Proposal on the Calculation of the Ionisation-Cluster Size Distribution

(B. Heide, Karlsruhe Institute of Technology (KIT), Institute for Nuclear Waste Disposal (INE), Bernd.Heide@kit.edu)

Abstract

A stochastic model for the calculation of the ionisation-cluster size distribution in nanodosimetry is proposed. It is based on a canonical ensemble and derives from the well-known nuclear droplet model. It is able to describe the ionisation-cluster size distributions caused by electrons. It can easily be extended to light ions. In principle, the model has no free parameters. The model especially can be seen as a refinement to B. Grosswendts model. It is shown that it leads to a cluster-size distribution function F_2 being more similar to of the yield of double-strand breaks in the DNA than the one calculated by B. Grosswendt. However, the results are still subject to major uncertainties. The focus of this work is on presenting the model and demonstrating its feasibility.

1. Introduction

There are several models for describing biological damage once a cell was exposed to ionising radiation. The reader is referred to Refs.⁽¹⁻⁹⁾, for instance. Besides the model of W. Friedland et al.⁽²⁾, S. A. Ngcezu and H. Rabus⁽⁶⁾, B. Grosswendt^(7, 8) as well as the model of F. Villegas et al.⁽⁹⁾, the models already start from an initial ionisation (energy deposition) aggregation or even from deoxyribonucleic acid (DNA) single-strand breaks (SSBs) and double-strand onces (DSBs). However, it is in general not explicitly stated the way the single ionisations are transformed into clusters of ionisations and clusters of DNA fragments respectively. On the other hand, the models that deal with clusterisation contain at least one free parameter (such as the cluster distance in Ref.⁽⁹⁾; it causes preselected ionisation-cluster sizes to some extent). In addition, all of the above models have one major disadvantage in common: their theoretical descriptions are based on classical trajectories. And this generally makes little sense for lowenergy particles that move in nanovolumes as the spatial extension of their wave packet is usually larger than the target volume itself! For example, if an initial electron is expected to move in a cube with a dimension of 2 nm and has an energy of 100 eV as well as a well defined momentum (i. e. a relative uncertainty of 1%) then Heisenberg's uncertainty principle gives a spatial extension of the electron wave packet of about 12 nm or more. However, it is assumed that the amount of ionisation interactions alone should not be affected by the Heisenberg uncertainty principle in contrast to the trajectories (see Ref.⁽¹⁰⁾). In the following, we depict a stochastic model for the calculation of the ionisation-cluster size (ics) distribution in nanodosimetry which has no free parameter. The amount of ionisation interactions is determined by the program package Geant4-DNA (cf. Ref.^(11, 12)). The stochastic model is based on a canonical ensemble and derives from the well-known nuclear droplet model (cf. Ref.^(17, 18)), which has already been applied successfully for the prediction of nuclear-cluster distributions. It is able to describe the ionisation-cluster size distributions caused by electrons. It can easily be extended to light ions. The model especially can be seen as a refinement to B. Grosswendts model (s. Ref.^(7, 8)). The focus of the following work is primarily on demonstrating that the proposed new model is feasible rather than providing results⁽²⁰⁾. The next section will describe the model in detail. Following on, some first results will be depicted in Section 3. And finally, a summary is given in Section 4.

2. Model

In the following, we consider a nanometric target volume made of DNA or liquid water which is irradiated by electrons. Ionisations occur due to the interactions of primary, secondary as well as higher

generation electrons with the material. We base our ionisation clustering model on the following nomenclature:

- nt: total number of ionisations
- $\begin{array}{ll} n_j: & \text{number of } j \text{ interrelated ionisations. The following applies:} \\ & j \in [1,...,k] \text{ and } n_k \leq n_t. \text{ We call } j \text{ interrelated ionisations} \text{ an "ionisation cluster} \\ & \text{ of size } j". \end{array}$
- q(I): number of partitions of I (I denotes a positiv integer), whereat a partition is a sequence of ionisation clusters
- $\vec{n_t}$: t-dimensional partition vector, $(n_1, n_2, ..., n_t)^t$, describing one of the $q(n_t)$ partitions. Please note: a partition vector is not a "real" vector in terms of Euclidean geometry.
- $\{\overrightarrow{n_t}\}$: set of all possible q(n_t) t-dimensional partition vectors
- M: ionisation-cluster multiplicity of a partition, i. e. number of ionisation clusters of a partition
- (n_t, M) : macrostate consisting of all microstates which refer to n_t ionisations and M ionisation clusters $q(n_t|M)$: number of partitions (microstates) of n_t with ionisation-cluster multiplicity M. Note: $q(n_t|M)$ is
- not equal with the conventional partition sum in general.
- L: likelihood of a macrostate
- V: nanometric volume
- T: temperature
- event: consists of a primary particle moving through V
- F: free energy. The following shall apply: $F(n_t, M)$ is the free energy which refers to macrostate (n_t, M) .
- ϵ_0 : vacuum permittivity
- k_B: Boltzmann constant

Clarification regarding partitions:

If there are $n_t = 5$ ionisations, then, there are q(5) = 7 partition vectors $\overrightarrow{n_{5,i}}$ (i = 1, ..., 7). This means, $\{\overrightarrow{n_5}\} = \{\overrightarrow{n_{5,i}} = (5, 0, 0, 0, 0)^t, \overrightarrow{n_{5,2}} = (3, 1, 0, 0, 0)^t, \overrightarrow{n_{5,3}} = (1, 2, 0, 0, 0)^t, \overrightarrow{n_{5,4}} = (2, 0, 1, 0, 0)^t,$ $\overrightarrow{n_{5,5}} = (0, 1, 1, 0, 0)^t, \overrightarrow{n_{5,6}} = (1, 0, 0, 1, 0)^t, \overrightarrow{n_{5,7}} = (0, 0, 0, 0, 1)^t \}$. The partition vector $\overrightarrow{n_{5,4}}$ refers to two ionisation clusters of size 1 and to one ionisation cluster of size 3. There are q(5|3) = 2 partition vectors with ionisation-cluster multiplicity M = 3 (which belong to macrostate (5, 3)): $\overrightarrow{n_{5,3}}$ and $\overrightarrow{n_{5,4}}$.

The basic idea of the model is as follows. For all events do:

- calculate all possible partitions of the amount of ionisation interactions,
- calculate free energy F and temperature T,
- choose a macrostate due to " $exp{-F((n_t, M), T, V)/T}$ " and then select a microstate with equal probability.

The methodology reads as follows in detail:

(1) Numerical calculation of n_t

To calculate the total number of ionisations, n_t , a scoring volume with shape of a cylinder is preconditioned (without loss of generality). The material inside the cylinder is DNA or DNA equivalent matter (which, for example, can be liquid water for the time being) as mentioned above. The numerical calculation is done using a classical particle transport code (like Geant4-DNA^(11, 12), MDM⁽¹³⁾, or PARTRAC⁽¹⁴⁾; an overview of common classical particle transport codes can be found in Ref.⁽¹⁵⁾). We presume here that n_t will not much change for a quantum multiple-scattering calculation since ionising interactions are inelastic ones, i. e. we suppose a circumstancial validity of the trajectory method (cf. Ref.⁽¹⁰⁾).

(2) Computation of $\{\overrightarrow{n_t}\}\$ and selection of $\overrightarrow{n_t}$

The number of partitions of n_t can become very large: if $n_t = 10$, then q(10) = 42, but if $n_t = 100$, then q(100) = 190569292 (and q(1000) = 24061467864032622473692149727991); s. Ref.⁽¹⁶⁾.

If the number of partitions is small, i. e. if, for example, all macrostates can be calculated within 2 hours cpu time, then we take into account all partition vectors and choose a macrostate and finally one partition vector as described in subsection (2.1) below.

If the number of partitions is not small, we propose to consider "biased" subsets of the multidimensional partition space (cf. Ref.⁽¹⁷⁾) and then apply the procedure of subsection (2.1).

