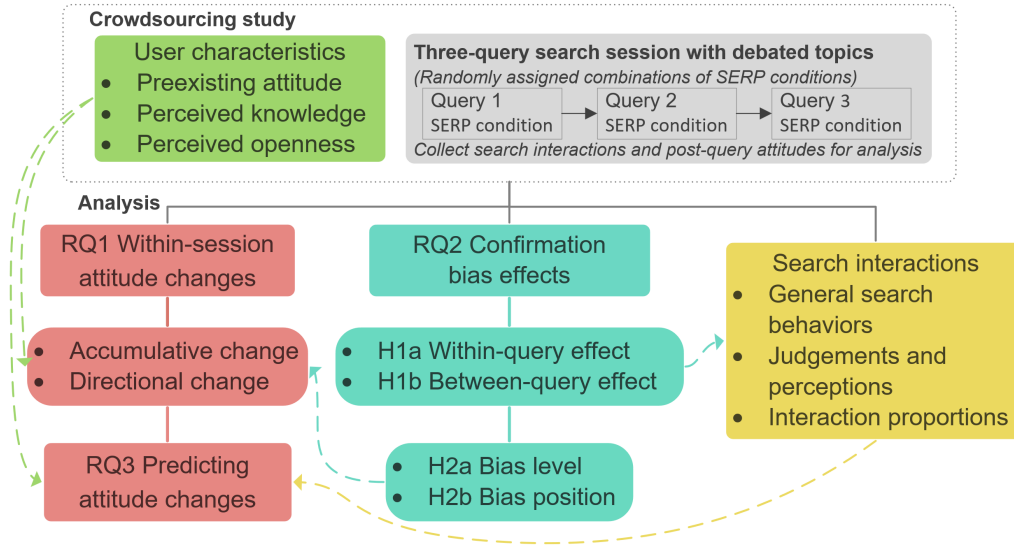

Fig. 1. Study design and analysis framework.

within-session attitude changes and investigates their relationships with query-wise changes and user characteristics. Section 4.2 explains the SERP conditions in a three-query session and investigates the effects of confirmation bias on search interactions and attitude changes. Section 4.3 explores the complex relationships between search interaction features and attitude changes by developing prediction models and investigating the feature importance. Finally, section 4.4 describes the recruitment process and characteristics of crowdsourcing participants.

#### 4.1 Investigating Characteristics of Within-session Attitude Changes

We adopted a method from previous studies to measure users' pre- and post-query attitudes in the scenario of searching debated topics. The topics and opinionated documents are from two public datasets<sup>1</sup> collected by Draws et al. [19] and Rieger et al. [57]. The topics include: (1) Are social networking sites good for our society? (2) Should zoos exist? (3) Is homework beneficial? (4) Should students have to wear school uniforms? Each document has a viewpoint score on a 7-point Likert scale from -3 to +3, representing the **direction** (+: supporting, or -: opposing) and the **strength** (1: somewhat, 2: normally, 3: strongly) towards debated topics. Users' attitudes can be measured on the same scale.

We collected self-reported attitudes at four points: preexisting attitude ( $Q_0$ ) and attitudes after each query ( $Q_1/2/3$ ), and calculated query-wise attitude changes between two consecutive queries ( $Q_{n+1} - Q_n$ ). Furthermore, we calculated two within-session attitude changes, including: *accumulative attitude change*, defined as the sum of absolute query-wise attitude changes, reflecting the total fluctuation of users' attitude; and the *directional attitude change*, defined as the differences between the preexisting attitude and the post-session attitude in the direction of preexisting attitude ( $(Q_3 - Q_0) \cdot \text{direction}$ ), representing the overall reinforcement (or mitigation) on attitude strength. We used "attitude changes" to denote the two within-session attitude changes unless otherwise specified.

<sup>1</sup><https://osf.io/6tbvw/>; <https://osf.io/32wym/>

Table 1. SERP conditions with opinionated documents.

rank	Biased		Bal- (anced)	Mitigated		
	R(ank)	D(iversity)		Counter-R	Counter-D	Obf(uscation)
1	-3	-2	-1	+3	+2	+1
2	-2	-2	+2	+2	+2	[-2]
3	-1	-1	+3	+1	+1	[-3]
4	+1	-3	-2	-1	+3	+2
5	+2	-3	-3	-2	+3	+3
6	+3	-1	+1	-3	+1	-1
7	-2	-2	-2	+2	+2	+2
8	+2	+2	+2	-2	-2	[-2]
9	-2	-2	-2	+2	+2	+2
10	+2	+2	+2	-2	-2	[-2]

The negative numbers represent results with opposing opinions, and the positive numbers represent supporting opinions. The [numbers in brackets] represent the obfuscated results. This table show conditions for users with opposing attitudes, and we have also included conditions for users with supporting attitudes in this study.

To address **RQ1**, we explored the characteristics of the attitude changes via descriptive analysis. First, we compared query-wise and within-session attitude changes. Then, we investigated the correlations between user characteristics and attitude changes. The user characteristics include preexisting attitude strength, perceived prior knowledge level, and perceived openness, self-reported and measured on 7-point Likert scales. The perceived openness is a degree to which participants agree to understand, respect, and be comfortable with a conflicting perspective when debating with others, which can reflect several key aspects of personality traits, such as openness to experience and conflict resolution skills [12].

## 4.2 Investigating Effects of Confirmation Bias

For **RQ2**, we analyzed how the confirmation bias at the session level affect search interactions and attitude changes.

