## Merger Analysis with Latent Price<sup>∗</sup>

Paul S. Koh†

July 30, 2024

#### Abstract

Standard empirical tools for merger analysis assume price data, which may not be readily available. This paper characterizes sufficient conditions for identifying the unilateral effects of mergers without price data. I show that data on merging firms' revenues, margins, and revenue diversion ratios are sufficient to identify the first-order price and welfare effects. Revenue diversion ratios are identified from consumer expenditure data under the standard discretecontinuous demand assumption. Merger simulations are also feasible with CES demand and competitors' margin and revenue data. I apply the framework to the Albertsons/Safeway merger (2015) and the Staples/Office Depot merger (2016).

Keywords: Merger, unilateral effect, diversion ratio, upward pricing pressure, merger simulation

## 1 Introduction

A horizontal merger is said to generate unilateral effects when it reduces competition between the merging parties and enables them to increase prices above their pre-merger levels. Standard empirical tools for evaluating the unilateral effects of mergers typically assume that price and quantity data are available (Davis and Garcés, [2009;](#page-37-0) [Valletti and Zenger,](#page-39-0) [2021;](#page-39-0) [Miller and Sheu,](#page-38-0) [2021\)](#page-38-0). Merger simulations use price data to estimate (or calibrate) demand functions [\(Hausman](#page-37-1) [et al.,](#page-37-1) [1994;](#page-37-1) [Werden and Froeb,](#page-39-1) [1994;](#page-39-1) [Nevo,](#page-38-1) [2000;](#page-38-1) [Epstein and Rubinfeld,](#page-37-2) [2001;](#page-37-2) [Werden and Froeb,](#page-39-2) [2002\)](#page-39-2). The first-order approach that measures unilateral effects via upward pricing pressures and compensating marginal cost reductions requires price data as direct inputs to the formulas and for estimating demand slopes and curvatures [\(Werden,](#page-39-3) [1996;](#page-39-3) [Farrell and Shapiro,](#page-37-3) [2010;](#page-37-3) [Jaffe and](#page-38-2) [Weyl,](#page-38-2) [2013;](#page-38-2) [Affeldt et al.,](#page-36-0) [2013;](#page-36-0) [Weyl and Fabinger,](#page-39-4) [2013;](#page-39-4) [Brito et al.,](#page-36-1) [2018\)](#page-36-1).

However, researchers often have difficulty accessing reliable price data. First, price and quantity data may not exist. Second, even if the data exist, the researcher may not have easy access to them. Third, even if the researcher can access the data, it may be extremely costly to process it. For example, if a merger involves retail firms (e.g., supermarket chains) whose outlets carry thousands of non-overlapping items with prices that frequently vary due to complex promotion activities, constructing the relevant price indices can be far from trivial and time-consuming. The lack of "clean" price data often creates considerable challenges for economists and antitrust agencies in predicting the price and welfare effects of mergers [\(Ferguson et al.,](#page-37-4) [2023\)](#page-37-4).<sup>[1](#page-1-0)</sup>

This paper contributes to the merger analysis literature by developing an empirical framework for estimating the unilateral effects of horizontal mergers without price data, extending the scope of applicability of the first-order approach and merger simulation. I consider the standard empirical Bertrand-Nash multiproduct oligopoly framework. Unlike the standard merger analysis framework, however, I study the identifiability of unilateral effects based on revenue and margin data, relaxing the standard data assumption that prices and quantities are observed separately. My key idea is to focus on revenue diversion ratios as opposed to quantity diversion ratios. While quantity diversion ratios have served as primary measures of demand-side substitutability between products since

<span id="page-1-0"></span><sup>&</sup>lt;sup>1</sup>For example, to calculate gross upward pricing pressure indices, it is common to assume the prices of merging firms' products are approximately equal [\(Ferguson et al.,](#page-37-4) [2023\)](#page-37-4), but such assumption is not innocuous. I show that such an assumption is unnecessary.

[Shapiro](#page-39-5) [\(1996\)](#page-39-5), revenue diversion ratios have received little attention.<sup>[2](#page-2-0)</sup>

I show that revenues, margins, and revenue diversion ratios of the merging parties are sufficient for identifying their gross upward pricing pressure indices, first-order welfare effects, and compensating marginal cost reductions.[3](#page-2-1) Using the algebraic relationship between quantity and revenue diversion ratios, I can express firms' first-order conditions and the gross upward pricing pressure statistics as functions of their margins, revenue diversion ratios, and own-price elasticity of demand. The own-price demand elasticities of products, in turn, can be identified from the owner firm's margins and revenue diversion ratios data via the profit maximization condition. Thus, the gross upward pricing pressure statistics are identifiable from the merging firms' revenues, margins, and revenue diversion ratios. Under an additional assumption that upward pricing pressures approximate the true merger price effects—an assumption supported by recent simulation studies [\(Miller et al.,](#page-38-3) [2017;](#page-38-3) [Dutra and Sabarwal,](#page-37-5) [2020\)](#page-37-5)—the welfare effects of mergers are also identified. Analogous arguments show that compensating marginal cost reductions are identified under the same data assumption. My identification arguments relax the data requirements assumed in [Werden](#page-39-3) [\(1996\)](#page-39-3), [Farrell and Shapiro](#page-37-3) [\(2010\)](#page-37-3) and [Jaffe and Weyl](#page-38-2) [\(2013\)](#page-38-2).

The standard discrete-continuous demand assumption facilitates the identification of revenue diversion ratios and merger simulation. Unlike the pure discrete choice demand models, where consumers make a discrete choice with unit-inelastic quantity demanded, I assume consumers make a discrete choice for every unit of their budget. Yet, the choice probabilities (budget shares) are derived from the standard additive random utility model, so the standard results for GEV discrete choice models can be applied.<sup>[4](#page-2-2)</sup> I show that if consumers are homogeneous in their responsiveness to price, data on consumers' expenditure (or product revenues if there is a single representative consumer) are sufficient to identify revenue diversion ratios via the [Hotz and Miller](#page-38-4) [\(1993\)](#page-38-4)'s in-version theorem.<sup>[5](#page-2-3)</sup> In particular, assuming consumers have CES preferences substantially simplifies the econometric problem since their expenditure shares admit multinomial logit probability forms,

<span id="page-2-1"></span><span id="page-2-0"></span><sup>&</sup>lt;sup>2</sup>I am unaware of works that explicitly discuss revenue diversion ratios except [Caradonna et al.](#page-36-2) [\(2023\)](#page-36-2).

<sup>&</sup>lt;sup>3</sup>Although gross upward pricing pressure indices are identified, upward pricing pressures are not identified since prices are assumed to be unobserved.

<span id="page-2-2"></span><sup>&</sup>lt;sup>4</sup>The demand model can be derived as the expected demand from consumers who solve utility maximization problem with homothetic perfect substitutes preferences (Dubé et al., [2022\)](#page-37-6).

<span id="page-2-3"></span><sup>&</sup>lt;sup>5</sup>Homogeneous price responsiveness assumption, although quite standard, is strong and rules out more flexible demand systems such as random coefficient models. However, relaxing the assumption without price data appears challenging and is beyond the scope of this paper.

and the revenue diversion ratios can be identified from consumers' expenditures on merging firms' products or with second-choice data.

