**Keywords**: Hypoxic-ischemic encephalopathy, neonatal EEG, perinatal asphyxia, quantitative EEG

# Highlights

- Delta power fluctuations from background activity in conventional EEG (cEEG) are found to be relevant biomarkers of hypoxic-ischemic encephalopathy (HIE) in term neonates (<6 hours of age).
- Spectral fluctuations of neonatal EEG background (summarized by the levels of delta power with respect to their duration) can correctly discriminate between EEG segments of the mild HIE group from those of requiring hypothermia. Our detection system provides a simple, robust and reliable marker of hypoxic-ischemic encephalopathy in neonate with high accuracy (98%) and sensitivity (99%), with high positive (99%) and negative predictive value (94%), a probability of false alarm of only 6% and a F1 score (the harmonic mean of the precision and sensitivity) of 99%.
- Our approach could be a simple and efficient clinical decision support tool for neonatologists to identify full-term neonates with HIE candidate to a therapeutic hypothermia.

#### Abstract

**Objective**: Indication of therapeutic hypothermia (TH) needs an accurate identification of hypoxic-ischemic brain injury in the early neonatal period. Early therapeutic decisions are crucial as TH must be started within 6 hours to optimize effectiveness on neurodevelopmental outcome. We aim to provide a simple hypothermia decision-making tool for the term neonates with hypoxic-ischemic encephalopathy (HIE) based on features of conventional electroencephalogram (EEG) taken less than 6 hours from birth.

**Methods**: EEG recordings from one hundred full-term babies with HIE were included in the study. Each EEG recording was graded by pediatric neurologists for HIE severity. Amplitude of each EEG segment was analyzed in the slow frequency bands. Temporal fluctuations of spectral power in delta (0.5 – 4 Hz) frequency band was used to characterize each HIE grade. For each grade of abnormality, we estimated level and duration (number of consecutive segments above a given level) probability densities for power of delta oscillations. This study is registered on <u>clinicaltrials.gouv</u> (NCT05114070).

**Results**: These 2D representation of EEG dynamics can identify mild HIE group from those of requiring hypothermia. Our discrimination system yielded high accuracy (98%) and sensitivity (99%), high positive (99%) and negative predictive value (94%), a low probability of false alarm (6%) and a F1 score (the harmonic mean of the precision and sensitivity) of 99%. These results provided an accurate discrimination of mild versus moderate or severe HIE, and only one mild case was erroneously detected as relevant for hypothermia.

**Conclusions**: Quantized probability densities of slow spectral features (delta power) from early conventional EEG (withing 6 hours of birth) revealed significant differences between infants with mild HIE grades and those relevant for hypothermia.

**Significance**: EEG segments can be represented by simple and interpretable biomarkers that can constitute a visual and efficient clinical decision support tool for physicians to identify full-term neonates with HIE candidate to a therapeutic hypothermia (TH).

#### 1. Introduction

Perinatal asphyxia is an imprecise term that corresponds to a severe alteration of uteroplacental gas exchange, leading to metabolic acidosis (Antonucci et al., 2014). In this context, all organs can be affected, but the neonate's brain is particularly vulnerable. Brain damage due to perinatal asphyxia constitutes hypoxic-ischemic encephalopathy (HIE) and is the most frequent severe neurological morbidity in newborns (Volpe et al, 2012).

Hypoxic-ischemic encephalopathy (HIE) defined by Sarnat and Sarnat (1976) is based on clinical criteria (e.g. level of consciousness, presence, or absence of reflexes in the newborn, etc.), biological (pH, lactate levels), and EEG markers (background rhythms and presence or not of critical discharge). The visual analysis of background EEG signals provide accurate prognostication in the two extremes of neonatal HIE grades (mild and severe). While minor HIE and normal or mildly affected EEG are associated with spontaneously favorable evolution and good clinical outcome (Gray, 1993), moderate and severe HIE may have a poor clinical outcome if therapeutic hypothermia (TH) is not applied on time (Lawn et al., 2005 and Dixon et al., 2002).