**4.2.1 Within- and between-query effects on search interactions.** We first designed biased SERP conditions with opinionated documents and investigated the effects on search interactions. The SERP conditions designed in this study can reflect biased situations in real search scenarios by simulating different types of biases that search engines might produce, such as the ranking bias (e.g., Figure 2a) and the diversity bias (e.g., Figure 2b), distinguished by the statistical (im)parity [24] to represent conditions when the main bias is from the positions or amount of attitude-confirming results.

Specifically, we organized the opinionated documents under the biased SERP conditions in Table 1, inspired by previous studies that focused on ranking bias [19, 57]. Beyond that, we also designed diversity biased conditions and their counterparts as mitigated conditions. Some SERP examples are illustrated in Figure 2. Basically, the SERP consists of ten (6+4) results. We changed the ranking or constitution of the top six documents to represent different bias levels and keep a fixed order of the rest four because users have the most interactions with the top results. The ranking orders of the balanced (**Bal**) and the ranking biased (**R**) conditions are based on a fairness score calculated by the sum of three metrics: normalized discounted difference (nDD), normalized discounted Kullback-Leibler divergence (nDKL), and normalized ranking bias (nRB) [18, 31], so **Bal** has the lowest bias, and **R** has the highest bias in all ranking permutations. In the diversity biased (**D**) condition, the top six results are all holding the same opinions. Mitigated conditions are counterparts of the ranking and diversity bias conditions (**Counter-R** and **-D**) and targeted obfuscation (**Obf**, illustrated in Figure 2c), which prioritize alternative opinions or obfuscates results with strong opinions to avoid reinforcing users' existing bias [54, 57, 74].

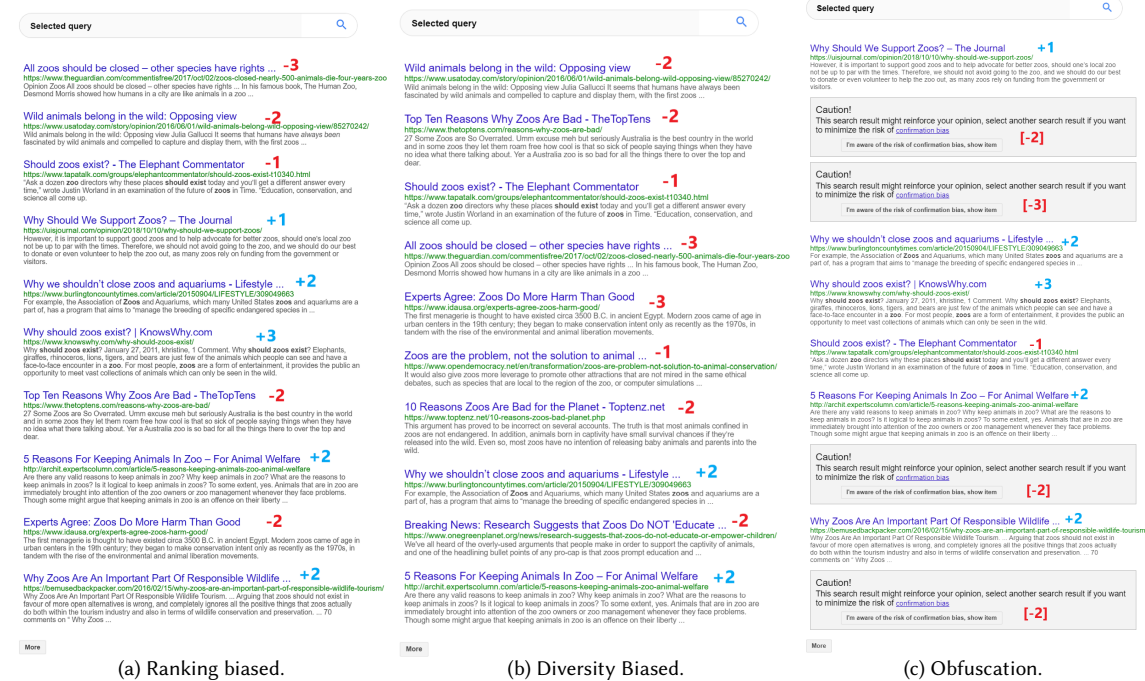

Fig. 2. Simulated SERP interface and examples in this study (The annotations indicate the opinions of the result, which were NOT displayed to participants during the study).

After setting the SERP conditions, we analyzed the effects of confirmation bias on query-level search interactions. These interactions (Table 2) are grouped from three perspectives: general search behaviors for all results, result judgements and perceptions, and *interaction proportions*: the ratio of the general behaviors and judgements on clicked attitude-confirming results to all results. Then, we investigated the effects by analyzing the differences in search interactions among SERP conditions. Under the three-query session, these effects can be investigated at the *within-query* level: the immediate effects on interactions in the current query, and the *between-query* level: extended effects of the previous query on interactions in subsequent query. Specifically, the hypotheses are:

- H1a** : Users' search interactions are likely to be different across SERP conditions in the current query.
- H1b** : Users' search interactions are likely to be different across SERP conditions in previous queries in the session.

For H1a, we examined the differences in search interactions across SERP conditions at the first query to avoid potential effects from previous queries. For H1b, we examined search interactions at the second or third query with a balanced condition to control the current query's SERP condition. We implemented the Kruskal-Wallis test as the non-parametric test to investigate the differences in each feature among these conditions. We utilized the Benjamini-Hochberg method to control the false discovery rate for testing multiple search interaction features. For features with significant differences, we then utilized the Conover-Iman test as the post hoc pairwise test to determine which groups have significantly difference [14].

