## ABSTRACT

The Influence Maximization (IM) problem seeks to discover the set of nodes in a graph that can spread the information propagation at most. This problem is known to be NP-hard, and it is usually studied by maximizing the influence (*spread*) and, optionally, optimizing a second objective, such as minimizing the *seed set size* or maximizing the influence *fairness*. However, in many practical scenarios multiple aspects of the IM problem must be optimized at the same time. In this work, we propose a first case study where several IM-specific objective functions, namely *budget*, *fairness*, *communities*, and *time*, are optimized on top of the maximization of *influence* and minimization of the *seed set size*. To this aim, we introduce MOEIM (Many-Objective Evolutionary Algorithm for Influence Maximization), a Multi-Objective Evolutionary Algorithm (MOEA) based on NSGA-II incorporating graph-aware operators and a smart initialization. We compare MOEIM in two experimental settings, including a total of nine graph datasets, two heuristic methods, a related MOEA, and a state-of-the-art Deep Learning approach. The experiments show that MOEIM overall outperforms the competitors in most of the tested many-objective settings. To conclude, we also investigate the correlation between the objectives, leading to novel insights into the topic. The codebase is available at <https://github.com/eliacunegatti/MOEIM>.

## 1 INTRODUCTION

Many real-world problems can be modelled through the interaction between multiple entities. Be it aimed at measuring the effect of political campaigns or commercial advertising, characterizing the connections over a social network such as Facebook or X, the mutual dependencies between parts of a distributed system, the co-purchasing of goods, or the impact of a scientific article over the research community, many such problems can be modelled through a *social network*, namely a graph  $\mathcal{G} = (\mathcal{V}, \mathcal{E})$  where  $\mathcal{V}$  denotes the set of entities in the network (i.e., the vertices, or nodes, of the graph) and  $\mathcal{E}$  denotes their connections (the edges). Such graph can be either *directed* or *undirected* (depending on the direction of the information over the edges), *weighted* or *unweighted* (depending on the possibility to quantify a given numerical property of each edge), and *static* or *dynamic* (if nodes and edges are time-variant).

The specific meaning of entities and connections, obviously, depends on the semantics of the application domain. Nevertheless, one common need in many domains is to identify the most *influential* nodes over the network, i.e., the subset (usually called *seed set*) of nodes from which the *influence* (a concept that is, in turn, application-dependent) can propagate over the highest possible

number of other nodes. The search for such seed set is usually referred to as the Influence Maximization (IM) problem, and has been originally defined by Kempe et al. in [26]. This problem has been proven to be NP-hard, attracting over the years a massive research effort from the machine learning and optimization community.

The earliest algorithmic attempts at effectively solving the IM problem resorted to greedy heuristics, such as [22, 30], with more recent methods combining greedy approaches with statistics-based models [51, 52]. Other works, such as [7, 10, 37], focused on the use of Evolutionary Algorithms (EAs). More recently, Deep Learning (DL) methods, e.g., based on deep Reinforcement Learning (RL) [11, 34], Learnable Embeddings [35, 41], or combinations of deep RL and EAs [38], have also been proposed.

An important limitation in the current state of the art is the fact that, apart from a few works that we will discuss in detail later, most research in the field focuses on the standard, single-objective IM problem formulation from [26], where the only goal is to maximize the number of influenced nodes. On the other hand, various other aspects of the IM problem can be of interest in practical applications, such as minimizing the *seed set size*, as well as achieving *fairness* (either at the beginning, or the end of the influence propagation) across the communities in the network, or optimizing the *time* and *budget* (also called *seed cost*) needed to propagate the influence.

The only works that tried to handle multiple objectives in the IM formulation, e.g., influence and seed set size [8, 9], influence and fairness [17, 20, 45], or influence and time/budget [6, 44], either consider at most two, or occasionally [5] three objectives, or model one of the objectives as an additional constraint. To the best of our knowledge, no work has addressed, so far, the problem of *many-objective Influence Maximization*, i.e., solving the IM problem by explicitly handling more than three objectives at the same time.

**Contributions.** In this work, we endeavor in a first attempt at effectively solving this many-objective IM problem. ① We consider six different many-objective IM problem formulations, with up to six objectives simultaneously handled in terms of Pareto optimization. ② We propose MOEIM (Many-Objective Evolutionary Algorithm for Influence Maximization), a Multi-Objective Evolutionary Algorithm (MOEA) based on NSGA-II [15] and leveraging on the graph-aware operators and smart initialization mechanism from [18]. ③ We compare MOEIM in two experimental settings, including a total of nine graph datasets, two heuristic methods [22, 30], another MOEA from [9], and a state-of-the-art DL technique, DeepIM [35]. ④ Our experimental analysis reveals that in most cases MOEIM significantly outperforms the competitors in terms of achieved hypervolumes, proving to be a competitive solution for many-objective IM problems. ⑤ We conduct a correlation analysis of the objective functions, to provide novel insights on IM.

The rest of the paper is structured as follows. In the next section, we introduce the main concepts on the IM problem. Then, Section 3 briefly summarizes the related work. The methods are presented in Section 4. Section 5 presents the experimental setup, while Section 6 discusses the results. Finally, we draw the conclusions in Section 7.