Early Therapeutic hypothermia (TH) is the standard of care and the reference neuroprotective treatment for neonatal HIE (Martinello et al., 2017). Despite its established neuroprotective action, TH is a quite "heavy" treatment requiring admission, within the first six hours of life, in a neonate intensive care unit (NICU) to place the child in hypothermia (whole body cooling) for 72 hours, most often including deep sedation and assisted ventilation of the child. Although this therapeutic action reduces the risk of death or disability in newborns with moderate to severe HIE (Jacobs et al., 2007, Edwards et al., 2010), it may have side effects, such as heart rhythm and coagulation disorders, with potential severe consequences (Jannatdoost et al., 2013).

Overall, identification of neonates suitable for TH, is a challenge in clinical care of asphyxiated neonates as rapid and accurate diagnosis must be done rapidly after birth. In the current practice at NICUs, resuscitators face with a very short time window of 6 hours, within which they must decide to initiate TH. Nevertheless, the decision to start TH is often made without EEG criteria, which deprives the resuscitator of a precise functional evaluation of the cerebral electrical activity of the child. and therefore, of the certainty of the presence/absence of cerebral lesions. Although continuous EEG is a widely available non-invasive bed-side test, it requires specific technical skills for its recording and interpretation to recognize neonatal brain function abnormalities in full-term infants born in a context of asphyxia. Among other characteristics,

pediatric neurologists often consider features of EEG activity such as amplitude, frequency, continuity and sleep-wake cycling (Korotchikova et all, 2009). The identification of low voltage background activity, inactive phase or burst-suppression, very long inter-bursts intervals (IBIs), and theta-delta inversion are some elements suggesting the existence of a brain injury. Nevertheless, the lack of access to continuous EEG recording and analysis, is crucial to identify a HIE grade requiring the initiation of hypothermia (Dilena et al., 2021). In France, for instance, only 7% of NICUs have recently reported having 24/7 access to continuous EEG (Chaton et al., 2023).

In contrast to continuous EEG captures much of the rich neonatal cortical dynamics, the amplitude integrated EEG (aEEG) offers a simplified, compressed trace derived from standard EEG (al Naqeeb N, et al. 1999; Hellstrom-Westas L, 2006). This compressed representation of EEG is a tool easier to access and requiring less expertise than continuous recordings analysis, which can also be used over longer periods of time (Shellhaas et al., 2007). Nevertheless, aEEG has also technical and interpretation pitfalls, and evidence has shown that it may underestimate HIE severity (Evans et al., 2010). Indeed, although aEEG can accurately detect normal or severely injured neonates, there is a lack of sensitivity for mild to moderate HIE severity (Marics et al., 2013). There is therefore a real need for an automatic system of continuous EEG interpretation, that could robustly characterize the large variety of background patterns to identify the progression of an encephalopathy in neonates with HIE.

Several algorithms have been proposed to identify, from the EEG analysis, full-term neonates with HIE candidate to a therapeutic hypothermia. Many studies have proposed many reliable EEG features, including parameters from the time, frequency or information theory domain to quantify EEG in full-term neonates with HIE (Löfgren et al., 2006; Korotchikova et al., 2011; Lacan et al., 2021). Some studies have proposed the interburst intervals as a parameter to quantify the evolution of encephalopathy in neonates with HIE (Thordstein et al., 2004; Löfhede et al., 2008; 2010). Nonstationary statistics, based on time-frequency decompositions (Stevenson et al., 2013; Raurale et al., 2021) or the analysis of long-range fluctuations (Matic et al., 2015), have been proved to be a useful tool to quantify the continuity of background EEG, providing thus a marker of the encephalopathy severity in neonates. Quantification of spatiotemporal dynamics of raw or parametrized EEG signals has also been proposed as discriminating features to identify HIE grades (Stevenson et al., 2013; Matic et al., 2014; Wang et al, 2022). In all these approaches, different feature sets are estimated from EEGs before combining with machine learning algorithms (Ahmed et al., 2016) or, more recently, with deep-

learning methods (Raurale et al., 2021; Moghadam et al., 2022), to provide an automated grading system of HIE.

Previous studies have shown that delta (0.5 – 4 Hz) and theta (4 Hz - 8 Hz) oscillations are predominant in newborn cortical activities compared with higher frequency waveforms (Tsuchida et al., 2013). Whereas theta/delta power ratio can be used as a marker of normality in neonatal EEG, spectral power in the delta frequency band is a robust physiological biomarker for monitoring the evolution of the encephalopathy severity (Govindan et al., 2017; Kota et al., 2021), and it can distinguish neonates with HIE that have significant brain injury from infants with favorable outcomes (Kota et al., 2020).