### 4.2.2 Effects of bias level and position on within-session attitude changes. To represent scenarios that users might experience in a three-query session, we designed session conditions with different *bias levels* and *positions* (Table 3).

Table 2. Search interaction features.

Variable	Description
<i>General search behaviors for all search results</i>	
NextQuery	Preference of the next query (positive/negative/neutral).
ClickNum	Number of clicks in the query.
Click@3	Click rate of results at top 3 ranks.
Click@6	Click rate of results at top 6 ranks.
ClickRank	Average rank of clicked results.
ClickDepth	The lowest rank of clicked results.
TimeAvg	Average dwell time of clicked results (Second).
MarkAvg	Average bookmark rate of clicked results.
<i>Result judgements or perceptions</i>	
UseAvg	Average usefulness score of clicked results (based on a 4-point scale annotation).
CredAvg	Average credibility score of clicked results (based on a 4-point scale annotation).
Diversity	Users' perceived diversity of clicked results (on a 7-point scale).
Familiarity	Users' perceived familiarity with clicked results (on a 7-point scale).
<i>Interaction proportions on attitude-confirming results</i>	
ClickProp	Ratio of clicks on attitude-confirming results to all clicks ( <b>Normalized by two times of percentage of attitude-confirming results in the SERP</b> ).
TimeProp	Ratio of average dwell time of attitude-confirming results to all clicked results.
UseProp	Ratio of average usefulness of attitude-confirming results to all annotated results.
CredProp	Ratio of average credibility of attitude-confirming results to all annotated results.

Table 3. Five main session conditions with different bias levels, each with sub-conditions of different bias positions.

Level	Position	SERP conditions		
		Query 1	Query 2	Query 3
No query biased	\	Bal	Bal	Bal
One query biased	First	R/D	Bal	Bal
	Second	Bal	R/D	Bal
	Third	Bal	Bal	R/D
Two queries biased	First&second	R/D	R/D	Bal
	Second&third	Bal	R/D	R/D
One query mitigated	First	Counter-R/D/Obf	Bal	Bal
	Third	Bal	Bal	Counter-R/D/Obf
Mitigated and biased	First	Counter-R/D/Obf	R/D	Bal
	Third	Bal	R/D	Counter-R/D/Obf

\*: Bal: balanced condition; R/D: ranking or diversity bias; Counter-R/D: mitigation with counterpart of ranking or diversity bias; Obf: targeted obfuscation.

The bias level represents the number of biased query(-ies), including "No query biased", "One query biased", "Two queries biased", "One query mitigated", and "Mitigated and biased". Each bias level condition contains two or three sub-conditions with biased query(-ies) at different positions. Then, we investigated the differences in attitude changes across session conditions. Specifically, we had two hypotheses:

**H2a** : Users' attitude changes are likely to be different when they encounter different bias levels.

**H2b** : Users' attitude changes are likely to be different when they encounter biased query at different positions in a session.

For H2a, we analyzed if there are differences in the attitude changes among the five bias level conditions. For H2b, we analyzed if there are differences in the attitude changes among sub-conditions of bias positions for each bias level condition. Furthermore, we also investigated the confounding effect between user characteristics and session conditions by controlling the use group. We implemented the Kruskal-Wallis test to examine the differences in attitude changes among session conditions (as the data was not normally distributed across groups) and utilized the Benjamini-Hochberg correction method to control the false discovery rate [7].

### 4.3 Feature Importance in Attitude Prediction

For **RQ3**, we analyzed how users' characteristics and search interactions relate to their attitude changes by investigating the *features importance* in predicting attitude changes. We developed linear regression models to investigate potential linear connections and random forest models to reflect nonlinear relationships [22, 37, 62].

Besides features of user characteristics and search interactions, we also involved additional predictor variables, including user demographics (e.g., age, gender), and decomposed some search interactions into the partial sum on attitude-confirming and -disconfirming results. For instance, ClickNum is decomposed into numbers of clicks on attitude-confirming results (i.e., ClickCon) and attitude-disconfirming results (i.e., ClickDis). We used Z-score normalization for numerical features and create dummy variables for categorical features. In the model settings, we use elastic net regularization in the linear regression model to prevent large coefficients. For the random forest model, we split training and test datasets and utilized randomized search with cross-validation to set the best parameters. After fitting the models, we measured feature importance by examining the coefficients in the linear regression model and the permutation importance in both the linear regression and random forest models. The coefficient indicates the linear relationship between the feature and the attitude change, and the permutation importance measures the change of the model performance involving randomly shuffling the values of each feature [3]. In addition, involving permutation importance and random forest models can help reduce the potential bias from collinearity [67].

### 4.4 Crowdsourcing Study and Participants

In the crowdsourcing procedure, participants was introduced to a scenario about searching a debated topic. They provided demographic information and characteristics and was randomly assigned one topic that they have opinions on. Participants who are not opinionated (i.e., neutral attitude) on all four topics was unqualified for this study. Qualified participants was then randomly assigned to one session condition and interacted with the simulated search interface. They first selected a query term from a pre-defined query set, which is from previous studies [19, 57] and contains 14 queries in a random order. The query selection would not affect the search results but can reflect user search intents and information needs. When interacting with the SERP, participants could click, browse, and bookmark results as they do in a normal search engine. For each clicked result, they assessed the usefulness and credibility (4-point scale). In each query, they were required to click at least three unique results to ensure sufficient user engagement. After each query, participants reevaluated their attitudes towards the assigned topic and answer questions about the perceived diversity of and familiarity with clicked results (7-point Likert scale). Then, they proceeded to the next query until completing three queries.