I establish the feasibility of merger simulation without price data under the CES utility assumption. Whereas the first-order approach only requires data from the merging firms, merger simulation demands data on all competitors' margins and revenues. I show that while the post-merger price levels cannot be identified, the percentage change in price in the post-merger equilibrium relative to pre-merger levels can be identified. Thus, this paper complements a body of research that finds the utility of using CES demand for theoretical and empirical merger analysis [\(Anderson et al.,](#page-36-3) [1987,](#page-36-3) [1988,](#page-36-4) [1992;](#page-36-5) Björnerstedt and Verboven, [2016;](#page-36-6) [Nocke and Schutz,](#page-38-5) [2018;](#page-38-5) [Nocke and Whinston,](#page-38-6) [2022;](#page-38-6) [Taragin and Sandfort,](#page-39-6) [2022;](#page-39-6) [Caradonna et al.,](#page-36-2) [2023;](#page-36-2) [Nocke and Schutz,](#page-38-7) [2023\)](#page-38-7).

Finally, I illustrate the methodology's usefulness using two empirical applications. First, I apply the framework to the Staples/Office Depot merger to illustrate the simplicity of my approach. The merger was proposed in 2014 but eventually blocked in 2016. In its complaint, the FTC claimed a cluster market for consumable office supplies that includes many individual items. The nature of the claimed market makes it difficult to construct price data that fit standard econometric frameworks. My framework does not require price data. Using publicly available data on the firms' revenues, margins, and market shares, I evaluate the unilateral effects of the merger using both the first-order approach and merger simulation. All approaches predict either the merger produces substantial harm or requires substantial cost reductions to offset upward pricing pressures.

Next, I apply the framework to analyze the Albertsons/Safeway merger. The merger is the largest grocery merger in US history to date. The Federal Trade Commission approved the merger in 2015, conditional on divesting 168 stores. I estimate a spatially aggregated nested CES demand model using cross-sectional data on store revenues to estimate revenue diversion ratios. I then calculate store-level merger price/welfare effects for thousands of stores before and after the divestiture. I find that the FTC-mandated divestiture significantly reduced annual consumer harm. My results complement the existing body of research on grocery mergers by providing new tools for empirically evaluating large-scale grocery mergers and divestiture remedies [\(Smith,](#page-39-7) [2004;](#page-39-7) [Hosken](#page-37-7) [et al.,](#page-37-7) [2016;](#page-37-7) [Allain et al.,](#page-36-7) [2017;](#page-36-7) [Thomassen et al.,](#page-39-8) [2017;](#page-39-8) [Hosken et al.,](#page-38-8) [2018;](#page-38-8) [Ellickson et al.,](#page-37-8) [2020\)](#page-37-8).[6](#page-3-0)

<span id="page-3-0"></span> $6$ [Smith](#page-39-7) [\(2004\)](#page-39-7) also uses profit margins data and equilibrium pricing conditions to analyze supermarket competition but develops a structural model tailored to fit consumer shopping patterns data in the supermarket industry. My framework follows the more standard Bertrand Nash pricing model. [Ellickson et al.](#page-37-8) [\(2020\)](#page-37-8) develops a spatial demand

The rest of the paper is organized as follows. In Section [2,](#page-4-0) I describe the firm-side model and introduce the concept of revenue diversion ratios. In Section [3,](#page-7-0) I establish identification conditions for gross upward pricing pressure indices and compensating marginal cost reductions. In Section [4,](#page-14-0) I characterize consumer demand assumptions that facilitate the estimation of revenue diversion ratios. In Section [5,](#page-21-0) I show merger simulation is feasible when consumers have CES preferences. In Sections [6](#page-23-0) and [7,](#page-26-0) I apply the proposed methodology to evaluate the Staples/Office Depot merger (2016) and the Albertsons/Safeway merger (2015). Finally, I conclude in Section [8.](#page-35-0) All proofs are in Section [A](#page-40-0) of the Appendix.

## <span id="page-4-0"></span>2 Model

In this section, I describe the firm-side model. I also introduce the concept of revenue diversion ratio and discuss its relationship with quantity diversion ratios.

#### 2.1 Setup

The firm-side model primitives are summarized by a tuple  $\langle \mathcal{J}, \mathcal{F}, (\pi_j)_{j \in \mathcal{J}} \rangle$ , where  $\mathcal{J}$  is the set of products, F is the set of multiproduct firms, and  $\pi_j$  specifies the product j's profit function. Set F forms a partition over  $\mathcal{J}$ , specifying firms' ownership over products. The set of products owned by firm  $F \in \mathcal{F}$  is denoted  $\mathcal{J}_F \subseteq \mathcal{J}$ . I assume the profit from product  $j \in \mathcal{J}$  is  $\pi_j = (p_j - c_j)q_j$  where  $p_j \in \mathbb{R}_+$ ,  $c_j \in \mathbb{R}_+$ , and  $q_j = q_j(p)$  denote price, constant marginal cost, and quantity demanded, respectively; I omit fixed costs for notational convenience. I also assume that the products are substitutes. I use  $m_j \equiv (p_j - c_j)/p_j$  to denote relative margins.

## 2.2 Firm's Problem

The multiproduct firms engage in a Bertrand-Nash pricing game. Each firm  $F \in \mathcal{F}$  maximizes its total profit  $\sum_{j\in\mathcal{J}_F}\pi_j$  with respect to a vector of prices  $(p_j)_{j\in\mathcal{J}_F}$ . Normalizing the first-order

framework that overcomes the absence of price data in the grocery competition setting but does not directly calculate merger price effects. My approach can calculate merger price effects under the same set of assumptions.

conditions to be quasilinear in margins yields

<span id="page-5-2"></span>
$$
-\epsilon_{jj}^{-1} - m_j + \sum_{l \in \mathcal{J}_F \backslash j} m_l D_{j \to l} \frac{p_l}{p_j} = 0,
$$
\n(1)

where  $\epsilon_{jj} \equiv \frac{\partial q_j}{\partial p_j}$  $\overline{\partial p_j}$  $p_j$  $\frac{p_j}{q_j}$  is the own-price elasticity of demand, and

<span id="page-5-0"></span>
$$
D_{j \to l} \equiv -\frac{\partial q_l / \partial p_j}{\partial q_j / \partial p_j} \tag{2}
$$

is the quantity diversion ratio from product j to product l. I defer derivations of firms' optimal pricing equations, gross upward pricing pressure indices, and compensating marginal cost reductions to Appendix [B](#page-46-0) as they are standard.