## 2 BACKGROUND

The IM problem is defined as a combinatorial optimization problem over a directed/undirected graph  $\mathcal{G}$ . The main goal of the problem is to find a subset of nodes, called *seed set* ( $S$ ), that can spread the influence the most under a given propagation model  $\sigma$ , i.e.,  $\text{argmax}_S |\sigma(S)|$ . The propagation model simulates the influence spread over discrete timesteps  $t \in [0, \tau]$ , such that at each timestep  $t_i$  each of the *active* nodes resulting from the previous timestep  $t_{i-1}$  tries to activate (i.e., propagate the influence to) the nodes in its neighborhood. The pseudocode of the generic propagation model is provided in Algorithm 1.

**Algorithm 1** Propagation model  $\sigma(S)$ .  $S$  is the seed set,  $G$  is the graph,  $\tau$  is the maximum number of timesteps,  $p$  (needed only for IC) is the probability that an edge will be activated.

**Input:**  $S$

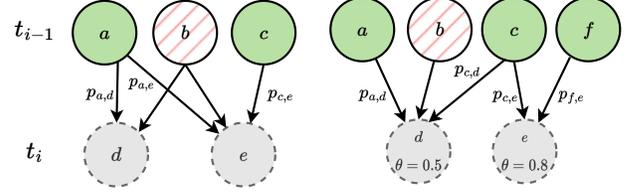

```

Require:  $\mathcal{G}, \tau, [p]$ 
1:  $A \leftarrow S$  ▷ The set of activated nodes
2:  $B \leftarrow S$  ▷ Nodes activated in the previous timestep
3:  $t = 0$  ▷ Timestep counter
4: while  $B$  not empty and  $t < \tau$  do
5:    $C \leftarrow \emptyset$  ▷ Nodes activated in the current timestep
6:   for  $n \in B$  do
7:     for  $m \in \text{neighbours}(n) \setminus A$  do
8:        $C \leftarrow C \cup \{m\}$  with probability  $p$  ▷ Activation attempt
( $p$  differs for IC/WC/LT)
9:    $B \leftarrow C$ 
10:   $A \leftarrow A \cup B$ 
11:   $t = t + 1$ 
12: return  $|A|$  ▷ Total number of activated nodes

```

The activation attempt (line 8 in the pseudocode) is probabilistic and depends on the specific propagation model considered. While various models do exist, the most used are: the **Independent Cascade** (IC), the **Weighted Cascade** (WC), and the **Linear Threshold** (LT) models, proposed in [26]. ① In IC, the probability of activating a new node is based on a hyperparameter  $p$ , that is given as input to the propagation model. Note that, here,  $p$  is equal for all the nodes. Referring to Figure 1 (left),  $p_{i,j} = p \forall i, j$ . ② In WC, which can be seen as a non-parametric version of IC, the probability of activating a node  $n$  is inversely proportional to its in-degree  $d_n^{\text{in}}$  (i.e.,  $p_{m,n} = 1/d_n^{\text{in}}$ ). Referring to Figure 1 (left),  $p_{a,d} = 1/2$  and  $p_{a,e} = p_{c,e} = 1/3$ . ③ Finally, in the LT model each edge has a weight  $p$  computed as in the WC model, but the stochasticity relies on the threshold activation  $\theta$  assigned to each node (the original model defined in [26] sets uniformly samples  $\theta$  in  $[0, 1]$  for each node), see Figure 1 (right). Namely, during the propagation process, a new node  $n$  can be activated if the sum of its incoming weights (corresponding to the active nodes among its neighbours) is higher than its threshold  $\theta_n$ , i.e.,  $\sum_{m \in \text{neighbours}(n)} p_{m,n} \geq \theta_n$ .

Due to the stochasticity of the propagation models, the influence propagation is computed through Monte Carlo simulations multiple times (usually 100, see [7]) for each seed set  $S$ , and then averaged.

**Figure 1:** Graphical representation of the IC and WC models (left), and LT model (right). The top row shows activated nodes (green circles) and non-activated nodes (dashed red circles) at timestep  $t_{i-1}$ . The bottom row shows the nodes that can be activated at timestep  $t_i$ .

## 3 RELATED WORK

We categorize the related works based on how they formulate the IM problem and, in particular, on the objectives they consider, which reflect the same objective functions we consider in our study.

**Influence** For solving the IM problem, the majority of works builds upon the milestone work [26], which uses a greedy algorithm with approximation guarantees. To reduce the computational cost, several heuristics have been proposed [13, 24, 30, 57]. A technique based on the statistical estimation of the number of nodes from which the seed set should be sampled has been proposed in [52], and then extended to online processing [51]. As an alternative, various approaches based on EAs emerged [7, 10, 37], which have a computational advantage over the heuristics. The most recent line of works instead focuses on DL approaches, either based on RL [11, 34], Learnable Embeddings [35, 41], or combination of deep RL with EAs [38]. Of note, all these works only focus on maximizing the influence, fixing a priori the seed set size.

**Seed set size** Several works proposed to optimize, along with the influence, the seed set size, so to have a min-max IM problem formulation. The earliest works proposed the use of MOEAs [8, 9, 14]. In [5], the authors employ a MOEA to optimize seed set size, influence, and budget jointly. Other approaches employ multi-objective Particle Swarm Optimization (with either scalarization or lexicographic ordering) to maximize the influence while minimizing the seed set size.

**Communities**<sup>1</sup> This objective aims to fairly distribute the influenced nodes across all the parts (i.e., the communities) of the network. In the literature, some works proposed to combine influence and communities into as single, monotone objective [1, 48, 55], while other works focused on Pareto optimization [17, 20] or Graph Embeddings [27].

**Fairness** This objective aims to fairly allocate the nodes in the seed set w.r.t. the network communities they belong to. This objective has been defined in [2, 50] and handled in various ways, e.g.,

<sup>1</sup> *Communities* and *fairness* have interchangeable definitions in the literature. In this section, we categorize them following the objective formulation defined in Section 4.

through multi-objective constrained optimization [45, 55], integer programming [16], and DL [17].