The objective of this study is to propose a simple real-time system, based on conventional EEG signal analysis before H6 of life, to identify any sign of brain injury during the evolution over the course of EEG monitoring, facilitating thus the indication or not for a therapeutic hypothermia for full-term neonates, born in a context of asphyxia. In this study, we show that the temporal fluctuations of slow EEG oscillations (summarized by the levels of delta power with respect to their duration) can accurately identify the group of neonates requiring hypothermia treatment. We show that, instead of characterizing EEG by the spectral power level alone, features from temporal fluctuations (level and duration) are statistically robust providing thus the basis for a simple and reliable decision support tool for neonatologists in the NICU.

#### 2. Methods

#### 2.1. Dataset

The 104 neonates included in this retrospective study were part of a larger cohort of more than 600 term neonates monitored between 2005 and 2020, at the NICU of the Armand Trousseau Hospital (Paris, France). Following the French Society of Neonatology, the inclusion criteria were (Saliba et al, 2010): gestational age > 36 weeks and a birth weight > 1,800 g; postnatal age <H6; and presenting an HIE (mild, moderate or severe) with at least one of the following features: (a) birth asphyxia and with clinical suspicious features (e.g. fetal distress, umbilical cord prolapse); (b) Apgar score  $\leq 5$  at 5 minutes; and (c) pH < 7, and/or lactates > 11 mmol/l in cord blood or in the first hour of life.

The parents of patients who satisfied the inclusion criteria were informed by a written document of the anonymized use of data, and non-opposition consent was obtained. The study was declared to the French National Commission on Informatics and Liberty (agreement reference CER-2021-023), and it had the approval from the local Ethics Committee of Sorbonne University. This study is registered on <u>clinicaltrials.gouv</u> (NCT05114070).

#### 2.2. EEG recordings

EEG signals were recorded with a Deltamed (2005-2016) and a Nihon-Khoden (2016-2020) systems. EEG recording from three patients were excluded from the analysis because of technical format problems. To monitor the evolution of a possible encephalopathy, all recordings continuous video EEG recordings were obtained during the first six hours of birth after perinatal asphyxia.

EEG signals were obtained with Deltamed (N=27) and Nohon-Khoden (N=77) recording systems, sampled at 256 Hz and 500 Hz, respectively. Although scalp electrodes were positioned according to the international 10-20 system, only signals from electrodes Fp1, Fp2, T3 and T4 were considered in this study. In both recording systems, the reference electrode was placed on the midline between Fz and Cz. During acquisition, EEG signals were filtered using high and low-pass filters at 0.19 Hz and 70 Hz. Electrode impedance was always maintained below 10 k $\Omega$  during the whole recordings. Physiological measures of heart activity (ECG), respiration and SpO2 were simultaneously recorded for some patients, but these signals were not used in this study. In all our analyses, EEG signals were visually identified, and the corresponding segments were removed from the analysis. Segments with artefacts caused by large motion interferences, or bad electrode-tissue contacts were thus removed. EEG recordings from 4 patients were discarded from the study as files were corrupted (n=3) or data were strongly contaminated by artifacts during the whole recording the whole recording (n=1).

For each patient, the degree of hypoxic-ischemic encephalopathy was evaluated according to Sarnat and Sarnat classification (Sarnat et al, 1976) within the first six hours after birth. Data were collected so that three HIE grades could be included: 17 of the 100 newborns included in the study were labelled as mild or with minor encephalopathy (continuous background with mild voltage depression [30-50  $\mu$ V]); 17 as moderate (discontinuous activity with IBIs < 10s, clear asynchrony), and 66 as severe (IBIs of 10-60 s, severe background attenuation [<30  $\mu$ V]) HIE. The demographics of the study is summarized in Table 1