We conducted this study on the online survey platform Qualtrics<sup>2</sup>, incorporating a commitment request (i.e., a pre-study question asking participants to provide thoughtful answers) and an attention check during the study (a question required a specific option) to ensure data quality<sup>3</sup>. We recruited participants from Amazon MTurk<sup>4</sup> with requirements: at least 18 years old and native English speakers. We compensated them \$2 for each 15-minute task. This study was approved by the Institutional Review Board. As a result, 1,500 participants were recruited, and 1,321 who passed quality checks were analyzed. The participants include 906 males, 410 females, and 5 not specified, with an average age at 34. Participants initially tended to have a supporting attitude to the topic (mean = 1.9±1.2), and perceived good or relatively good knowledge and openness of the topic (mean = 5.9±0.9; mean = 5.9±0.8).

Accumulative	0.10**	-0.10**	-0.07*	-0.53**

\*:  $p < 0.5$ , \*\*:  $p < 0.1$ 

## 5 RESULTS

### 5.1 Within-session Attitude Changes

To answer RQ1, we used descriptive analysis to explore the within-session attitude changes. On average, participants in this study experienced an accumulative change of 1.59 and a directional change of -0.82, indicating a minor fluctuation and a slight mitigation from an extreme attitude to a neutral attitude. Table 4 presents the components of directional and accumulative changes, which are linearly composed of either directional or absolute query-wise changes. In general, the attitude change after the first query contributes most to the directional change and accounts for about half of the accumulative change. Although the average change after the second or the third query is close to zero, the large standard deviation indicates that participants experienced either reinforced or mitigated attitude strength. Thus, the absolute values of those changes are not zero, contributing to a portion of the accumulative change. We then analyzed the correlations between attitude changes and user characteristics. Table 5 presents the correlation matrix of Spearman's Rho. According to the results, participants with stronger preexisting attitudes tended to show more significant accumulative and mitigated changes. In addition, although attitude strength is positively correlated with perceived knowledge and openness, participants with higher perceived knowledge or openness showed less accumulative attitude change. We also did analysis within individual task topics respectively and obtained similar results.

In summary, these results underscore the influential role of the first query in shaping directional attitude changes, and the second and third queries still contribute to the accumulative change during the session. The within-session attitude changes are also influenced by user characteristics. Notably, some results, particularly regarding the negative relationships between accumulative changes and preexisting attitude strength & perceived openness, were counter-intuitive, prompting further exploration in our discussion section.

### 5.2 Effects of Confirmation Bias

*5.2.1 SERP conditions affecting search interactions.* To answer RQ2, We first investigated the within- and between-query effects of SERP conditions on search interactions. Table 6 shows the average values of interaction across SERP conditions in the first query, reflecting the within-query effect. Generally, the results show that there are significant differences mainly in click-based interactions among different SERP conditions. The mitigated conditions of counterpart of ranking bias (**Counter-R**) and targeted obfuscation (**Obf**), differ significantly in these features from other conditions. Specifically,

Table 6. Search interaction features across different SERP conditions in the first (current) query.

SERP condition	Bal	R	D	Counter-R	Counter-D	Obf
Count	138	133	131	131	132	128
<i>General search behaviors for all search results</i>						
NextQuery	0.05	0.11	0.08	0.04	0.11	0.09
<b>ClickNum**</b>	3.97	3.80	3.62	<u>5.30</u>	3.55	3.54

Bal: balanced condition; R/D: ranking or diversity bias; Counter-R/D: mitigation with counterpart of ranking or diversity bias; Obf: targeted obfuscation.

Features in **boldface** indicate significant differences across SERP conditions with corrected  $p < 0.01$ . The value with underscore indicates significant differences between the condition and two or three other conditions with corrected  $p < 0.05$ .

<sup>1</sup> The rate of participants who clicked both attitude-confirming and disconfirming results.

in these two conditions, users had more clicks and/or clicks at lower ranks compared to other conditions, probably for seeking more attitude-confirming results at lower ranks. Nevertheless, with lower TimeProp, they would spend less time in attitude-confirming results than users in other conditions.

The normalized ClickProp is different among all conditions, where the condition of ranking bias (**R**) has the highest and the condition of targeted obfuscation has the lowest. Although normalized by the number of attitude-confirming results, these differences could be caused by manipulating the result presentation to affect users' clicks. Nevertheless, confirmation bias could be observed when comparing the rates of participants who clicked both attitude-confirming and disconfirming results between the conditions of ranking bias (67%) and counterpart of ranking bias (91%), in which they might tend to find more attitude-confirming results at lower ranks if reading attitude-disconfirming results at top ranks.

However, the interactions related to result judgements do not exhibit any significant differences among the SERP conditions. This suggests that the SERP condition settings and confirmation bias did not impact users' perception of the usefulness or credibility of the search results in the current query. Thus, we partially accepted hypothesis H1a that users' click-based behaviors and the spending time proportion are likely to be different when they encounter SERPs with different bias conditions in the current query.