**Budget** The budget, along with the seed set size, is the most studied objective function in IM. The idea behind this objective is that each node in the seed set has a *cost* (that is usually assumed to be proportional to its out-degree) that needs to be smaller than (or equal to) a fixed value. While this problem could be trivially solved by selecting in the seed set the  $k$  nodes with the highest out-degree in the graph, this may represent a sub-optimal solution, depending on the topological structure of the graph at hand. Instead, it is more practical to consider only the sum of the out-degrees of the nodes in the seed set as the actual budget, without imposing any predefined limit on it. Limited budget optimization has been explored in [4, 43, 44], while explicit multi-objective settings taking budget into account have been investigated in [6].

**Time** As shown in Algorithm 1, the propagation process can stop in two cases: either where no new nodes can be activated anymore, or once a given timestep limit  $\tau$  is reached. Using as proxy for the time the number of timesteps of propagation is therefore crucial to reduce the computational cost needed to solve the IM problem. The earliest work that attempted to optimize the propagation time over IM problem relies on a greedy approach [36]. Later, specific algorithms have been proposed [12, 44] to avoid the complexity of greedy heuristics. The trade-off between influence and time has been empirically analyzed in [53], while the relation between fairness and time has been studied in [1].

## 4 METHODS

We now introduce the objective functions adopted in the experimentation and the proposed MOEIM algorithm.

### 4.1 Objective functions

We consider a total of six different objective functions<sup>2</sup> that are specific to the IM problem, namely:

- (1) **Influence** ( $\mathcal{I}^\uparrow$ ): This refers to the number of nodes in a graph that, starting from a given seed set  $S$ , are activated throughout the propagation process returned by Algorithm 1. We refer to the set of nodes activated starting from the seed set  $S$  as  $\sigma(S)$ . This function has to be *maximized*.
- (2) **Seed set size** ( $\mathcal{S}^\downarrow$ ): This is the number of nodes in the seed set ( $|S|$ ), as given in input to Algorithm 1. This function has to be *minimized*.
- (3) **Communities** ( $\mathcal{C}^\uparrow$ ): For a given set of activated nodes that are not present in the seed set, namely  $\sigma(S) \setminus S$ , this metric measures the distance between the ideal distribution of activated nodes in each community (i.e., a uniform distribution), and the empirical distribution of activated nodes [16]. Throughout this whole work, the communities are referred to as subsets of nodes in a graph that are strongly connected among them while being less connected with the other parts of the graph, and have been computed using the Leiden algorithm [54]. Since we treat Communities as a problem of matching an empirical distribution of probability with an ideal one, we employ the

<sup>2</sup>For clarity, we use the symbols “ $\uparrow$ ” and “ $\downarrow$ ” to indicate that an objective has to be maximized or minimized, respectively.

Jensen-Shannon distance, defined as:

$$JSD(p, q) = \frac{1}{2}KL(p||M) + \frac{1}{2}KL(q||M) \quad (1)$$

where  $KL$  is the Kullback-Leibler divergence,  $p$  and  $q$  are the two probability distribution functions, and  $M = \frac{(p+q)}{2}$ . The Jensen-Shannon divergence is bound in  $[0, 1]$ . As said, in the IM problem one of the probability distributions is fixed (namely, a uniform distribution  $\mathcal{U}(1, c)$ , where  $c$  is the number of communities). Thus, we normalize  $JSD$  by dividing it by the maximum  $JSD$  distance that can occur in our setup, which is obtained by measuring the distance between a uniform distribution function and the Kronecker’s delta function  $\delta$  (which represents the case in which only nodes from a single community are influenced):

$$JSD_N(p, \mathcal{U}(1, c)) = \frac{JSD(p, \mathcal{U}(1, c))}{JSD(\delta, \mathcal{U}(1, c))} \quad (2)$$

In other words, this metric measures if all communities are influenced fairly *at the end* of the propagation process. This function has to be *maximized*.

- (4) **Fairness** ( $\mathcal{F}^\uparrow$ ): Fairness has the same core idea of Communities, i.e., optimizing the nodes’ allocation throughout all the communities. However, differently from the previous metric that is calculated over  $\sigma(S) \setminus S$ , fairness is measured on the seed set  $S$ , i.e., it measures if the propagation *starts* fairly from each community. It is computed exactly as Communities, but on  $S$ . This function has to be *maximized*.
- (5) **Budget** ( $\mathcal{B}^\downarrow$ ): The budget refers to the sum of the out-degrees of the nodes in the selected seed set  $S$ , i.e.,  $b = \sum_{n \in S} d_n^{out}$ . This function has to be *minimized*.
- (6) **Time** ( $\mathcal{T}^\downarrow$ ): This is the total propagation time to influence the nodes for which we use, as a proxy, the number of timesteps in the while loop of Algorithm 1. This function is usually referred to as the number of hops of the propagation model. This function has to be *minimized*.

### 4.2 MOEIM

Here we present MOEIM, which is composed of three main components, namely: (1) smart initialization (2) many-objective evolutionary optimization, and (3) graph-aware evolutionary operators, described below.