## Table 1

Demographic data		
Total (N)		100
Gender (M/F)		60/40
Gestational age at birth (weeks+days)		39+3 [34+6-42+4]
Apgar 1 minute		2 [0-8]
Apgar 5 minutes		6 [1 – 10]
Umbilical cord gas PH		7.05 [6.67 – 12]
Lactates mmole/l		10.8 [1.7 – 21]
EEG recordings		
Age at EEG recording (h)		5 [2 6]
Analyzed EEG recording time (minutes)		30.8 [5.8 - 56]
HIE severity groups (n)		
Not requiring hypothermia	Mild HIE	17
Candidate to hypothermia	Moderate HIE	17
	Severe HIE	66

Demographic characteristics of study group (median values [min-max])

## 2.3. EEG processing

A general scheme of our method is illustrated in Fig. 1. For all EEG recordings, bipolar channels Fp1-T3 and Fp2-T4 were constructed, and power spectral density was estimated in all 1-second segments using Welch periodogram method. All segments where the alpha (8-12 Hz) spectral power was above  $10^5 \,\mu\text{V}^2/\text{Hz}$  were considered as artefacts and removed.

Although aEEG was originally developed as a bedside monitor for adult intensive care, it is now a widely used method for continuous monitoring of brain activities in NICUs. This signal is generally obtained from the EEG by asymmetric bandpass filtering (to reduce the effects of artefacts), rectifying (to transform biphasic into monophasic waveforms), smoothing and compression by a semi-logarithmic amplitude compression, followed by a time compression such that maxima and minima of transformed signal in a time window are displayed. This reduction of the EEG's information and time compression make continuous monitoring and bedside interpretation possible for long recordings. In this study, we created a more general representation of conventional EEG background dynamics by quantizing power levels of EEG and measuring the durations that the spectral power stays at those different levels. Based on the main spectral content of EEG in full-term neonates, here we considered slow EEG oscillations at the delta (0.5 - 4 Hz) frequency band. We also assessed the theta/delta power ratio as a marker of normality in neonatal EEG. For each EEG segment, we first quantified the power of delta band oscillations and the theta/delta ratio. For these features, we use a logarithmic transformation (Log<sub>10</sub>), and we quantize the values to the first decimal. In this way, small changes remain visible, while an overloading due to large values is avoided. theta/delta spectral ratio.

Fig. 2. Overview of the proposed feature extraction (delta power) for each EEG channel.

Pivot tables were then created with the sequence of levels/duration, capturing the information about the quantized power level (or power ratio) changes across EEG segments. Tables were normalized resulting in a joint duration/level probability table. Finally, a Gaussian smoothing was applied to obtain 2D smooth probability densities.

#### 2.4. HIE grade severity classification

We first evaluated the ability of level-duration distributions to discriminate between different HIE grades using a simple nearest-neighbor classifier. To assess the classifier's performances, we considered a leave-one- out cross-validation: for each fold, one EEG recording was randomly assigned to the testing dataset, while the remaining recordings were used to train the algorithm. An average probability distribution of each grade is firstly estimated from EEG recordings of the training set. Then, the 2D level-duration representation of the test data is compared with the three reference distributions to identify the nearest category (grade). The corresponding grade of the nearest neighbor is finally allocated to the test data. To compare two probability distributions  $P_i$  and  $P_j$  on sample space  $\xi$ , we evaluated a distance (Basseville,

1989) with the L<sub>2</sub> norm, simply defined as  $d(P_i, P_j) = \sqrt{\sum_{x \in \xi} |P_i(x) - P_j(x)|^2}$ .

We finally evaluated the ability of our classifier to distinguish mild HIE group from those requiring hypothermia (severe and moderate HIE merged in a single class). Classification performances were assessed by the accuracy (to measure how often the learning model correctly predicts the outcome), recall or sensitivity (to quantify how good the learning model is at finding all the positives), precision (also called positive predictive value, which quantifies the proportion of true positives to the amount of total positives that the model predicts), balanced accuracy (the average of sensitivity and specificity that accounts for both the positive and negative outcome classes, and thus for class imbalance), negative predictive value, false positive rate (false alarm ratio) and F1-score, which is the harmonic mean of the recall and precision.

#### 3. Results

#### 3.1. Results on the French dataset

Figure 2 shows the densities corresponding to the fluctuations of delta power, for the mild, moderate and severe HIE categories. We can notice that these 2D representations, created for the EEG signals of each patient, show shape differences for all HIE grade categories that can be easily recognizable by humans.