Beyond the within-query effects, we also investigated the between-query effect, exploring how these conditions in earlier queries might influence user interactions in subsequent queries. We found that the perceived familiarity with clicked results in the third query exhibited significant differences when participants experienced different conditions in

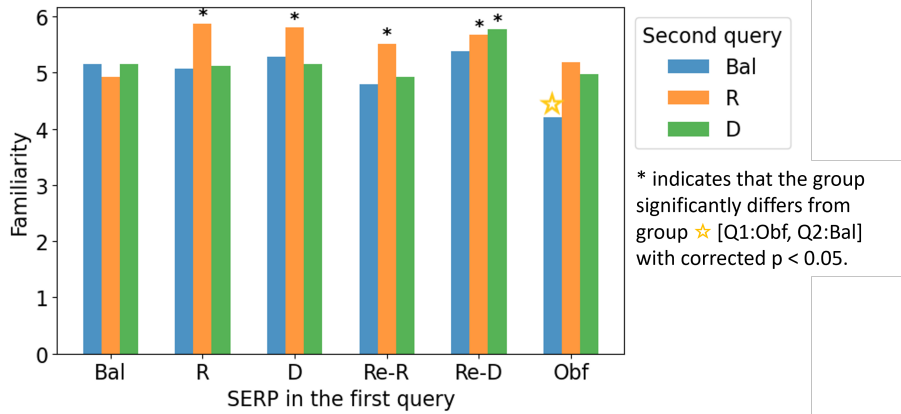

Fig. 3. Perceived familiarity of the third query with balanced SERPs ([Q1: Obf, Q2: Bal] represents the condition where the first query has a SERP with obfuscation, and the second query has a balanced SERP).

the first and second queries (see Figure 3). Specifically, participants reported lower perceived familiarity in the third query if they were presented obfuscation in the first query and a balanced SERP in the second query. Conversely, higher perceived familiarity was mainly reported if participants experienced ranking biased conditions in the second query. Thus, we partially accepted hypothesis H1b that users' perceived familiarity with clicked results are likely to be different if they encountered SERPs with different conditions in the previous queries, indicating that participants under these conditions could be exposed to more (or less) familiar results.

*5.2.2 attitude changes among session conditions.* We compared the attitude changes among session conditions to investigate the effects of bias level and positions. However, we did not observe significant differences in accumulative or directional change among five conditions of bias levels or among sub-conditions of bias positions. This indicates that the session conditions did not lead to significant variations in the impact of confirmation bias on attitude changes.

We then investigated the confounding effect of user characteristics and session conditions on attitude changes. We divided participants into groups based the median values of preexisting attitude strength, perceived knowledge, and perceived openness, separately, and tested the differences in attitude changes among five conditions of bias levels or among sub-conditions of bias positions. We found significant differences in directional attitude changes across conditions of bias positions within the user group that had perceived openness lower than the median (<6). Table 7 presents the different directional changes with query-wise change portions. According to the results, the attitude strength was slightly mitigated after the first query regardless of the SERP condition but could be reinforced after the second or third query with the first and/or second queries biased. This finding indicates that users with lower perceived openness are more susceptible to directional attitude changes when influenced by the sequence position of biased SERPs in sessions.

However, it's important to note that we did not control for user characteristics during the recruiting process, leading to imbalanced user groups in certain conditions. These imbalanced data may result in inaccurate estimations and comparisons. Nevertheless, as we recruited participants and assigned task conditions independently, the results reveal a confounding effect of the bias positions and users who reported lower perceived openness. Therefore, we partially

Table 7. attitude changes in the user group with lower openness (&lt;6) across conditions of bias positions.

Bias level	Bias position	Count	Q1-Q0	Q2-Q1	Q3-Q2	Directional change
One query biased	First	30	-0.83	-0.07	-0.37	-1.27
	Second	38	-0.71	-0.03	0.24	-0.50
	Third	19	-0.74	-0.11	-0.05	-0.89
Two queries biased	First&second	39	-0.74	0.28	-0.13	-0.59
	Second&third	46	-0.96	-0.09	-0.02	-1.07

The directional changes are significantly different across bias positions with corrected  $p < 0.05$ .

accepted H2b, suggesting that users with lower perceived openness are likely to have different directional attitude changes if encountering biases at different query positions in the session.

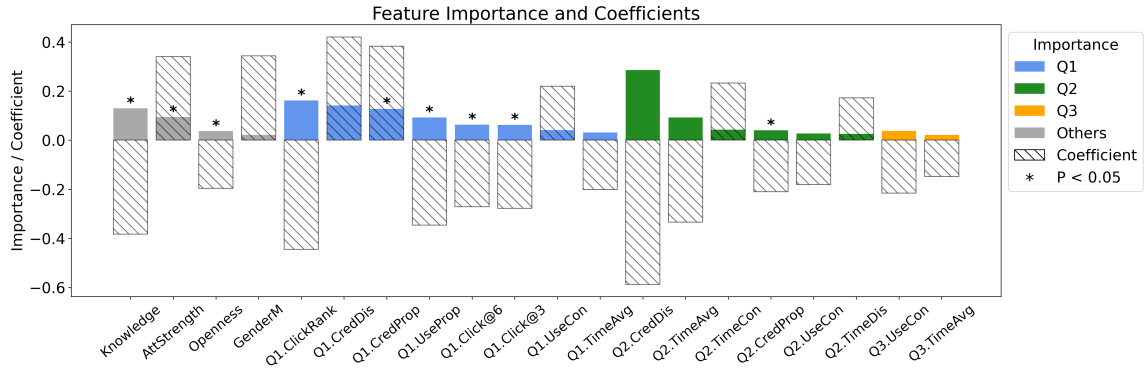

### 5.3 Features Related to Attitude Changes

To investigate features' relationships with attitude changes at a finer scale and answer RQ3, we developed regression models to predict accumulative and directional attitude changes. The  $R^2$  scores for the linear regression model are 0.1766 for predicting accumulative change and 0.2531 for directional change, indicating that the model explains about 17% and 25% of the variance in the respective attitude changes, considered a moderate effect size [13]. The  $R^2$  scores for the random forest model are 0.1759 for accumulative change and 0.1693 for directional change, suggesting that the linear regression model performs slightly better than the random forest model and can explain the directional change better than accumulative change.