**Smart initialization.** Each candidate solution represents a possible seed set (i.e., each solution is a set of nodes used as starting points for the propagation process). Practically, each individual consists in a set of integers where each integer is the id of a node used in the seed set. Taking inspiration from [28], we apply a smart initialization technique that generates an initial population based on the individual capability of each node to influence the network. More specifically, to improve diversity in the initial population, a ratio of  $(1 - \lambda)$  initial solutions (with  $\lambda$  being a hyperparameter) is initialized randomly with a size randomly sampled in  $[1, k]$ , while a ratio of  $\lambda$  is created using the following procedure. First of all, we simulate the influence propagation of each *single* node for  $\tau = 3$  hops. Then, we keep the best  $k$  nodes (i.e., those that, taken individually, are able to influence the highest number of nodes in the graph), where  $k$  is again the maximum size of the individual. Among these

$k$  nodes, we filter out those with a out-degree lower than  $\Theta$ , which is another hyperparameter. Each individual in the  $\lambda$  fraction of the initial population is then created with a size randomly sampled in  $[1, k]$  by inserting the filtered nodes with probabilities proportional to their out-degree, akin to roulette selection.

**Many-objective evolutionary optimization.** For the evolutionary optimization core, we rely on the NSGA-II algorithm modified to solve the IM problem as in [9], and made available in [18]. Such an algorithm has been employed due to its ability to seamlessly add new objective functions to the optimization process. However, unlike the existing multi-objective approaches to IM, which as seen earlier employ at most two or three objectives, here we extend the number of objectives up to six. In fact, we study: (1) the case in which we optimize  $\mathcal{I}^\uparrow$  and  $\mathcal{S}^\downarrow$  (as in [8, 9, 14]); (2) the case in which  $(\mathcal{I}^\uparrow - \mathcal{S}^\downarrow)$  plus each objective among  $\mathcal{C}^\uparrow$ ,  $\mathcal{F}^\uparrow$ ,  $\mathcal{B}^\downarrow$ , and  $\mathcal{T}^\downarrow$  are optimized, resulting in four three-objectives problems; and (3) the case in which we optimize all the metrics from Section 4.1, thus resulting in a six-objectives problem.

**Graph-aware evolutionary operators.** As demonstrated in previous works [10, 28], while standard one-point crossover is effective for obtaining state-of-the-art performance on the IM problem, graph-aware mutation operators can provide a dramatic performance boost w.r.t. naïve mutations such as random node sampling.

Here, we employ a total of five different mutation operators previously introduced in [28], of which two are stochastic, while three are graph-aware, to draw a balance between stochasticity and graph-based knowledge. As for the stochastic operators, we use: (1) *Global Random Insert Mutation* and (2) *Global Random Removal Mutation*, which respectively randomly adds nodes to the individual, or removes nodes from it. As for the graph-aware operators, we use: (1) *Local Neighbor Mutation*, where a new node is randomly selected among the neighbors of the node to mutate; (2) *Local Neighbor Second-Degree Mutation*, which selects a new node in the neighborhood of the nodes to mutate, with probability proportional to its out-degree; (3) *Global Low Degree Mutation*, where the new node is selected from the whole graph with probability inversely proportional to its out-degree. At each mutation, one of the above mutation operators is selected with uniform probability.

## 5 EXPERIMENTAL SETUP

We perform two separate experimental analyses of MOEIM. The first setting ① compares our proposed method against two existing heuristics from [30, 57] and the state-of-the-art MOEA from [9]. The second setting ② is focused on comparing the performances of MOEIM w.r.t. a state-of-the-art DL technique, DeepIM [35].

**Datasets.** For the first experimental setting ①, we selected six different datasets to include directed and undirected, sparse and dense graphs (with an average out-degree from 6 to 50), ranging from  $\sim 1k$  to  $\sim 9k$  nodes and  $\sim 25k$  to  $\sim 100k$  edges. We also selected such datasets to cover a broad spectrum of values w.r.t. the number of communities, from 6 to 46. The selected datasets are: **email-core**\* [32], where nodes represent European research institutions and edges are emails exchanged among them; **facebook-combined**\* [33], where nodes are Facebook profiles and edges corresponds to friendship among users; **gnutella**\* [32], which is a peer-to-peer file sharing network; **wiki-vote**\* [31], where nodes

corresponds to administrators of Wikipedia and edges corresponds to who-vote-for-whom during an internal election; **lastfm**\* [3] is the social network LastFM of Asian users, where nodes are users and edges correspond to mutual following; and **Ca-HepTh**\* [32] is a collaboration network of High Energy Physics Theory among the arXiv papers of who-cites-whom<sup>3</sup>.

For the second experimental setting ②, we selected the three publicly available datasets used in [35], to allow for a direct comparison with the results presented in the original paper. In particular, the three datasets tested are **Jazz**<sup>+,-</sup> [19], which is a collaboration network among Jazz musicians/bands, **Cora-ML** [39], where nodes are Computer Science papers and edges are citations among them, and **Power Grid**<sup>+,-</sup> [58], where nodes are power relay points and edges correspond to line connecting them.

For both settings, each dataset has been pre-processed, to remove disconnected components (i.e., portions of the graph disconnected from the largest component of the graph) and low-quality communities. For that, we so relied on the pre-processing approach designed in [48], where each final graph represents the largest weakly connected components<sup>4</sup> of the original graph and the communities with less than 10 nodes are removed<sup>5</sup>. The properties of all datasets, after this pre-processing, are available in Table 1.

**Baselines.** For the first experimental setting ①, we selected as baselines two heuristic algorithms, namely Generalized Degree Discount (GDD) [57] and Cost-Effective Lazy Forward selection (CELf) [30]. They are both designed to maximize the influence under a constraint on the seed set size, and they both work by adding nodes iteratively until reaching the selected budget. More specifically, GDD adds nodes to the seed set nodes greedily based on the nodes' out-degree, while CELf is a faster version of the GDD designed to work as a hill-climbing two-pass greedy approach. As a third baseline, we chose the MOEA presented in [9], since it was the first EA proposed for solving the multi-objective IM problem.