## 2.3 Revenue Diversion Ratios and Their Properties

#### Definition

Standard empirical frameworks for evaluating the unilateral effects of mergers have focused on quantity diversion ratios [\(2\)](#page-5-0) as the key statistics for measuring the degree of substitution between products [\(Shapiro,](#page-39-5) [1996;](#page-39-5) [Farrell and Shapiro,](#page-37-3) [2010;](#page-37-3) [Conlon and Mortimer,](#page-37-9) [2021\)](#page-37-9). To establish the identifiability of merger price effects without price data, I will rewrite price elasticities and gross upward pricing pressure indices in terms of revenue diversion ratios. Revenue diversion ratio from product  $j$  to  $k$  is defined as

<span id="page-5-3"></span>
$$
D_{j\to k}^R \equiv -\frac{\partial R_k/\partial p_j}{\partial R_j/\partial p_j},\tag{3}
$$

where  $R_l \equiv p_l q_l$  is the revenue from product l. It measures the substitutability between two products by studying how revenue shifts from one product to another following a unilateral price increase. Under standard regularity conditions, revenue diversion ratios are non-negative in equilibrium.<sup>[7](#page-5-1)</sup>

<span id="page-5-1"></span><sup>&</sup>lt;sup>7</sup>First,  $\partial R_k/\partial p_j \geq 0$  if j and k are substitutes. Second,  $\partial R_j/\partial p_j < 0$  if and only if  $\epsilon_{jj} < -1$ , which holds in any Bertrand-Nash equilibrium. In sum,  $D_{j\to k}^R > 0$ . The only exception is the revenue diversion ratio for self-pair  $D_{j\rightarrow j}^R \equiv -1 < 0.$ 

#### Relationship to Quantity Diversion Ratios

Revenue and quantity diversion ratios are different, but they are closely related. Let  $\epsilon_{jj} = \frac{\partial q_j}{\partial n_j}$  $\overline{\partial p_j}$  $p_j$  $\overline{q_j}$ and  $\epsilon_{jj}^R = \frac{\partial R_j}{\partial p_j}$  $\partial p_j$  $p_j$  $\frac{p_j}{R_j}$  denote the own-price elasticity of demand and the own-price elasticity of revenue, respectively. Similarly, let  $\epsilon_{kj} = \frac{\partial q_k}{\partial p_i}$  $\overline{\partial p_j}$  $p_j$  $\frac{p_j}{q_k}$  and  $\epsilon_{kj}^R = \frac{\partial R_k}{\partial p_j}$  $\overline{\partial p_j}$  $p_j$  $\frac{p_j}{R_k}$  denote the cross-price elasticities. The following lemma summarizes their relationship.

<span id="page-6-0"></span>Lemma 1 (Relationship between revenue-based and quantity-based measures). For an arbitrary pair of products  $i$  and  $k$ ,

<span id="page-6-2"></span><span id="page-6-1"></span>1. 
$$
D_{j\to k}^R = -\frac{\epsilon_{kj}^R}{\epsilon_{jj}^R} \frac{R_k}{R_j}
$$
 and  $D_{j\to k} = -\frac{\epsilon_{kj}}{\epsilon_{jj}} \frac{q_k}{q_j}$ ;  
\n2.  $\epsilon_{jj}^R = \epsilon_{jj} + 1$ , and  $\epsilon_{kj}^R = \epsilon_{kj}$  for  $j \neq k$ ;  
\n3.  $(1 + \epsilon_{jj}^{-1})D_{j\to k}^R = D_{j\to k} \frac{p_k}{p_j}$  for  $j \neq k$ , and  $D_{j\to j}^R = D_{j\to j} = -1$ .

<span id="page-6-4"></span>Lemma [1](#page-6-0) is independent of the underlying demand model as it only relies on the algebraic definition of diversion ratios and elasticities. Lemma [1](#page-6-0)[.1](#page-6-1) relates diversion ratios to elasticities. Lemma [1.](#page-6-0)[2](#page-6-2) shows how own- and cross-price elasticities are related.<sup>[8](#page-6-3)</sup> Finally, Lemma [1](#page-6-0)[.3](#page-6-4) shows how quantity diversion ratios may be substituted out for revenue diversion ratios.

Lemma [1](#page-6-0)[.3](#page-6-4) plays a key role in my main identification arguments. The terms  $D_{j\to k} \frac{p_k}{p_j}$  $\frac{p_k}{p_j}$  enter the firms' optimal pricing equation, gross upward pricing pressure indices, and compensating marginal cost reductions. Conventional approaches to merger analysis calculate them by separately obtaining price data and quantity diversion ratio data. However, for  $j \neq k$ ,

$$
D_{j\to k}\frac{p_k}{p_j} = -\frac{\frac{\partial q_k}{\partial p_j}p_k}{\frac{\partial q_j}{\partial p_j}p_j} = -\frac{\frac{\partial R_k}{\partial p_j}}{\frac{\partial R_j}{\partial p_j} - q_j} = \underbrace{\left(-\frac{\frac{\partial R_k}{\partial p_j}}{\frac{\partial R_j}{\partial p_j}}\right)}_{D_{j\to k}^R}\underbrace{\left(\frac{\frac{\partial R_j}{\partial p_j}}{\frac{\partial R_j}{\partial p_j} - q_j}\right)}_{1+\epsilon_{jj}^{-1}}.
$$

That is, the analyst can replace the term  $D_{j\to k} \frac{p_k}{p_j}$  $\frac{p_k}{p_j}$  with the revenue diversion ratio  $D_{j\to k}^R$ , multiplied by an "adjustment factor"  $(1 + \epsilon_{jj}^{-1})$ . In the following sections, I show how to estimate revenue diversion ratios and own-price elasticities of demand based on revenue and margin data.

<span id="page-6-5"></span><span id="page-6-3"></span><sup>&</sup>lt;sup>8</sup>Thus, the own-price elasticity of revenue is closer to zero than the own-price elasticity of demand.

<sup>&</sup>lt;sup>9</sup>In other words, while the numerator of  $D_{j\to k} \frac{p_k}{p_j}$  is  $\frac{\partial R_k}{\partial p_j}$ , its denominator is  $\frac{\partial R_j}{\partial p_j} - q_j$ , making it fall short of revenue diversion ratios. The term  $(1 + \epsilon_{jj}^{-1})$  serves as an adjustment factor that "corrects" the denominator to  $\frac{\partial R_j}{\partial p_j}$ .

#### Sum of Diversion Ratios Over Products

Whether the diversion ratios sum to one depends on the underlying demand model. In discrete choice demand models where the total quantity consumed is fixed, quantity diversion ratios from a product to all other alternatives sum to one. However, revenue diversion ratios need not sum to one because the total market revenue may change. Symmetrically, in discrete-continuous choice models where consumers' total budget is fixed, revenue diversion ratios from a product to all other alternatives sum to one. However, quantity diversion ratios need not sum to one because the total units consumed may not be fixed.

## <span id="page-7-0"></span>3 Identification of Unilateral Effects

In this section, I characterize sufficient conditions for identifying the price and welfare effects of a merger following the first-order approach developed in [Farrell and Shapiro](#page-37-3) [\(2010\)](#page-37-3) and [Jaffe and](#page-38-2) [Weyl](#page-38-2) [\(2013\)](#page-38-2). I also show that [Werden](#page-39-3) [\(1996\)](#page-39-3)'s compensating marginal cost reductions are identified. I begin by stating the key assumptions on data and the claims I aim to establish.

<span id="page-7-1"></span>Assumption 1 (Baseline data). The analyst observes revenues and relative margins for the merging parties' products.

<span id="page-7-3"></span>Assumption 2 (Revenue diversion ratios data). The analyst observes the revenue diversion ratios for all pairs of the merging parties' products.

<span id="page-7-4"></span>Assumption 3 (Merger-specific efficiencies). The analyst knows the percentage decrease in marginal costs for the merging parties' products.