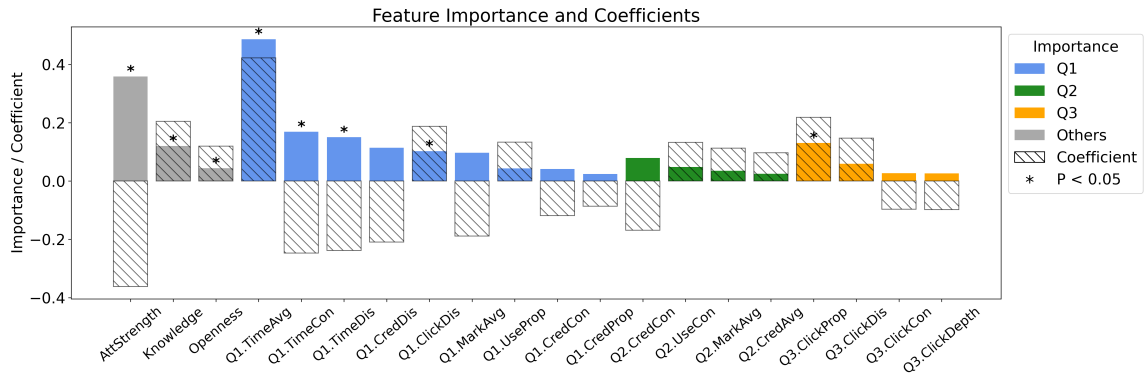

To further explain the features contributing to attitude changes, we analyzed the feature importance of both models. Figure 4 shows the features with top-20 permutation importance in linear regression and random forest models predicting accumulative and directional attitude changes. The features can be categorized based on search interactions in different query positions, interaction proportions, and user characteristics. We used colored labels and prefix (Q1, Q2, or Q3) to represent the query sequence position and suffix (Avg, Prop, Con, or Dis), to identify the type of each feature.

Analyzing the color patterns in Figures 4c and 4d, it is evident that features with high importance are predominantly concentrated in search interactions from the *first query*. However, a few search interactions not in the first query (e.g., Q2.CreDis for predicting accumulative attitude change) and user characteristics (e.g., AttStrength for predicting directional attitude change) also exhibit high importance. Figures 4c and 4d emphasize the dominant impact of user characteristics, especially the influence of preexisting attitude strength on directional attitude change. This indicates an intense nonlinear relationship between users' initial attitude toward the topic and directional attitude change. Additionally, there are more time-based behavioral features in the second and third queries with top importance compared to the features in Figures 4c and 4d. These findings suggest that users' attitude changes are primarily linearly correlated with their search behaviors in the first query. User characteristics and time-based interactions in subsequent queries mostly contribute to attitude changes in a nonlinear manner.

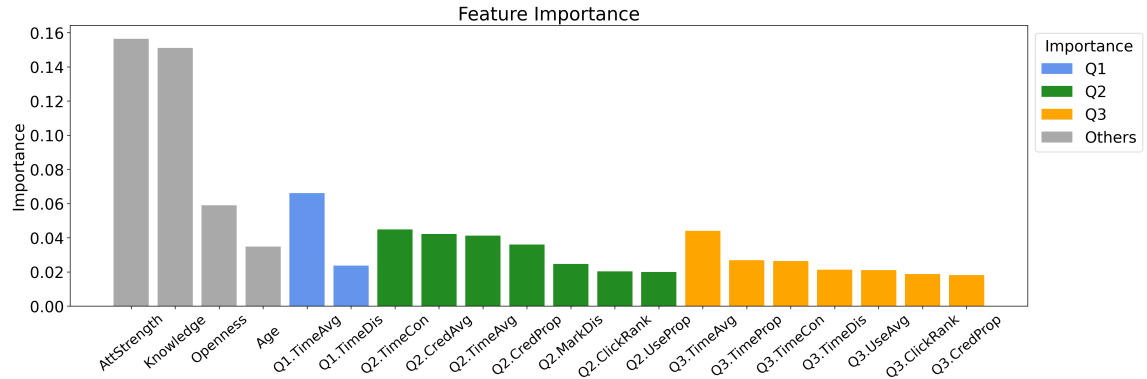

Considering the coefficients as indicators of linear relationships, for accumulative attitude change, Q2.CreDis—with the highest absolute coefficient and permutation importance—suggests that more credible, attitude-disconfirming results clicked in the second query reduce the likelihood of attitude change. Q1.TimeAvg shows a positive correlation with directional attitude change, indicating that spending longer time in the first query tends to enhance attitude strength. In contrast, AttStrength has the highest negative coefficient, implying that stronger preexisting attitudes are more prone to bias mitigation in whole-session search interactions.