For the second experimental setting ②, we only compare to DeepIM [35], since, from the numerical results reported in the original paper, this method outperformed other DL-based approaches when tested on the three selected datasets we tested in our experiments.

**Hyperparameter setting.** For the first experimental setting ①, we set the maximum seed set size to  $k = 100$  for all the algorithms under comparison, as done in [9]. Regarding the time limit ( $\tau$ ), it is worth mentioning that several works [21, 28, 29] empirically showed how setting  $\tau$  to a value as low as 2 (i.e., 2-hop) provides a computationally efficient approximation of influence propagation, yielding final influence values that are practically equivalent to those achieved by CELf. Here, we opt for a value of  $\tau = 5$  (as [20]),

<sup>3</sup>The apex “\*” means that the dataset is available on the SNAP repository [25], “+” means that it is available on the Network Repository [47], while “-” refers to availability on the Netzscheuler network catalogue [42]

<sup>4</sup>In directed graphs, weakly (strongly) connected components are defined as the largest connected components of the graph whose nodes are reachable in at least one direction (both directions). In undirected graphs, weakly and strongly connected components coincide.

<sup>5</sup>To note that the final pre-processed graphs used in the experimental setting ② have the same properties as in the original paper [35], given that the three datasets used in this setting do not present communities with less than 10 nodes.

**Table 1: Tested datasets. Top (bottom) rows: setting 1 (2).**

Network	Nodes	Edges	Communities			Nodes' degree			Type
			Num.	Min.	Max.	Avg.	Std.	Max.	
email-eu-Core	986	25552	7	57	308	51.83	60.32	546	Directed
facebook-combined	4039	88234	17	19	548	43.69	52.41	1045	Undirected
gnutella	6299	20776	20	11	753	6.6	8.54	97	Directed
wiki-vote	7066	103663	6	29	1959	29.34	60.55	1167	Directed
lastfm	7624	27806	23	11	1015	7.29	11.5	216	Undirected
CA-HepTh	8638	24827	46	15	625	5.75	6.46	65	Undirected
Jazz	198	2742	3	61	73	27.7	17.41	100	Undirected
Cora-ML	2810	7981	22	12	441	5.68	8.45	246	Undirected
Power Grid	4941	6594	38	31	233	2.67	1.79	19	Undirected

which provides a fair compromise between the the 2-hop approximation and an unbounded spread process (i.e.,  $\tau = \infty$ ). For a fair comparison, such time limit has been applied to all the baselines (GDD, CELF, and MOEA) as well as to MOEIM in the various combinations of objectives (see Section 6.1). In this experimental setting, we use two different propagation models (as in [9, 14]), namely WC and IC, setting  $p = 0.05$  in the latter.

For the second experimental setting 2, for a fair comparison, we relied on the same IM setting adopted in [35], where  $k$  was set to 20% of nodes in the graph, while no limits on  $\tau$  and budget were applied. As in [35], in this case we use as propagation models WC and LT, setting the threshold of each node uniformly sampled in  $[0.3, 0.6]$  in the latter.

For all the experiments, the evolutionary hyperparameters of MOEIM and MOEA [9] have been kept fixed in both experimental settings 1 and 2, setting the population size to 100, the number of offspring to 100, the number of elites to 2, the tournament size to 5 (as in [14]), and the number of generations to  $100^6$ . For both experimental settings, the fitness evaluation of MOEA and MOEIM solutions have been computed by running 100 Monte Carlo simulations of the tested propagation model. Only for MOEIM the  $\lambda = 0.33$  of the initial population has been initiated with smart initialization presented in Section 4.2 where  $\Theta$  is set to the average out-degree of the graph. The rest of the population is randomly initialized.

## Computational setup

To run the experiments, we employed a workstation with an Intel(R) Core(TM) i9-10980XE CPU @3GHz with 18 cores (36 threads) and 125 GB of RAM. Our code is implemented in Python3.8, running in multi-threading.

## 6 RESULTS

We present now the results of the two experimental settings, followed by a detailed statistical analysis. We conclude this section with an analysis of the correlation between the objective functions.

### 6.1 Setting 1: MOEIM vs. optimization methods

The first experimental setting aims to analyze the performance of MOEIM w.r.t. the existing optimization methods for IM. These experiments are designed to understand if in the classical ( $\mathcal{I}^\uparrow$ - $\mathcal{S}^\downarrow$ ) setting MOEIM can produce better results, but also to analyze

<sup>6</sup>Of note, in [9] the number of generations was set to 500. However, as we will show in the experimental results, MOEIM outperforms CELF in a much lower number of generations, keeping all the other parameters the same for both EAs. For this reason, and for the sake of computational efficiency, we reduced the number of generations to 100 for both algorithms.