The detection of different EEG segments yielded a direct grade match for 81% of EEGs, specifically 53% severe, 16% mild, and 12% moderate. The remainder is an adjacent grade

matching with only one mild graded as moderate, four moderate graded as severe, and thirteen severe misclassified as moderate. No mild was identified as severe or vice versa. The discrimination of mild HIE group from those infants requiring hypothermia (severe and moderate) yielded a high accuracy (98%), recall or sensitivity (99%), positive predictive value or precision (99%) and negative predictive value (94%), a balanced accuracy of 96%, a low false alarm ratio (6%) and a F1-score of 99%. Only one mild was misclassified as requiring hypothermia.

**Fig 2.** Joint level-duration probability densities of delta power for the three grades of HIE. The normalized densities correspond to the average densities obtained from all mild, moderate, and severe cases.

Although the combination of other spectral features could also be used as a marker of normality in neonatal EEG, the discrimination between EEG segments of the mild HIE group from those relevant for hypothermia yielded moderate performances. The theta/delta spectral ratio, for instance, provided an accuracy of 80%, a sensitivity of 96%, a precision of 79%, and a negative predictive value of 70%, a balanced accuracy of 82%, an important false alarm ratio of 55% and F1-score of 87%.

#### 3.1. Results from a public EEG-HIE dataset

For clarity and reproducibility purposes, we tested our method on a publicly available dataset made available by the Cork University Maternity Hospital, Ireland (O'Tool et al., 2023). This dataset consists of more than 100 multichannel EEG files, recorded at the NICU from 53 full-term newborns with a diagnosis of HIE. In the absence of pre-frontal electrodes, for the analysis of this dataset we used the signals recorded at the frontal regions (electrodes F3 and F4). Each 1-hour EEG recording was graded for severity of background abnormalities. It is worthy to notice that contrary to our EEGs obtained before 6 hours of age, the public dataset includes EEG recordings obtained for a prolonged period up to 100 hours after birth. Further, graduation of Cork data considers four HIE grades: normal or mildly abnormal, moderately abnormal, severely abnormal, and inactive.

When applied to this dataset, the classification based on the delta power yielded a direct grade match for 77% of EEGs, the remainder was an adjacent grade matching with 9.6% of normal graded as moderately abnormal, whereas 1.9% of moderately abnormal were misclassed as severely abnormal, and only 0.95% of severe were erroneously matched as inactive. The discrimination of the normal HIE group (normal and mildly abnormal considered together) from those infants requiring hypothermia (severely abnormal and inactive merged as a single class) yielded an accuracy, recall, positive predictive value (precision), balanced accuracy, negative predictive value, false alarm ratio and F1-score of 94%, 86%, 86%, 96%, 91%, 3.6% and 86%, respectively.

#### 4. Discussion

From a French large cohort of full-term neonates, presenting mild, moderate and severe HIE, with annotated clinical characteristics and conventional EEGs (recorded before H6é), we demonstrated that spectral fluctuations of EEG background (summarized by the levels of delta power with respect to their duration) can correctly discriminate mild, moderate and severe HIE categories. We validated our prediction algorithms on an independent replication publicly available EEG-HIE cohort (Cork, Ireland) including normal term newborns and mild, moderate and severe HIE. Moreover, we provided visual individual representation of HIE severity that can be easily recognizable by clinicians. Our approach could be a simple and efficient clinical decision support tool for neonatologists to identify full-term neonates with HIE candidate to therapeutic hypothermia.

Our results are consistent with those of prior studies using quantitative EEG in full-term neonates, and support simple automated EEG analysis as an accessible, generalizable method

for generating biomarkers of brain injury in neonates with HIE. It is worth noticing that the 2D level-duration probability distributions obtained for each EEG capture well some characteristics of different HIE grade categories that can be easily recognizable by clinicians: for the mild grade, the shape of the distribution allows a clear distinction between awake and sleep states. The two main pics reflect the distinctive patterns of high voltage and lower-voltage waveforms observed in the trace alternant activity during the quiet sleep, whereas the rich variability of EEG fluctuations of the awake state is captured in the bumpy central values. The decrease of EEG amplitude, characteristic of moderate HIE grade, can also be observed in the right shift of the density toward lower values of power. Finally, when compared with the level-duration distribution of the mild group, the 2D density associated to severe HIE grade clearly reflects the discontinuous and very low amplitude of EEGs.