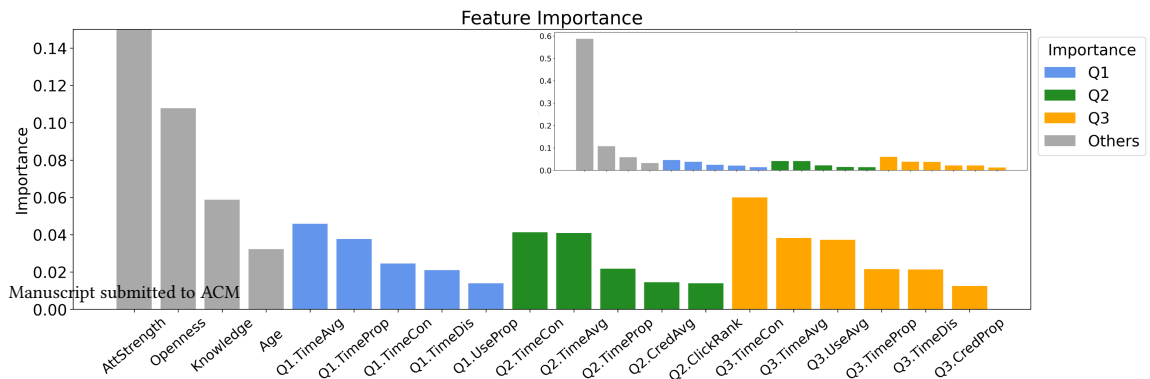

(a) Linear regression model predicting accumulative attitude change.

(b) Linear regression model predicting directional attitude change.

(c) Random Forest model predicting accumulative attitude change.

(d) Random Forest model predicting directional attitude change.

Fig. 4. Features with top-20 importance in linear regression and random forest models. The feature prefix (Q1, Q2, or Q3) indicates the query position. The suffix (Avg, Prop, Con, or Dis) refers to average value, interaction proportion, or partial sum on confirming or disconfirming results respectively. The color of the bar indicates the search feature type or query sequence (*others* refer to user characteristics features).

Table 8. Summary of hypothesis testing results under RQ2.

<b>Hypothesis result</b>	
H1a	<b>Partially accepted</b> that users' click-based behaviors and the spending time proportion are likely to be different when they encounter SERP with different bias conditions in the current query.
H1b	<b>Partially accepted</b> that users' perceived familiarity with clicked results are likely to be different if they encountered SERPs with different conditions in the previous queries
H2a	<b>Not accepted</b>
H2b	<b>Partially accepted</b> that users with lower perceived openness are likely to have different directional attitude changes if encountering biases at different query positions in the session.

However, there are some counter-intuitive observations when comparing the same features at different query positions. For example, when predicting accumulative change, the coefficients of CredDis at the first and second queries are opposite, suggesting different impacts on users' attitudes at different query sequences. We further discussed the effects in the next section.

## 6 DISCUSSION

In this study, We analyzed users' interactions under confirmation bias and SERP bias in three aspects: the characteristics of attitude changes, effects of confirmation bias on search interactions and attitude changes, and relationships between attitude changes and features of user characteristics and search interactions. We tested hypotheses about the effect of SERP bias conditions, with most hypotheses partially confirmed under specific conditions or for certain user groups (results summarized in Table 8). We further explored how these findings enhance our understanding of the RQs.

### 6.1 RQ1. Within-session Attitude Changes

To answer RQ1, we examined directional and accumulative attitude changes in relation to query-wise changes and user characteristics. Our results reveal that the majority of attitude changes occur in the first query. Preexisting attitude strength positively correlates with accumulative changes and negatively with directional changes, while perceived prior knowledge and openness to conflicting opinions show negative correlations with accumulative changes.

Regarding the most attitude changes in the first query, it is possible that the participants perceived new information with primacy effect during the first query, which had a more significant impact on their attitudes and search behaviors than subsequent queries [21, 45]. Participants might be exposed to new information in the first query. After the first query, participants might reach a saturation point due to information overload [60]. With other potential inherent biases in user study (e.g., Hawthorne effect [1] and demand characteristics [47]), participants might assume that the study expects them to show attitude change and be ready to adjust their opinions regardless of conditions. This bias may not cause significant difference in attitude changes across conditions if the search activities occur in traditional short single-query sessions [19].

Regarding user characteristics, it is reasonable that users with higher perceived level of knowledge are likely to have more stable attitudes and opinions, probably because they have a more established understanding of the topic. However, for the counterintuitive observations, users with stronger initial attitudes experienced greater changes and mitigation probably because they have more room for mitigation and *polarization reduction*. Strong or extreme attitudes might naturally become less extreme when exposed to information with alternative perspectives [6]. As the perceived knowledge and openness to conflicting opinion are positively correlated, users with higher perceived openness may

already be familiar with diverse perspectives and arguments of the debated topics, making their attitudes more stable. In addition, they may scrutinize new information more thoroughly before accepting it. Furthermore, as we used a single statement to represent this complex construct, users may perceive this statement and openness differently. Thus, a more comprehensive survey may allow us to measure different facets of openness to diverse perspectives more accurately.

## 6.2 RQ2. Confirmation Bias Effects

To answer RQ2, we investigated the effect of confirmation bias on search interactions and attitude changes. We observed differences in most click-based behaviors across SERP bias conditions in the current query. The SERP presentation could also affect users' perceived familiarity with results in subsequent queries. Also, we found that users with lower openness to conflicting opinions could be influenced by the sequence position of biased SERPs.

The differences in click-based behaviors could be influenced both by SERP presentation and affected by confirmation bias. On one hand, certain presentations (e.g., the counterpart of ranking biased SERP and obfuscation) prioritize results with alternative opinions, leading users to engage with those results first. On the other hand, these presentations still provide an equal amount of attitude-confirming results, and users increase their engagement with results even at lower ranks because of confirmation bias. However, interventions involving obfuscation or the counterpart of diversity bias might backfire, reducing user engagement due to *cognitive dissonance* [34, 52, 58, 74]. In addition, users encountering ranking biased SERPs also demonstrated potential confirmation bias in terms of perceived familiarity in subsequent queries. Their higher familiarity might be caused by clicking more attitude-confirmation results. Conversely, if users initially encountered an obfuscated SERP and then shifted to a non-biased (i.e., balanced) SERP, they might not have been exposed to familiar results as extensively as users in other conditions. They could also be more adaptable in engaging with unfamiliar results in subsequent queries.