the performance of MOEIM when considering additional objective functions. We tested MOEIM in six different optimization settings, namely the ( $\mathcal{I}^\uparrow$ - $\mathcal{S}^\downarrow$ ) setting used in [9], four different settings where each of the additional objective functions (i.e.,  $\mathcal{C}^\uparrow$ ,  $\mathcal{F}^\uparrow$ ,  $\mathcal{B}^\downarrow$ ,  $\mathcal{T}^\downarrow$ ) are added to ( $\mathcal{I}^\uparrow$ - $\mathcal{S}^\downarrow$ ) in the optimization process and, to conclude, a setting called “(all)” where all the six objective functions are optimized together. The baselines are computed as proposed in the original papers, i.e., GDD [57] and CELF [30] are executed under a seed set size constraint, while MOEA is executed on the base case ( $\mathcal{I}^\uparrow$ - $\mathcal{S}^\downarrow$ ), as in [9]. The results of such experiments are available in Table 2, where for each algorithm we extracted the hypervolume [49] w.r.t. all the six optimization settings mentioned above. The hypervolume is computed over the normalized values of each objective function as:  $\mathcal{I}^\uparrow \in [0, |\mathcal{V}|]$ ,  $\mathcal{S}^\downarrow \in [0, k]$ ,  $\mathcal{C}^\uparrow \in [0, 1]$ ,  $\mathcal{F}^\uparrow \in [0, 1]$ ,  $\mathcal{B}^\downarrow \in [0, b]$ , where  $b = \sum_i^k a_{v_i}^{out}$  with  $v$  being the list of the top- $k$  nodes by out-degree, and  $\mathcal{T}^\downarrow \in [0, \tau]$ .

Overall, MOEIM (in any of its 6 configurations) turns out to outperform the three baselines in 61 cases out of 72 (namely, 6 datasets  $\times$  2 propagation models  $\times$  6 combinations of objectives), see the colored cells. In 10 of out of the remaining 11 cases, one of the 6 MOEIM configurations turns out to be the second best (the only case where this does not happen is when calculating the hypervolume in the ( $\mathcal{I}^\uparrow$ - $\mathcal{S}^\downarrow$ - $\mathcal{B}^\downarrow$ ) space on the email-eu-Core dataset, where GDD and CELF are respectively the first and second best algorithms). More interesting, we notice that our proposed MOEIM turns out not to be the best only in some cases that present a pattern: 1) on sparse graphs (such as gnutella, CA-HepTh, and lastfm, see Table 1); and 2) in the ( $\mathcal{I}^\uparrow$ ,  $\mathcal{S}^\downarrow$ ) and the  $\mathcal{B}^\downarrow$  settings with the WC model. In the first case, our proposed algorithm struggles since its design is based on smart initialization and graph-aware operators, which require strong connectivity of the graphs and high variance between node’s out-degrees to be effective. Hence, in the sparser graphs, even if the solutions are at least always the second best, the low connectivity and low variance of out-degree leads to suboptimal results. The case of  $\mathcal{B}^\downarrow$  is instead most likely due to smart initialization, which by design selects in the seed set the nodes with the highest out-degree, while the other baselines do not have this kind of bias on the seed set initialization.

The final consideration concerns the combination of objective functions. Ideally, when optimizing a third objective function (i.e., ( $\mathcal{I}^\uparrow$ - $\mathcal{S}^\downarrow$ ) plus either  $\mathcal{C}^\uparrow$ ,  $\mathcal{F}^\uparrow$ ,  $\mathcal{B}^\downarrow$  or  $\mathcal{S}^\downarrow$ , see the “Algorithm” column in Table 2), the hypervolume w.r.t. ( $\mathcal{I}^\uparrow$ - $\mathcal{S}^\downarrow$ ) plus the third objective (top row of the table) should provide the highest results. This happens in several cases, as in the ( $\mathcal{I}^\uparrow$ - $\mathcal{S}^\downarrow$ ), “all”, and when optimizing  $\mathcal{C}^\uparrow$ ,  $\mathcal{F}^\uparrow$ , and  $\mathcal{B}^\downarrow$ . On the other hand, when optimizing  $\mathcal{T}^\downarrow$ , the best hypervolume turns out to be related to ( $\mathcal{I}^\uparrow$ - $\mathcal{S}^\downarrow$ - $\mathcal{B}^\downarrow$ ) for the “all” setting, shading lights to possible correlation between objective functions, that we discuss below. The analysis of the correlation is also motivated to explain why, when the additional objective functions are added to ( $\mathcal{I}^\uparrow$ - $\mathcal{S}^\downarrow$ ), the hypervolume of ( $\mathcal{I}^\uparrow$ - $\mathcal{S}^\downarrow$ ) decreases.

### 6.2 Setting 2: MOEIM vs. DeepIM

In this section, we compare MOEIM with DeepIM [35], a state-of-the-art DL approach for the IM problem. DeepIM is a Graph Neural Network (GNN)-based Diffusion Model designed to translate the

**Table 2: Avg.  $\pm$  std. dev. hypervolume (HV) achieved by the algorithms under comparison and our proposed MOEIM, across 10 runs for MOEIM, MOEA, and GDD, and (because of computational limits, as discussed in [9]) 3 runs for CELF ( $\mathcal{I}^\uparrow$ : Influence;  $\mathcal{S}^\downarrow$ : Seed set size;  $\mathcal{C}^\uparrow$ : Communities;  $\mathcal{F}^\uparrow$ : Fairness;  $\mathcal{B}^\downarrow$ : Budget;  $\mathcal{T}^\downarrow$ : Time). The column  $HV_{\mathcal{I}^\uparrow, \mathcal{S}^\downarrow}$  indicates the HV in the 2D ( $\mathcal{I}^\uparrow$ - $\mathcal{S}^\downarrow$ ) space, while the next four columns indicate the HV calculated in the corresponding 3D space, and  $HV_{\text{all}}$  indicates the HV calculated in a 6D space in which all objectives ( $\mathcal{I}^\uparrow$ - $\mathcal{S}^\downarrow$ - $\mathcal{C}^\uparrow$ - $\mathcal{F}^\uparrow$ - $\mathcal{B}^\downarrow$ - $\mathcal{T}^\downarrow$ ) are considered. For MOEIM, we show the case where 2 objectives ( $\mathcal{I}^\uparrow$ - $\mathcal{S}^\downarrow$ ), the combinations of 3 objectives ( $\mathcal{I}^\uparrow$ - $\mathcal{S}^\downarrow$  plus either  $\mathcal{C}^\uparrow$ ,  $\mathcal{F}^\uparrow$ ,  $\mathcal{B}^\downarrow$  or  $\mathcal{S}^\downarrow$ ), and all objectives ( $\mathcal{I}^\uparrow$ - $\mathcal{S}^\downarrow$ - $\mathcal{C}^\uparrow$ - $\mathcal{F}^\uparrow$ - $\mathcal{B}^\downarrow$ - $\mathcal{T}^\downarrow$ ) are considered during the evolutionary process. The colored (underlined) cells indicate the highest (second highest) value per column, separately per each dataset, propagation model, and combination of objectives considered to calculate the HV.**