Assumption [1](#page-7-1) is mild for antitrust authorities as merging parties' financial data are typically available during merger reviews; note that I only require the analyst to observe product-specific revenues but not necessarily price and quantity separately.<sup>[10](#page-7-2)</sup> Assumption [2](#page-7-3) departs from [Farrell](#page-37-3) [and Shapiro](#page-37-3) [\(2010\)](#page-37-3), which focuses on quantity diversion ratios. For now, I take revenue diversion

<span id="page-7-2"></span><sup>&</sup>lt;sup>10</sup>Margins data can come from various sources. See [Sacher and Simpson](#page-39-9) [\(2020\)](#page-39-9) for a discussion on how to estimate incremental margins using an accounting approach. See [De Loecker and Warzynski](#page-37-10) [\(2012\)](#page-37-10) for the production approach to estimating firms' markups; [Raval](#page-38-9) [\(2023\)](#page-38-9) applies the method with store-level production-side data from a major US retailer. [Nocke and Schutz](#page-38-5) [\(2018\)](#page-38-5) shows that firms charge uniform relative margins over their products when consumers have CES demand; such assumptions can simplify margin estimation when product-level data are unavailable.

ratios as known and defer the estimation problem to Section [4.](#page-14-0) In general, the analyst may obtain estimates of revenue diversion ratios from the merging firms' business documents or demand models. Finally, Assumption [3](#page-7-4) is standard since estimating merger-specific cost-savings can be quite challenging. $^{11}$  $^{11}$  $^{11}$ 

Claim 1 (Identification of price and welfare effects under the first-order approach). Suppose As-sumptions [1,](#page-7-1) [2,](#page-7-3) and [3](#page-7-4) hold.

- 1. The gross upward pricing pressure indices are identified.
- 2. If upward pricing pressures approximate the true merger price effects, the welfare effects are identified.

## 3.1 Identification of Gross Upward Pricing Pressure Index

#### Definition

Consider a merger between two firms  $A$  and  $B$ . Under the unilateral effects theory, the merger shifts the merging firms' pricing incentives upward because they can internalize the opportunity to recapture consumers that would divert to the merger counterparty's products. [Farrell and](#page-37-3) [Shapiro](#page-37-3) [\(2010\)](#page-37-3) proposes measuring the incentives by upward pricing pressure (UPP), defined as the difference between the pre- and post-merger first-order conditions that are normalized to be quasilinear in marginal cost and evaluated at the pre-merger price [\(Jaffe and Weyl,](#page-38-2) [2013\)](#page-38-2).

The primary measure of interest in this paper is the unit-free measure of upward pricing pressure dubbed gross upward pricing pressure index (GUPPI), defined as the upward pricing pressure normalized by the pre-merger price, i.e.,  $GUPPI_j \equiv UPP_j/p_j$  [\(Salop and Moresi,](#page-39-10) [2009;](#page-39-10) [Moresi,](#page-38-10) [2010\)](#page-38-10). The GUPPI associated with product  $j \in \mathcal{J}_A$  can be written as

<span id="page-8-1"></span>
$$
GUPPI_j = \ddot{c}_j(1 - m_j) + \sum_{k \in \mathcal{J}_B} m_k D_{j \to k} \frac{p_k}{p_j},\tag{4}
$$

where  $\ddot{c}_j \equiv \Delta c_j/c_j^{\text{pre}} \in (-1,0)$  represents the percentage decrease in marginal cost from the premerger equilibrium, and  $\Delta c_j = c_j^{\text{post}} - c_j^{\text{pre}} < 0$  represents the reduction in marginal cost due

<span id="page-8-0"></span> $11$ [Farrell and Shapiro](#page-37-3) [\(2010\)](#page-37-3) also attests to the difficulty of predicting merger-specific efficiencies, even for the firms themselves, but especially for antitrust agencies and courts. A standard practice is to test a range of cost efficiency assumptions or study compensating marginal cost reductions.

to merger-specific efficiencies.<sup>[12](#page-9-0)</sup> Those of firm  $B$  are defined symmetrically. When prices are unobserved, economists have often measured GUPPIs by obtaining data on margins and quantity diversion ratios and assuming that  $p_k/p_j \approx 1$  [\(Ferguson et al.,](#page-37-4) [2023\)](#page-37-4), which is not innocuous and may bias the GUPPI estimate substantially. My identification result shows that such an assumption is not necessary.

#### Identification

Using Lemma [1](#page-6-0)[.3,](#page-6-4) I can rewrite the first-order conditions for an arbitrary firm  $F \in \mathcal{F}(1)$  $F \in \mathcal{F}(1)$  and the gross upward pricing pressure indices for product  $j \in \mathcal{J}_A$  [\(4\)](#page-8-1) as

<span id="page-9-3"></span><span id="page-9-1"></span>
$$
-\epsilon_{jj}^{-1} - m_j + (1 + \epsilon_{jj}^{-1}) \sum_{l \in \mathcal{J}_F \backslash j} m_l D_{j \to l}^R = 0,
$$
\n<sup>(5)</sup>

$$
GUPPI_j = \ddot{c}_j(1 - m_j) + (1 + \epsilon_{jj}^{-1}) \sum_{k \in \mathcal{J}_B} m_k D_{j \to k}^R,
$$
\n
$$
(6)
$$

respectively. If the pre-merger margins and revenue diversion ratios are known, the analyst can use the first-order conditions [\(5\)](#page-9-1) to identify the own-price elasticities of demand.

<span id="page-9-6"></span>**Lemma 2** (Identification of own-price elasticities of demand). Let  $F \in \mathcal{F}$  be an arbitrary firm. For each product  $j \in \mathcal{J}_F$ ,

<span id="page-9-2"></span>
$$
\epsilon_{jj} = -\frac{1 - \sum_{k \in \mathcal{J}_F \backslash j} m_k D_{j \to k}^R}{m_j - \sum_{k \in \mathcal{J}_F \backslash j} m_k D_{j \to k}^R}.
$$
\n(7)

Plugging in  $(7)$  into  $(6)$  to identifies the GUPPIs of the merging firms.<sup>[13](#page-9-4)</sup>

<span id="page-9-5"></span>Proposition 1 (Identification of GUPPI). Under Assumptions [1,](#page-7-1) [2,](#page-7-3) and [3,](#page-7-4) the gross upward pricing pressure indices are identified.

Unlike the standard approach to GUPPI calculation, Proposition [1](#page-9-5) leverages the firms' profit maximization conditions to identify GUPPI. If the analyst observes prices, costs, and quantity diversion ratios—as assumed in [Farrell and Shapiro](#page-37-3) [\(2010\)](#page-37-3)—the upward pricing pressures—and

<span id="page-9-0"></span><sup>&</sup>lt;sup>12</sup>See Appendix [B](#page-46-0) for full derivation. I occasionally omit the superscript "pre" when it is clear the object is that of the pre-merger equilibrium.

<span id="page-9-4"></span> $13$ Once the own-price elasticities are identified, the cross-price elasticities can also be recovered using the relationships  $D_{jk}^R = -\frac{\epsilon_{kj}^R}{\epsilon_{jj}^R}$  $\frac{R_k}{R_j}$ ,  $\epsilon_{jj}^R = \epsilon_{jj} + 1$ , and  $\epsilon_{kj}^R = \epsilon_{kj}$ .

thus the GUPPIs—are directly identified, leaving no role for the firms' profit maximization conditions. However, when prices are unobserved, the analyst can leverage the first-order conditions to calculate the merging firms' own-price demand elasticities, which, together with margins and revenue diversion ratios, identify the GUPPIs. My use of firms' profit maximization assumption here reverses the role of margins and price elasticities compared to the more standard approach [\(Rosse,](#page-39-11) [1970\)](#page-39-11); rather than using the knowledge of demand price elasticities to recover margins (and thus marginal costs), I use the knowledge of margins to recover the price elasticities.