In contrast with the EEG's content recorded in healthy adults, delta waves are predominant in the cortex of full-term neonates (Tsuchida et al., 2013). Our findings show that the spectral fluctuations of EEG background, captured by the 2D level-duration distributions of delta power, can reliably be used to discriminate mild versus moderate or severe HIE. Indeed, with the proposed approach, we obtained an accuracy of 98%, with only one mild case erroneously detected as relevant for hypothermia (1%). When applied to a public dataset with four HIE grades, the proposed system achieved an overall classification accuracy (considering the four grades) of 77%, with only 0.19% of moderately abnormal EEGs misclassed as severely abnormal, and 2.8% of severely abnormal or inactive misclassified as normal or mild.

Our results confirm previous findings suggesting that automated classification of neonatal EEG can be achieved from the fluctuations of delta power with good levels of accuracy. The proposed 2D level-duration distributions can also be obtained from the theta/delta spectral ratio, often used as a marker of EEG normality. Nevertheless, we found that its use for identifying the HIE group relevant for hypothermia yielded moderate performances (accuracy of 80%). A grading system based on features extracted from quadratic time-frequency decompositions of EEG segments reported a classification accuracy of 78%, which could be augmented by incorporating supplementary information about sleep states (Stevenson et al., 2013). Similar performances (AUC $\approx$ 79%) were reported by (Kota et al., 2021) by using the delta power. Improved classification performances (accuracy of 83%) were obtained by including a large feature set with a combination of probabilistic models (Gaussian Mixture Models) and supervised machine learning algorithms (Support Vector Machines, SVM), followed by additional prost-processing (Ahmed et al., 2016). Similarly, in (Moghadam et al., 2021) the

combination of a large feature set with different classifiers (SVMs and neural networks) yielded very good classification performances with accuracy levels larger than 90%. More complex grading systems based on deep learning methods have been shown to provide very good accuracy levels (>85%), when applied to different EEG-based features (Raurale S, et al., 2021; Yu et al., 2023).

It is important to notice that the studies mentioned above were conducted on datasets with four HIE groups. Our findings are, however, also consistent with previous classification results on datasets with three grades (mild, moderate and severe). In (Matic et al., 2014) the three groups of increasing HIE severity could be correctly identified with an accuracy of 89%. Such results were obtained by using a complex system that integrated spatial EEG information as the feature set for supervised classification methods (Matic et al., 2014). With a much simpler and faster method, we obtained a direct matching of 81% in our dataset and and 77% in the public EEG database.

The correct discrimination of adjacent grades (e.g. mild-moderate, moderate-severe, or moderate-severely abnormal) has been found to be a challenging task (Matic et al., 2014; Ahmed et al., 2016). In our database, only one EEG mild graded (5.8%) was identified as moderate and vice versa. When applied to the public dataset with four grades, our approach mismatched 9.5% of moderately abnormal as severely abnormal. For the discrimination of the mild-normal HIE group from those infants requiring hypothermia, our method yielded only one misclassification (5.8%) in our dataset, and only 13% in the Cork's data. Clinical trials have shown that therapeutic hypothermia is most beneficial for neonates with moderate grade of HIE. Whereas the detection of normal or mild EEG is important to confirm a good clinical outcome, an accurate detection of moderate HIE cases is crucial for the identification of neonates suitable for TH. Our results also showed a very good accuracy for identifying the normal or mild encephalopathy. We obtained a match in 94% of mild graded in our database, whereas for the Cork's data the accuracy was of 88.7% and 57% for the normal and moderately abnormal, respectively.

Compared with the amplitude-integrated EEG, our 2D representation can be seen as a more general representation of EEG background dynamics that quantizes, for different levels, the duration of spectral power at a given frequency band (the delta band). From the plots in Fig. 2 one can observe, for instance, that the distribution of durations of high oscillations cannot clearly distinguish the three HIE groups, especially the mild and moderate cases. Similarly, the fluctuations of low-power levels cannot discriminate between moderate and severe HIE grades.