after which DeepIM shows superior performance. As discussed in the previous experimental setting, this trend is most likely due to the fact that this dataset is the sparsest one (i.e., the one with the lowest avg. out-degree) among those tested in this setting, which makes the initialization and graph-aware operators less effective.

On the other hand the superiority of MOEIM is particularly clear on the Jazz dataset with the LT model, where it only needs a seed set size of 10% of the graph size to influence the whole network, while DeepIM achieves the same results using twice the number of nodes. Overall, it appears that in most cases MOEIM tends to provide better performance than DeepIM, which as said is currently the best DL-based approach available in the literature.

### 6.3 Statistical analysis

To ensure the statistical relevance of our results, we performed a statistical comparison on the hypervolumes achieved by the algorithms under comparison in the first experimental setting **1**, by using the Holm-Bonferroni procedure [23], with significance threshold  $\alpha = 0.05$  and the null hypothesis of statistical equivalence. From this test (whose results are shown in Table 3), it emerges that the best-performing method is MOEIM in the “all” setting (i.e., the one considering all six objective functions), which allows rejecting the null hypothesis in all the cases. This is clearly a confirmation of an expected result, as we expect the hypervolume to be maximized when we optimize all the objectives simultaneously.

Moreover, to statistically assess the pairwise comparisons among the algorithms, we also performed a Tukey HSD test [56] for multiple comparisons, keeping the same significance threshold and null hypothesis. These results (presented in Table 4) show that, while in Table 2 all the MOEIM settings seem to outperform the baseline methods, only the “all” setting reliably does so. It is worth noting that this may result be due to the fact that, since this test is based on the actual Hypervolumes (instead of their ranking, as in the Holm-Bonferroni test) and we are aggregating the results obtained

**Table 4: Results of the statistical tests using the Tukey HSD procedure [56] for pairwise comparisons. Note that, for simplicity of notation, we omit “MOEIM” from the settings of our algorithm. “Mean difference” refers to the mean of the difference on the hypervolume achieved by the methods in each pairwise comparison, “p-adj” refers to the adjusted p-value, “Lower CI” and “Upper CI” refer to the lower and upper bound for the 95% CI (Confidence Interval). “Reject” indicates if the null hypothesis (of statistical equivalence between Methods 1 and 2) can be rejected or not. We highlight the cases for which the hypothesis can be rejected.**

across several datasets, the standard deviation of the Hypervolumes obtained with the other MOEIM settings proposed in this paper is too high to lead to statistically significant results.

Finally, it is important to note that we could not perform any statistical test between our methods and DeepIM considered in the second experimental setting **2**, since the DeepIM results have been taken directly from the original paper without raw data availability.

### 6.4 Analysis of objective function correlation

We conclude our analysis studying the correlation between the objective functions. This study has been conducted to better understand the hypervolume trend on  $\mathcal{T}^\downarrow$  of Table 2 and explain the reason why the hypervolume computed over  $(\mathcal{I}^\uparrow\text{-}\mathcal{S}^\downarrow)$  decreases when adding objective functions. Figure 3 displays the Pearson correlation among the proposed objective functions. Such correlation has been computed separately for each (dataset, propagation