#### 3.2 Identification of Merger Price Effects

In order to translate GUPPI statistics to merger price effects, I use the following assumption.

<span id="page-10-3"></span>Assumption 4 (UPP and price effects). Upward pricing pressures approximate the true merger price effects.

In general, translating upward pricing pressure statistics to merger price effects requires knowledge of the merger pass-through rates, which quantify how a change in firms' opportunity cost impacts their prices at the margin. [Jaffe and Weyl](#page-38-2) [\(2013\)](#page-38-2) shows that a first-order approximation of the merger price effects gives

$$
\Delta p \approx M \cdot UPP,\tag{8}
$$

where  $\Delta p \equiv (\Delta p_j)_{j \in \mathcal{J}_A \cup \mathcal{J}_B}$  with  $\Delta p_j \equiv p_j^{\text{post}} - p_j^{\text{pre}}$  $j^{\text{pre}}$ , and M is the merger pass-through matrix.<sup>[14](#page-10-0)[15](#page-10-1)</sup> However, merger pass-through rates are difficult to estimate because they depend on the second-order properties of underlying demand.<sup>[16](#page-10-2)</sup> Fortunately, [Miller et al.](#page-38-3)  $(2017)$  and [Dutra and Sabarwal](#page-37-5) [\(2020\)](#page-37-5) present simulation evidence that upward pricing themselves are often good proxies for the

<span id="page-10-0"></span> $14$ Note that the first-order approach assumes that non-merging parties' prices remain fixed at the pre-merger levels because the first-order approximation arguments only accounts for one round on reactions by the merging parties after the ownership structure changes. In contrast, merger simulations find the post-merger equilibrium prices that fully account for the reactions of all competitors in the market.

<span id="page-10-1"></span><sup>&</sup>lt;sup>15</sup>The pass-through matrix M can be calculated using the first-order approximation of either the pre-merger first-order conditions [\(Farrell and Shapiro,](#page-37-3) [2010\)](#page-37-3) or post-merger first-order condition [\(Jaffe and Weyl,](#page-38-2) [2013\)](#page-38-2) around the pre-merger equilibrium. [Jaffe and Weyl](#page-38-2) [\(2013\)](#page-38-2) notes that the choice between merger pass-through and cost pass-through may not be empirically significant.

<span id="page-10-2"></span><sup>&</sup>lt;sup>16</sup>Identifying the pass-through matrices requires overcoming a number of challenges that are not always easy to resolve. Although merger pass-through rates can be calculated using cost pass-through rates [\(Miller et al.,](#page-38-11) [2016\)](#page-38-11), identifying cost pass-through rates can be difficult due to a lack of sufficient identifying variation as marginal costs tend to be highly correlated [\(Miller et al.,](#page-38-12) [2013;](#page-38-12) [Miller and Sheu,](#page-38-0) [2021\)](#page-38-0). [Miller et al.](#page-38-3) [\(2017\)](#page-38-3) reports that misspecification of the demand system may induce larger errors than the approximation error from replacing  $M$  with an identity matrix.

true merger price effects, providing support for Assumption [4.](#page-10-3) In Appendix [D,](#page-49-0) I complement their findings by providing simulation evidence that upward pricing pressure is a conservative predictor of the true merger price effect when the demand is CES.

Assumption [4](#page-10-3) amounts to replacing unknown M with the identity matrix and implies

<span id="page-11-0"></span>
$$
\ddot{p}_j \approx GUPPI_j,\tag{9}
$$

where  $\ddot{p}_j \equiv \Delta p_j/p_j$ . Thus, merger price effects are directly identified from GUPPIs. The assumption substantially relaxes the methodological and data requirement for approximating the true merger price effects. The analyst can refine the estimates for merger price effects when further information on the pass-through rates is available. Note that the use of  $(9)$  does not hinge on the availability of price data; the researcher who does not have information on demand curvature (as is often the case during merger reviews) would follow [Miller et al.](#page-38-3) [\(2017\)](#page-38-3)'s recommendation even if price data were available.

#### 3.3 Identification of Welfare Effects

I measure the impact of a merger on consumer surplus as

<span id="page-11-1"></span>
$$
\Delta CS = \sum_{j \in \mathcal{J}_A \cup \mathcal{J}_B} \Delta CS_j,\tag{10}
$$

where each  $\Delta CS_j$  measures the welfare effect assuming a unilateral price change of  $p_j$  holding all else fixed. Measure [\(10\)](#page-11-1) assumes that the total welfare effect of a merger is additively separable in product-specific welfare effects, each of which assumes a ceteris paribus variation in price. The additive separability feature ignores externalities or cross-market price effects but allows for simple calculation.[17](#page-11-2) The impact on producer surplus is measured analogously.

Figure [1](#page-12-0) visualizes a scenario where the price of a product increases from  $p_j^0$  to  $p_j^1$  so the quantity demanded decreases from  $q_j^0$  to  $q_j^1$ . The product also enjoys a marginal cost reduction from  $c_j^0$  to  $c_j^1$ . The figure shows that the associated impacts on consumer surplus and producer surplus can

<span id="page-11-2"></span> $17$  For instance, computing consumer surplus variation following multiple price changes can be difficult if the integral is not path-independent [\(Chipman and Moore,](#page-36-8) [1980\)](#page-36-8). In practice, to capture the total welfare effects, it is common to use the sum of product-specific welfare effect, each of which assumes a *ceteris paribus* price change [\(Araar and](#page-36-9) [Verme,](#page-36-9) [2019\)](#page-36-9).

<span id="page-12-0"></span>

Figure 1: Calculating welfare effects from a merger

be approximated as

- $\Delta CS_j \approx -(\Delta p_j \times q_j^0 + \frac{1}{2} \times \Delta p_j \times \Delta q_j),$
- $\Delta PS_j \approx \Delta p_j \times q_j^1 + \Delta q_j \times (p_j^0 c_j^0) \Delta c_j \times q_j^1$ .

The impact on consumer surplus is approximated using the trapezoid defined by  $p_j^0$  and  $p_j^1$  and the residual demand function.<sup>[18](#page-12-1)</sup> The impact on producer surplus is the sum of gained revenue  $(\Delta p_j \times q_j^1)$ , lost revenue  $(\Delta q_j \times (p_j^0 - c_j^0))$ , and cost savings  $(-\Delta c_j \times q_j^1)$ . The impact on social surplus is their sum. The following lemma shows that the analyst can calculate  $\Delta CS_j$  and  $\Delta PS_j$ using revenue, margin, own-price elasticity, the percentage increase in price, and the cost-efficiency savings, all of which are identified or known under the previous assumptions.

<span id="page-12-3"></span>Lemma 3 (Approximation of welfare effects). The changes in consumer surplus and producer surplus associated with a price increase of product j are approximately

$$
\Delta CS_j \approx -\ddot{p}_j R_j (1 + \frac{1}{2} \epsilon_{jj} \ddot{p}_j),
$$
  
\n
$$
\Delta PS_j \approx \ddot{p}_j R_j (1 + \epsilon_{jj} \ddot{p}_j) + \epsilon_{jj} R_j \ddot{p}_j m_j - \ddot{c}_j (1 - m_j) R_j (1 + \epsilon_{jj} \ddot{p}_j).
$$

<span id="page-12-2"></span>Proposition 2 (Identification of welfare effects). Under Assumptions [1,](#page-7-1) [2,](#page-7-3) [3,](#page-7-4) and [4,](#page-10-3) the welfare effects of a merger—measured in consumer surplus and producer surplus—are identified up to first-

<span id="page-12-1"></span><sup>18</sup>Compensating variations and equivalent variations are equal to consumer surplus variation up to first-order approximation with price change of a single product [\(Willig,](#page-39-12) [1976\)](#page-39-12). The three measures are identical when there is no income effect.

order approximation.