Regarding attitude changes of users with lower openness, if this openness represents users' knowledge or previous experience in diverse perspectives, the lower openness could mean that these users are more sensitive to hidden biases instead of being reluctant, leading them to react strongly when confronted with biased opinions. When bias occurs early in the search session (e.g., bias at the first query), it could evoke an immediate and intense reaction, resulting in a more significant directional change towards mitigating their initial extreme attitudes. On the other hand, encountering biased results later in the session (e.g., biased SERPs at the second or third query) might lead these users to a more thoughtful change in their attitudes. This sequence effect of biased SERPs might also suggest that the confirmation bias could be confounded with *reference-dependent* effect in multi-query search sessions [5, 10, 40].

## 6.3 RQ3. Features Related to Attitude Changes

With respect to RQ3, we investigated the feature importance of user characteristics and search interactions on predicting their attitude changes. The majority of important features belong to the search interactions in first query in terms of linear relationships and consist of dwell-time-based features in the second and third queries in terms of nonlinear relationships, suggesting potentially different mechanisms of exposure frequency and intensity effects [5]. We also found that user characteristics, particularly preexisting attitude strength, caused significant impacts on directional attitude change. This finding echoes that of the previous studies [e.g. 53, 73, 74].

We discovered that some features at different query positions had different effects on attitude changes. For example, users exposed to more credible results in the first query are more likely to change attitudes, while users exposed to more credible results in the second query are not. It is possible that users who are exposed to more credible information in the first query may be more likely to encounter new information that challenges their preexisting attitudes, leading

to attitude change. On the other hand, users who are exposed to more credible information in the second query may reach a *local saturation point* (where the collected information appears to be satisfying or "good enough" [2, 17]). As a result, subsequent exposure to credible information may not have as much of an impact on potential attitude change but consolidate their attitudes.

Overall, these findings have important implications for understanding how user characteristics and search interactions influence attitude changes under mixed effects of cognitive and SERP biases. Besides, our findings also contribute to the development of *bias-aware* searcher models, and also inform the design and evaluation of bias identification and mitigation techniques in search interactions.

#### 6.4 Implications and Limitations

As Rieger et al. [57, 58] suggested, the *Elaboration Likelihood Model* [cf. 51], which differentiates between the *peripheral route* (e.g., manipulation effects of changing result presentations) and the *central route* (e.g., guiding users in reflective process) in influencing user attitudes, can also explain results in our study. The results in users' attitude changes and search interactions observed in the first query primarily reflect the peripheral route, which are consistent with previous research on single-query sessions [57, 58]. However, as users progress to later queries, a shift towards the central route may occur. This shift is evidenced by the influence of the sequence position of biased queries (in certain user groups) and the nonlinear relationships with time-based behaviors, suggesting deeper cognitive processing and dynamic engagement in subsequent queries. Thus, this study highlights the importance of investigating user interactions in multi-query sessions under the impact of biases from both human and system sides, especially considering user characteristics and bias positions, and helps complement mainstream research focusing on algorithmic biases and simulation-based evaluations. The findings also raise important ethical considerations regarding the potential risks of *algorithmic manipulation* in human-information interactions [15]. To avoid misuse of these techniques for profit-driven search optimizations and deceptive purposes, intelligent safeguards need to be put in place by search engine developers, researchers, and AI policy makers. Furthermore, our findings can also inform the development of human-centered guidelines on building unbiased IIR systems and ethical AI audit techniques [63].

Our study has several limitations, including employing a limited set of topics, potential variations in participant populations, and utilizing self-reported values in measuring user perceptions. These limitations call for future efforts to continue this line of research on the interplay of cognitive biases, algorithmic biases, and search contexts. To mitigate the impact of limitations, our study employs a wide range of topics that are diverse and more appropriate and accessible as common debatable topics than other controversial topics. With self-reported characteristics, our work revealed the effect of confirmation bias in certain user groups and paves the way for future experiments on mixed bias effects in search sessions. Furthermore, the regression analysis showed the importance of features in the first query and user characteristics. In spite of its limitations, the study contributes to our understanding of the confirmation bias in multi-query sessions and demonstrates a viable approach to examining task-driven interactions between cognitively biased users and algorithmically biased SERPs under reasonably authentic experimental settings. Future studies can explore a broader range of high-stake topics (e.g. medical decisions, personal health management, financial investments), investigate the long-term effects of biased results and system-generated contents on attitude change in natural environments, and examine the role of social contexts and neural correlates of biased search behaviors. Knowledge about biases can also help reduce the gap between IR evaluation measurements and users' *in-situ* judgments and experiences [10, 39].

## 7 CONCLUSION

In conclusion, this study provides insight into the interaction between users, affected by confirmation bias, and algorithmically biased SERPs in whole-session searches on debated topics. It advanced our understandings of the long-term effects of confirmation bias on users' search interactions, judgments, and attitudes. Future study can continue to investigate the complex effects of biases in a broader range of human-AI interaction scenarios, identify the hidden biases in retrieved information and system-generated responses, and deploy effective bias mitigation techniques.