(2.1) Calculation of likelihood L

To clarify the structure of the calculation of the likelihood L, we divide this section into several subsections, termed (2.1.1), (2.1.1.1) and so on, where subsection having "i +1" times the term ".1" has to be calculated before the subsection having "i" times the term ".1". For the calculation of L, we assume that a macrostate (n_t , M) can be described within the canonical approximation , i. e. the likelihood of (n_t ,M) is given by

$$L = c * \exp\{-F((n_t, M), T, V)/T\},$$
(1)

where "c" is a normalisation constant, "F" is the free energy of the system being in macrostate (n_t , M) as well as in thermal equilibrium, and "T" is the temperature. The nanometric target volume is designated with "V". Having choosen a macrostate (n_t , M), one of its microstates, described by $\overline{n_t}$, is selected with equal probability then.

(2.1.1) Calculation of free energy F

The free energy "F" of a macrostate is assumed to be the sum of "translational" parts " $F_j^{tr,Z}$ " and "inner" parts " $n_i F_j^{in"}$,

$$F((n_t, M), T, V)) = \sum_{j=1}^{n_t} (F_j^{tr,Z} + n_j F_j^{in}),$$
(2)

with " n_j " is the number of ionisation clusters of size "j". Each n_j contains the contributions of the corresponding microstates:

$$\mathbf{n}_{j} = \sum_{k=1}^{MIS} n_{j,k},\tag{3}$$

where " $n_{j,k}$ " refers to the number of ionisation clusters of size "j" of microstate "k", and "MIS" denotes the amount of microstates which belong to macrostate (n_t , M).

For the explicit calculation of the translational part " $F_j^{tr,Z}$ " of the free energy, we assume that the ionisation clusters behave in the same way as particles of a Boltzmann gas, i. e. the distribution of the positions of the ionisation clusters is similar to the distribution of the positions of Boltzmann particles. We assume further that the ionisation clusters are within a sphere of volume V. Furthermore, the Coulomb interaction is treated by means of the mean-field approximation. Let \vec{x} contain the coordinates of all ionisation clusters. The canonical partition sum reads then,

$$Z(T, n_j, V) = \frac{\lambda_T^{-sn_j}}{n_j!} \int e^{-\beta V_m(\vec{x})} d^{3n_j} x .$$
⁽⁴⁾

The integration is over volume V. The abbreviation λ_T indicates the thermal de Broglie wavelength,

$$R_{\rm T} = \frac{h}{\sqrt{2\pi m k_{\beta} T}} \quad , \tag{5}$$

where "h" denotes Plank constant and "m" is the mass of the ionisations clusters of size "j". The mass results from mass density and volume, and the volume from a radius " \tilde{r}_k " (which computation is depicted when the calculation of "F_jⁱⁿ" is discussed [s. below]). The factor "k_B" is the Boltzmann constant, and the thermodynamic beta reads, $\beta = 1/(k_\beta T)$. The term with respect to the mean-field potential, i. e. the Coulomb energy of the ionisation clusters in their own field, is denoted by V_m. It explicitly reads,

$$V_{\rm m} = \frac{1}{4\pi\varepsilon_0} \frac{3}{5} \frac{e^2 j^2 n_j^2}{R},\tag{6}$$

where " ε_0 " is the vacuum permittivity, "e" is the elementary charge, and "R" is the radius of the spherically symmetrical target volume. It follows for the canonical partition sum after integration:

$$Z(\mathbf{T}, n_j, \mathbf{V}) = \frac{\lambda_T^{-3n_j}}{n_j!} V^{n_j} e^{-\beta V_m}.$$
(7)

Finally, we find for the translational part " $F_1^{tr,Z}$ ":

$$F_j^{tr,Z} = -k_B T \ln Z(T, n_j, V).$$
(8)