Remark 1 (Identifying bounds on consumer welfare effects). Laspeyres variation and Paasche variation are other measures of consumer welfare that are useful and easy to interpret. Laspeyres variation, defined as  $LV_j \equiv -\Delta p_j \times q_j^0$ , represents the change in income necessary to purchase the same bundle of goods purchased before the price variation. Paasche variation, defined as  $PV_j \equiv -\Delta p_j \times q_j^1$ , represents the change in income required to purchase the final bundle of goods at initial prices. They are useful because they provide bounds on consumer welfare variation: If good j is normal, under standard regularity conditions,  $LV_j < CV_j < \Delta CS_j < EV_j < PV_j < 0$  following an increase in p<sub>j</sub>. It is straightforward to verify that  $LV_j = -\ddot{p}_jR_j$  and  $PV_j \approx -(1 + \epsilon_{jj}\ddot{p}_j)\ddot{p}_jR_j$ . Thus, Laspeyres and Paasche variations are also identified under the same conditions as Proposition [2.](#page-12-2) In Appendix [C,](#page-48-0) I show that compensating variation can be calculated without approximation under CES utility.

#### 3.4 Identification of Compensating Marginal Cost Reductions

Compensating marginal cost reductions (CMCR) are defined as the percentage decrease in the merging parties' costs (relative to the pre-merger levels of marginal costs) that would leave the pre-merger prices unchanged after the merger.<sup>[19](#page-13-0)</sup> [Werden](#page-39-3) [\(1996\)](#page-39-3) shows that CMCRs are identified when prices, margins, and diversion ratios are observed. I show that CMCRs are identified under weaker data requirement.

<span id="page-13-1"></span>Assumption 5 (CMCR). A merger reduces the marginal costs of the merging parties' products up to the level that leaves the prices unchanged.

Let  $\ddot{c}_j = (c_j^1 - c_j^0)/c_j^0$  denote the percentage reduction in marginal costs, where  $c_j^1$ 's are the post-merger marginal costs defined by Assumption [5.](#page-13-1)

<span id="page-13-2"></span>Lemma 4 (CMCR). Suppose the post-merger marginal costs satisfy Assumption [5.](#page-13-1) The compen-

<span id="page-13-0"></span><sup>&</sup>lt;sup>19</sup>Compensating marginal cost reductions capture the effects of simultaneous changes in marginal costs. On the other hand, upward pricing pressure assumes other products' marginal costs are fixed. Upward pricing pressure can be more conservative because the value of sales diverted to the merging counterparty is larger if profit margins increase due to reduction in marginal costs. [Farrell and Shapiro](#page-37-3) [\(2010\)](#page-37-3) endorses upward pricing pressure on grounds of simplicity and transparency while acknowledging that compensating marginal cost reductions can be more accurate.

sating marginal cost reductions for each product j is equal to

<span id="page-14-2"></span>
$$
\ddot{c}_j = \frac{m_j^0 - m_j^1}{1 - m_j^0}.\tag{11}
$$

The post-merger margins  $m_j^1$ 's are implicitly defined by the post-merger first-order conditions

<span id="page-14-1"></span>
$$
-\epsilon_{jj}^{-1} + (1 + \epsilon_{jj}^{-1}) \sum_{l \in \mathcal{J}_A} m_l^1 D_{j \to l}^R + (1 + \epsilon_{jj}^{-1}) \sum_{k \in \mathcal{J}_B} m_k^1 D_{j \to k}^R = 0.
$$
 (12)

Note that the own-price demand elasticities and revenue diversion ratios in [\(12\)](#page-14-1) correspond to the pre-merger levels as prices are assumed to remain fixed after the merger. The analyst can calculate the compensating marginal cost reductions in two steps. First, identify the postmerger margins implied by Assumption  $5$  using the post-merger first-order conditions  $(12)$ , which constitutes a system of linear equations. Second, given the pre- and post-merger margins, compute the percentage change in marginal costs from the pre-merger equilibrium via [\(11\)](#page-14-2).

<span id="page-14-3"></span>**Proposition 3** (Identification of CMCR). Under Assumptions [1,](#page-7-1) [2,](#page-7-3) and [5,](#page-13-1) the compensating marginal cost reductions are identified.

The data requirement in Proposition [3](#page-14-3) is weaker than that described in [Werden](#page-39-3) [\(1996\)](#page-39-3). [Werden](#page-39-3) [\(1996\)](#page-39-3) assumes that the analyst observes price, quantity, margin, and quantity diversion ratios. However, such data are sufficient to identify revenue, margin, and revenue diversion ratios, satisfying the conditions of Proposition [3.](#page-14-3)

## <span id="page-14-0"></span>4 Consumer Demand and Revenue Diversion Ratios

In this section, I show that assuming consumers have discrete-continuous demand facilitates the identification and estimation of revenue diversion ratios.

#### 4.1 Setup

I specify consumer-side model primitives as a tuple  $\langle \mathcal{I}, (\mathcal{C}_i, U_i, B_i)_{i \in \mathcal{I}} \rangle$ , where  $\mathcal{I}$  is the set of consumers,  $C_i$  is consumer i's consideration set<sup>[20](#page-14-4)</sup>,  $U_i : \mathbb{R}^{\dim(C_i)} \to \mathbb{R}$  is consumer i's utility function,

<span id="page-14-4"></span> $^{20}$ While consumers' consideration sets can be dropped from the model primitives without loss of generality, it is conceptually and computationally helpful to make them explicit. In my second empirical application, consumers'

and  $B_i \in \mathbb{R}_+$  is i's budget. I assume consideration sets always include an outside option  $j = 0$ . To simplify the exposition, I assume that the analyst knows every consumer's consideration set  $\mathcal{C}_i$  and budget  $B_i$ , although the analyst may need to estimate them in practice.

### 4.2 Consumer's Problem

Each consumer  $i \in \mathcal{I}$  maximizes utility  $U_i$  with respect to consumption vector  $q_i \equiv (q_{ij})_{j \in \mathcal{C}_i}$  subject to a budget constraint  $\sum_{j\in\mathcal{C}_i} p_j q_{ij} \leq B_i$ . The Marshallian demand function induces consumer *i*'s expenditure on each product j as

<span id="page-15-3"></span>
$$
e_{ij} = \alpha_{ij} B_i,\tag{13}
$$

where  $\alpha_{ij} \in [0,1]$  represents the expenditure share, i.e., the optimal share of i's budget allocated to purchasing product  $j^{21}$  $j^{21}$  $j^{21}$  The revenue from product j is the sum of consumers' expenditure on the product,

<span id="page-15-1"></span>
$$
R_j = \int_{i \in S_j} e_{ij} d\mu,\tag{14}
$$

where  $i \in S_j$  (i is a shopper of j) if and only if  $j \in C_i$  (i considers j), and  $\mu$  is a measure on the set of consumers.