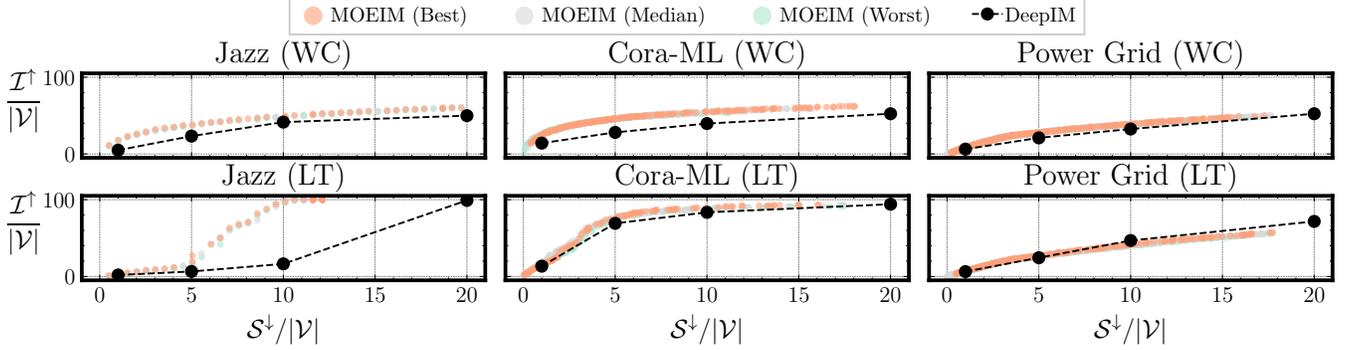

Figure 2: Non-dominated solutions found MOEIM and DeepIM [35]. For MOEIM, we provide the worst, median and best sets of non-dominated solutions found across 10 runs. To allow for a direct comparison with the results reported in [35], the x-axis and y-axis show, respectively, the seed set size  $S^\downarrow$  and the final influence  $\mathcal{I}^\uparrow$ , both normalized w.r.t. the size of each network,  $|\mathcal{V}|$ . For DeepIM, we show the results available in the original paper, where they are reported separately for each value of  $S^\downarrow/|\mathcal{V}|$ .

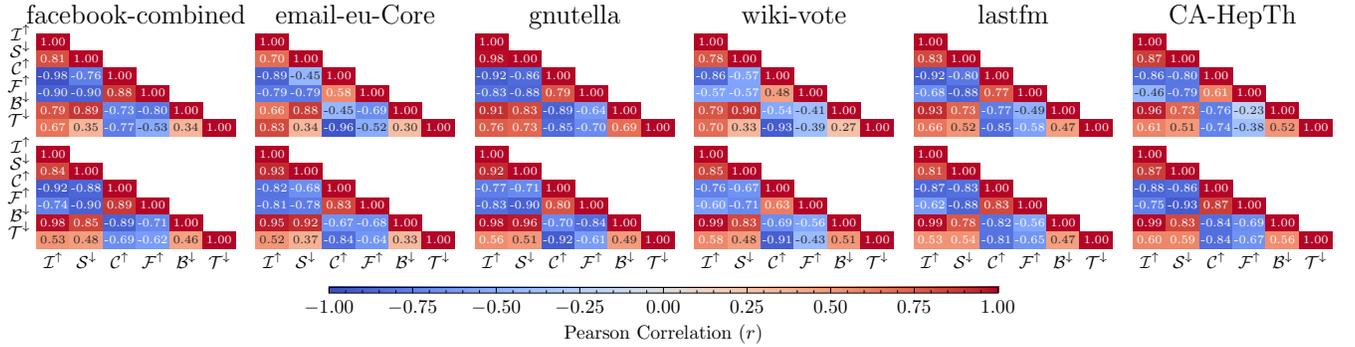

Figure 3: Pearson correlation among the objectives ( $\mathcal{I}^\uparrow$ : Influence;  $S^\downarrow$ : Seed set size;  $C^\uparrow$ : Communities;  $\mathcal{F}^\uparrow$ : Fairness;  $\mathcal{B}^\downarrow$ : Budget;  $\mathcal{T}^\downarrow$ : Time). This correlation has been computed over the results of the 10 runs available for the “MOEIM (all)” setting (see Table 2 for details). Top row: IC model, bottom row: WC model.

model) combination on the results of MOEIM (all). For this analysis, each entry corresponds to the vector of the normalized objectives (see Section 6.1) for each non-dominated solution found across the 10 runs of MOEIM (all). The analysis clearly shows how all the objective functions added to the base setting objectives (i.e.,  $\mathcal{I}^\uparrow$  and  $S^\downarrow$ ) are negatively correlated with them. In fact,  $C^\uparrow$  and  $\mathcal{F}^\uparrow$  are negatively correlated (w.r.t. to both  $\mathcal{I}^\uparrow$  and  $S^\downarrow$ ), while  $\mathcal{B}^\downarrow$  and  $\mathcal{T}^\downarrow$  are positively correlated (always w.r.t.  $\mathcal{I}^\uparrow$  and  $S^\downarrow$ ), but these latter two objectives are minimized. The highest correlation turns out to be between  $\mathcal{B}^\downarrow$  and  $\mathcal{I}^\uparrow$ , since as expected selecting (in the seed set) nodes with high out-degree leads to improving the overall influence spread, and between  $S^\downarrow$  and  $\mathcal{I}^\uparrow$ . Of note, the correlation between  $C^\uparrow$  and  $\mathcal{F}^\uparrow$  turns out to be extremely high, since such objectives, even though formulated differently, share the same spirit of fair allocation on either the final influence or the seed set allocation. To conclude, the reason why, in some cases, the hypervolume in the  $\mathcal{B}^\downarrow$  or “all” settings is higher w.r.t.  $(\mathcal{I}^\uparrow - S^\downarrow - \mathcal{T}^\downarrow)$  is due to the positive correlation between  $\mathcal{T}^\downarrow$  with both  $\mathcal{B}^\downarrow$  and  $S^\downarrow$ .

## 7 CONCLUSIONS

We presented a new setting for the IM problem, where up to six objective functions are considered in the optimization process. For solving such a task, we proposed MOEIM, a MOEA designed to leverage graph information thanks to the use of graph-aware operators and a smart initialization of the initial population. The numerical results confirm the effectiveness of the proposed approach w.r.t. the state of the art, including a recently proposed DL-based method. Moreover, our results allowed us to investigate the correlation objectives, providing insightful information on IM.

The approach presented in this work opens up several possibilities to expand the IM problem even further, as new objectives can be easily added to our codebase. Moreover, while in this work we mainly focused on static graphs and propagation models taken independently, another possibility for future works could be to conduct similar multi-objective studies on dynamic graphs, or to aim at assessing the solutions robustness w.r.t. multiple propagation models.