The term " F_j^{in} " of the inner parts is obtained using a generalisation of the well-known droplet model. For the time being, we consider the Coulomb contribution only for the calculation of F_j^{in} . Starting point is the Coulomb energy E_j^C of "j" charges which are homogeneously distributed within a sphere of radius " $\tilde{\tau}_k$ ":

$$E_{j}^{C} = \frac{1}{4\pi\varepsilon_{0}} \frac{3}{5} \frac{e^{2} j^{2}}{\tilde{r}_{k}}.$$
(9)

The radius " \tilde{r}_k " is obtained as follows: first of all, we assume that a molecule has an admittedly somewhat inadaquate cubic shape and the ions should touch each other. The error resulting from the inadequate shape of volume should be negligible due to the small dimension of the volume (the same applies to further changes to the geometric shape further below). One side " r_j " of the cube of an ionisations clusters of size "j" is then given by,

$$\mathbf{r}_{j} = (j \, V_{molecule})^{\frac{1}{3}} \,, \tag{10}$$

where $V_{molcule}$ is the molecule volume. Next, we scale r_j such that the molecule density inside the cube of the ionisations clusters of size "j" is equal to the molecule density " ρ " of the target volume:

$$r_j \to r_k = k r_j , \qquad (11)$$

with

$$k = (j^2 \rho \, V_{molecule})^{-\frac{1}{3}}.$$
 (12)

Then radius " \tilde{r}_k " is calculated as

$$\tilde{r}_k = (3/(4\pi))^{\frac{1}{3}} r_k , \qquad (13)$$

where the factor $"(3/(4\pi))^{\frac{1}{3}"}$ results from the conversion of the cubic volume into a spherical volume of the same size. We assume E_j^C to be (almost) not dependent on the temperature. Therefore, there is only one microstate which is associated with this energy. The respective entropy is hence zero. So, we can write

$$\mathbf{F}_{\mathbf{j}}^{\mathrm{in}} = \mathbf{E}_{\mathbf{j}}^{\mathrm{C}}.\tag{14}$$

(2.1.1.1) Calculation of temperature T

The temperature T is obtained from the absorbed energy "Eabs", which is determined by

$$E_{abs} = \frac{3 e^2 n_t^2}{20 \pi \varepsilon_0 R} + \sum_{j=1}^{n_t} n_j \left[F_j(T, V) - T \left(\frac{\partial F_j(T, V)}{\partial T} \right)_V \right] - E_0.$$
(15)

The first term on the right hand side refers to the Coulomb energy of a homogeneously charged sphere of radius R. Then follows the internal energy. The term " E_0 " denotes the ground-state energy. We approximate E_0 by the corresponding expression for an ideal gas,

$$E_0 = \frac{3}{2} n_t k_B T. (16)$$

The absorbed energy can be computated by one of the classical particle transport codes mentioned above (see section (1)); just as n_t . After a very tedious (albeit elementary) calculation, Equation (15) can finally be transformed in a simple but very long term for the temperature. This long term takes the form "absorbed energy multiplied by a factor minus an additional term". For the sake of simplicity, this long term is not specified. As an alternative to Eq. (15), one could also calculate the temperature using the Saha equation¹⁹ or using the specific heat capacity for the temperature increase (see section "Results" for the second option).

(3) Sorting ionisation clusters into a histogramm

This is done as usual.

(4) Repeating No 1 to 3 until end is reached

The end is determined by the total number of events.

3. Results

In the following, first results are depicted which refer to this scenario (described by B. Grosswendt⁽⁸⁾): monoenergetic electrons, having kinetic energies between 70 eV and 5 keV, are homogeneously emitted from a planar circular area with a diameter of 2 nm. Their direction is parallel to the surface normal. The electrons impinge on a cylinder with a diameter and height of 2 nm. The planar circular area is located such that the centre-line of the area is perpendicular to the cylinder's main axis and crosses the latter at half its height. Both the planar circular area and the cylinder are in vacuum. The cylinder consists of liquid water.

We caculated " E_{abs} " as well as " n_t " using the program package Geant4-DNA^(11, 12). The model itself was realised by means of an in-house object-oriented C++ program. The cpu time required for the computation of all macrostates was in the region of seconds.