Example 1. [Ellickson et al.](#page-37-8) [\(2020\)](#page-37-8) estimates a spatial demand model to analyze grocery store competition. Each  $i \in \mathcal{I}$  represents a census tract, and each  $j \in \mathcal{J}$  represents a grocery store. The authors assume that consumers consider all stores that are within 15 miles from their location. The grocery budget  $B_i$  is a constant fraction of the tract's aggregate income. Measure  $\mu$  is a counting measure, so [\(14\)](#page-15-1) reduces to  $R_j = \sum_{i \in S_j} e_{ij}$ , i.e., the total revenue of each store is the sum of tract-level expenditures on that store.  $\triangle$ 

### 4.3 Identification of Revenue Diversion Ratios

Rewriting the definition of revenue diversion ratio [\(3\)](#page-5-3) using [\(14\)](#page-15-1) and rearranging allows us to express the diversion ratio as a weighted sum of consumer-level diversion ratios. $^{22}$  $^{22}$  $^{22}$ 

consideration sets are determined by the distance from their residences to grocery stores.

<span id="page-15-0"></span> $^{21}$ Equation [\(13\)](#page-15-3) holds for an arbitrary demand function.

<span id="page-15-2"></span> $^{22}$ A quantity diversion ratio analog appears in [Hosken and Tenn](#page-37-11) [\(2016\)](#page-37-11).

<span id="page-16-7"></span>Lemma 5 (Revenue diversion ratio as a weighted sum). Assuming that Leibniz's rule applies,

<span id="page-16-0"></span>
$$
D_{j \to k}^{R} = \int_{i \in \mathcal{S}_k} w_{ij} D_{i,j \to k}^{R} d\mu,
$$
\n(15)

,

where

$$
w_{ij} = \frac{\partial e_{ij}/\partial p_j}{\int_{\tilde{i}\in S_j} \partial e_{\tilde{i}j}/\partial p_j d\mu}
$$

$$
D_{i,j\to k}^R = -\frac{\partial e_{ik}/\partial p_j}{\partial e_{ij}/\partial p_j}.
$$

Consumers whose expenditures are more sensitive to price receive higher weights. At first glance,  $(15)$  requires prices to be observed. However, it is possible to relax the data requirement by imposing the following assumption motivated by the discrete-continuous demand literature.

<span id="page-16-1"></span>**Assumption 6** (Latent utility). Let  $u_{ij}^* = u_{ij} + \varepsilon_{ij}$  be the latent utility of consumer i from consuming product j for each unit of expenditure, where  $u_{ij}$  is the deterministic component and  $\varepsilon_{ij}$ the random component of latent utility. Assume that the latent utility from the outside option is normalized to  $u_{i0} = 0$ .

- <span id="page-16-2"></span>1. For each consumer i and product j,  $\alpha_{ij} = \mathbb{E} [\mathbb{I}\{j = \arg \max_{l \in \mathcal{C}_i} u_{il}^* \}]$ .
- <span id="page-16-4"></span>2. For each consumer i, price  $p_j$  only enters  $u_{ij}$  but not  $u_{il}$  for  $l \neq j$ .
- <span id="page-16-5"></span>3. For each product j,  $\frac{\partial u_{ij}}{\partial x_j}$  $\frac{\partial a_{ij}}{\partial p_j}$  is homogeneous across all consumer  $i.$

Assumption [6.](#page-16-1)[1](#page-16-2) creates a duality that allows the analyst to treat consumers as if they were making a discrete choice for every unit of their budgets.<sup>[23](#page-16-3)</sup> Assumption  $6.2$  $6.2$  imposes an exclusion restriction that price  $p_j$  only affects consumer i's expenditure through  $u_{ij}$ . Finally, Assumption [6.](#page-16-1)[3](#page-16-5) imposes a strong condition that simplifies the identification of revenue diversion ratios; it rules out models in which consumers' sensitivity with respect to price may be heterogeneous (e.g., randomcoefficients models).[24](#page-16-6) In sum, Assumption [6](#page-16-1) admits a large class of GEV models (e.g., nested CES demand) but restricts the price responsiveness to be homogeneous across consumers.

<span id="page-16-3"></span><sup>&</sup>lt;sup>23</sup>Below, I use constant elasticity of substitution utility function assumption to derive  $\alpha_{ij}$  as a softmax (multinomial logit) function of vector  $u_i \in \mathbb{R}^{\dim(\mathcal{C}_i)}$ .

<span id="page-16-6"></span><sup>&</sup>lt;sup>24</sup>It is possible to relax this assumption and allow  $\gamma_i \equiv \partial u_{ij}/\partial p_j$  to vary across individuals, but it would require the analyst to estimate the relevant distributions. To see this, note that the invertibility of the mapping  $u_i \mapsto \alpha_i$  is unaffected by the presence of heterogeneous coefficients in so far as the distribution of the coefficients is known (e.g.,

Dubé et al.  $(2022)$  provides a foundation for Assumption [6](#page-16-1) by driving an analog demand as the expectation of the demand of consumers who make discrete-continuous choices by choosing from perfect substitutes. Specifically, suppose consumer  $i$  has constant marginal utility for each product, where the marginal utility for product j depends on the random utility shock  $\varepsilon_{ij}$ . <sup>[25](#page-17-0)</sup> The linear preference induces the individual to make a discrete choice over products as it is optimal to consume at most one good. Taking expectation of the discrete-continuous demand over  $\varepsilon_i$  leads to a form of Assumption [6,](#page-16-1) but with the mean utility per unit consumed of product  $u_{ij}$  log-linear in price  $p_j$ .<sup>[26](#page-17-1)</sup>

Assumption [6](#page-16-1) simplifies the diversion ratio formulas by allowing  $\partial u_{ij}/\partial p_j$  to cancel out from the numerator and the denominator.

<span id="page-17-2"></span>**Lemma [6](#page-16-1)** (Revenue diversion ratios with latent utility). Assumption 6 implies

$$
w_{ij} = \frac{(\partial \alpha_{ij}/\partial u_{ij})B_i}{\int_{\tilde{i}\in S_j} (\partial \alpha_{\tilde{i}j}/\partial u_{\tilde{i}j})B_{\tilde{i}}d\mu}
$$

$$
D_{i,j\to k}^R = -\frac{\partial \alpha_{ik}/\partial u_{ij}}{\partial \alpha_{ij}/\partial u_{ij}}.
$$

,

Lemma [6](#page-17-2) shows that computing  $D_{j\to k}^R$  only requires finding the sensitivity of consumers' expenditure shares with respect to their mean utility for product  $j$  at the margin. I provide sufficient conditions to identify revenue diversion ratios as follows.

<span id="page-17-3"></span>**Assumption 7** (Hotz-Miller inversion). Let  $H_i$  be the distribution of preference shock  $\varepsilon_i = (\varepsilon_{ij})_{j \in C_i}$ .