In contrast, our findings suggest that the joint information of power level-duration accurately identify enfants from the mild HIE group, and clearly distinguish those from the moderate/severe grade that require neuroprotective therapy.

Although other statistical distances such as Kullback-Leibler, Hellinger or Bhattacharyya (Basseville, 1989) could be used to compare the probability distributions, the discrimination obtained from the simple variational distance outperforms those obtained from other alternatives. The increase of accuracy when using the Bhattacharyya distance in the Cork's data was, for instance, of less than 3%. In contrast to complex feature sets or classification algorithms, our proposed system using only a single spectral feature and a very simple classifier, yields comparable classification performances. The clinical interpretation of EEG features is of paramount importance for the development of informative biomarkers of neurological injury in infants with HIE. We think that the proposed 2D representation of neonatal EEG background constitutes a useful clinical decision support tool as it visually provides a traceable clue to neonathologists for the identification of full-term neonates with HIE candidates to a therapeutic hypothermia; without the black box effect of more complicated deep learning-based models (Raurale et al., 2021; Moghadam et al., 2022), or undisclosed algorithms used for automated grading systems (Hathi et al., 2010).

## 5. Conclusion and future work

An accurate identification of neonates with HIE requiring a therapeutic hypothermia is of great significance to optimizes outcomes. Our results show that the spectral fluctuations of EEG background, captured by the 2D level-duration distributions of delta power, can reliably be used to identify full-term neonates with HIE candidates to a therapeutic hypothermia. Our system accurately identified all EEGs that should be proposed for hypothermia (moderate and severe categories), and all mild EEGs are correctly identified, except for one EEG, classified as moderate.

While our findings are encouraging, our study has some limitations. First, the HIE severity was retrospectively assessed in a dataset of limited sample size. Future studies on larger patient series with prospective HIE grading are needed to validate our approach. Second, during long-term monitoring, EEG grade can change because the evolving nature of HIE. A clinical decision-making tool should integrate this dynamical behavior of HIE grades for obtaining a more flexible automated grading system (Raurale et al., 2021). Finally, our results were obtained on preselected data where EEG epoch with major artefacts were excluded. A quality

index of the EEG recording could also be obtained with the inclusion of more complex artefact detection methods (Webb et al., 2021; O'Sullivan et al., 2023) to provide a more robust and informative decision support system. To expand the clinical implications of our findings, it will therefore be important to evaluate our method on larger datasets without preselecting clean EEG segments.

Given the heterogeneity of electrodes location among the different NICUs, we cannot generalize a single unique discriminating model. Our proposed approach is based on the information recorded at pre-frontal regions (or frontal electrodes for the Cork's data). We notice, however, that HIE discriminating power can be improved by combining combine information from multiple EEG channels (Stevenson et al., 2013; Matic et al., 2014; Yu et al., 2023), or by building more complex models that account for spatio-temporal organisation of EEGs (Garvey et al., 2021; Syvälahti et al., 2023). Nevertheless, such systems have only limited clinical utility because the newborn EEG is typically recorded at NICU with only a few channels, many of which might need rejection because of various artifacts. More sophisticated and accurate clinical decision support system could also be obtained by integrating clinical markers (Mooney et al., 2021). Similarly, functional near-infrared spectroscopy signals (Tang et al., 2024), or from other physiological variables such as heart rate variability (Pavel et al., 2023) would be interesting to develop (Chock et al., 2023).

Although much larger cohorts of patients are needed to map out the limits of our approach, the results suggest that our method can provide a robust and simple automated tool for the assessment of brain injuries in neonates with HIE. Information provided by the fluctuations of spectral power in other frequency bands could also be used to detect the sleep-wake transitions, or the tracé alternant activity in quiet sleep of neonates.

Results suggest that with the proposed system, the nursing and clinical staff could decide, based on objective arguments of the presence or absence of brain injury, whether to place a child in hypothermia. This easy-to-use decision support tool would also make it possible to reduce the delays between birth and the start of treatment when it is necessary. Above all, it will avoid imposing unjustified heavy treatment on a newborn and will allow many newborns to benefit from hypothermia and therefore limit or even eliminate future neurological disability. Deployed in a NICU, the proposed system is a could provide a real hope of reducing the number of children or adults with disabilities.