Figure 1 shows the energy dependence of the yield of single-strand breaks "SSBs" and the probability of cluster-size one "P₁", respectively. The SSBs were calculated by W. Friedland et al.⁽²⁾, and the P₁ distribution either by B. Grosswendt⁽⁸⁾ or with our model. Here and regarding to Figure 2, we consider the values computed by W. Friedland et al. to be appropriate for comparison – in agreement with B. Grosswendt – as W. Friedland et al. use a very sophisticated DNA target model (which includes five levels of DNA organisation). Our purple P1 distribution refers to temperature values which were calculated by means of Eq. (15). Our green P₁ distribution relates to temperature values that were obtained by using the specific heat capacity where we have assumed an initial temperature of 310.15 K. It can be inferred from Figure 1 that our model gives approximately the same results as the model of B. Grosswendt – regardless of the respective temperature calculation. All P₁ values (red, purple, green) are more or less close to the SSB values.

Figure 1: energy dependence of SSB yield in $10^{-11}Gy^{-1}Da^{-1}$ (blue) as well as P_1 distributions (red, purple, green). The data points refer to 70 eV, 200 eV, 700 eV, 2000 eV, and 5000 eV

(abscissa). The SSB yield was calculated by W. Friedland et al.⁽²⁾, the red P_1 distribution was computed by B. Grosswendt⁽⁸⁾. All data were taken from B. Grosswendt⁽⁸⁾. The purple and green P_1 values were calculated by our model. The P1 values were scaled with the energy absorbed (B. Grosswendt) or with the mean No of ionisations (our model) for each data point. All P_1 values were normalised to the SSB value at 5000 eV. See text for further explanation.

This behaviour changes regarding to the DSB values and F_2 values, respectively. The F_2 values denote the probability that ionisation clusters of size 2 or more are produced. Figure 2 shows the energy dependence of the yield of double-strand breaks "DSBs" and of the F_2 values. Analogue to the P_1 values, our purple F_2 distribution refers to temperature values which were calculated by means of Eq. (15), whereas our green F_2 distribution relates to temperature values that were obtained by using the specific heat capacity where we have assumed an initial temperature of 310.15 K. It can be seen from Figure 2 that both of our F_2 distributions match better with the DSB values than the F_2 distribution of B. Grosswendt. In particular, the purple F_2 curve is very similar to the DSB values. This result strengthens our belief that our model is an improvement on the model of B. Grosswendt. However, our results here and also with respect to Figure 1 are subject to major uncertainties. The relative error is likely to be in the range between 30% and 40%. Much more calculations need to be carried out for a proper validation!

Figure 2: energy dependence of DSB yield in 10^{-11} Gy⁻¹Da⁻¹ (blue) as well as F_2 distributions (red, purple, green). The data points refer to 70 eV, 200 eV, 700 eV, 2000 eV, and 5000 eV (abscissa). The DSB yield was calculated by W. Friedland et al.⁽²⁾, the red F_2 distribution was computed by B. Grosswendt⁽⁸⁾. All data were taken from B. Grosswendt⁽⁸⁾. The purple and green F_2 values were calculated by our model. The F_2 values were scaled with the energy absorbed (B. Grosswendt) or with the mean No of ionisations (our model) for each data point. All F_2 values were normalised to the DSB value at 5000 eV. See text for further explanation.

4. Summary

A proposal on the calculation of the ionisation-cluster size distribution was depicted. The proposal is essentially based on the well-known nuclear droplet $model^{(17, 18)}$ and can be seen as a supplement to Bernd Grosswendts model^(7, 8). It was shown that our model leads to a cluster-size distribution function F_2 being more similar to of the yield of double-strand breaks in the DNA than the one calculated by B. Grosswendt. Our primary results strengthens our belief that our model is an improvement on the model of B. Grosswendt. However, our results contain large uncertainties. Much more calculations need to be carried out for a proper validation! The focus of this work was on presenting the model and demonstrating its feasibility.