- 1. Distribution  $H_i$  is absolutely continuous with full support on  $\mathbb{R}^{\dim(\mathcal{C}_i)}$ .
- 2. The analyst observes  $\alpha_i = (\alpha_{ij})_{j \in \mathcal{C}_i}$  for all i.
- 3. The analyst knows the distribution  $H_i$ .

see [Berry et al.](#page-36-10) [\(1995\)](#page-36-10)). Then the analyst can compute  $D_{j\to k}^R = \int_{i \in S_k} w_{ij} D_{i,j\to k}^R d\mu$  with  $w_{ij} = \frac{(\partial \alpha_{ij}/\partial u_{ij})\gamma_i B_i}{\int_{i \in S_j} (\partial \alpha_{ij}/\partial u_{ij})\gamma_i B_i d\mu}$ and  $D_{i,j\to k}^R = -\frac{\partial \alpha_{ik}/\partial u_{ij}}{\partial \alpha_{ij}/\partial u_{ij}}$ . However, it will be challenging to estimate the distribution of random coefficients without price data.

<span id="page-17-0"></span><sup>&</sup>lt;sup>25</sup>Note that the utility function here is different from the primitive utility function  $U_i$ , which does not depend on  $\varepsilon_i$ . The demand system derived from  $U_i$  corresponds to the *expected* demand system derived from the discrete choice additive random utility assumption, where the expectation is taken with respect to  $\varepsilon_i$ .

<span id="page-17-1"></span> $^{26}$ I do not require the mean utilities to be log-linear in price because the assumption is not essential for simplifying the calculation of revenue diversion ratios, which is the focus of the current paper. However, Dubé et al. [\(2022\)](#page-37-6) shows that the log-linearity is crucial for establishing the Hurwicz-Uzawa integrability of the demand system; a demand system derived from an arbitrary functional form assumption on  $u_{ij}$ 's may not be integrable.

Assumption [7](#page-17-3) lays out the classical conditions for applying [Hotz and Miller](#page-38-4) [\(1993\)](#page-38-4)'s inversion theorem, which says that the mapping from  $u_i$  to  $\alpha_i$  is invertible.<sup>[27](#page-18-0)</sup> Since the analyst knows the inverse mapping from  $\alpha_i$  to  $u_i$  as well as the pre-merger values of  $\alpha_i$ , the analyst can evaluate the partial derivatives, and thus the consumer-level weights and revenue diversion ratios shown in Lemma [6.](#page-17-2)

<span id="page-18-3"></span>**Proposition 4** (Identification of revenue diversion ratios with latent utility). Under Assumptions [6](#page-16-1) and [7,](#page-17-3) the revenue diversion ratios across all pairs of products of the merging firms are identified.

While the above proposition assumes knowledge of budgets, expenditure shares, and the distribution of preference shocks, it is also common to estimate them using parametric assumptions, i.e., let  $B_i = B_i^{\theta}$ ,  $\alpha_i = \alpha_i^{\theta}$ , and  $H_i = H_i^{\theta}$ , and estimate  $\theta$  using available moment conditions. The feasibility of this strategy relies on the availability of a rich set of covariates that can control for the effects of unobserved prices.<sup>[28](#page-18-1)</sup>

**Example 2** (Continued). In [Ellickson et al.](#page-37-8) [\(2020\)](#page-37-8), the authors assume that (i)  $B_i^{\theta}$  is a constant fraction of total income, (ii)  $u_{ij}^{\theta}$  is a linear function of distance and a rich set of tract and store characteristics and their interactions, and (iii)  $\alpha_{ij}^{\theta}$  follows a nested logit model, where the nests are defined by grocery store formats. They then estimate the parameters using store-level revenue data and the moment condition  $(14)$ . The authors control for unobserved prices using chain indicators, citing recent empirical findings that prices tend to be uniform across stores within a chain [\(DellaVigna and Gentzkow,](#page-37-12) [2019;](#page-37-12) [Hitsch et al.,](#page-37-13) [2021\)](#page-37-13).  $\triangle$ 

#### 4.4 CES Utility Function

Assuming that consumers have a constant elasticity of substitution utility function [\(Spence,](#page-39-13) [1976;](#page-39-13) [Dixit and Stiglitz,](#page-37-14) [1977\)](#page-37-14) further simplifies the econometric problem.

<span id="page-18-2"></span>Assumption 8 (CES utility). Consumers' preferences can be described by a constant elasticity of

<span id="page-18-0"></span> $^{27}$ Although I adhere to the original assumptions of [Hotz and Miller](#page-38-4) [\(1993\)](#page-38-4) since they hold in most applications, recent works allow for weaker assumptions. See, e.g., [Chiong et al.](#page-36-11) [\(2016\)](#page-36-11), [Galichon](#page-37-15) [\(2018\)](#page-37-15), and [Sørensen and](#page-39-14) [Fosgerau](#page-39-14) [\(2022\)](#page-39-14).

<span id="page-18-1"></span><sup>&</sup>lt;sup>28</sup>For example, suppose  $u_{ij}^{\theta} = \delta_{ij} - \lambda p_j$  where  $\delta_{ij}$  is a function of covariates. Suppose the analyst observes  $w_j$  such that  $p_j = w_j^{\top} \kappa$ . Then estimating the model with  $w_j$  in place of  $p_j$  may be sufficient to estimate the mean utilities although the coefficients may not be identified.

substitution (CES) function

$$
U_i(q_i) = A \left( \sum_{j \in C_i} \beta_{ij}^{\frac{1}{\eta}} q_{ij}^{\frac{\eta - 1}{\eta}} \right)^{\frac{\eta}{\eta - 1}}
$$
(16)

with parameters  $A, \eta, \beta_{ij} > 0$ .<sup>[29](#page-19-0)</sup>

<span id="page-19-1"></span>Lemma 7 (Revenue diversion ratios under CES utility). Under Assumption [8,](#page-18-2) the fraction of consumer i's budget spent on each product  $j \in C_i$  is

$$
\alpha_{ij} = \frac{\exp(u_{ij})}{\sum_{k \in \mathcal{C}_i} \exp(u_{ik})},\tag{17}
$$

where  $u_{ij} \equiv \log \beta_{ij} + (1 - \eta) \log p_j$ . Furthermore, the weights and consumer-level diversion ratios are

$$
w_{ij} = \frac{\alpha_{ij}(1 - \alpha_{ij})B_i}{\int_{\tilde{i}\in\mathcal{S}_j} \alpha_{\tilde{i}j}(1 - \alpha_{\tilde{i}j})B_{\tilde{i}}d\mu},\tag{18}
$$

$$
D_{i,j\to k}^R = \frac{\alpha_{ik}}{1 - \alpha_{ij}},\tag{19}
$$

respectively.

Lemma [7](#page-19-1) shows consumers with CES preferences determine their expenditure shares as if they were making discrete choices with preference shocks that independently follow the Type-1 Extreme Value distribution. Furthermore, it shows that the analyst needs consumers' expenditure shares only for the merging firms' products to calculate the diversion ratios, allowing Assumption [7](#page-17-3) (which requires the analyst to observe the expenditure shares on all products) to be relaxed. If there is a single representative consumer in the market, then the diversion ratio formula collapses to  $D_{j\rightarrow k}^{R}=\frac{\alpha_{k}}{1-\alpha}$  $\frac{\alpha_k}{1-\alpha_j}$ , so the merging firms' product-specific market shares are sufficient to identify their revenue diversion ratios.

<span id="page-19-2"></span>Assumption 9 (Consumer expenditure share data). The analyst observes consumers' expenditure shares on the merging firms' products.

<span id="page-19-0"></span><sup>&</sup>lt;sup>29</sup>Parameter A is an arbitrary scaling factor,  $\eta$  is the elasticity of substitution between products, and  $\beta_{ij}$  is the product j's quality perceived by consumer i. Note that (i) if  $\eta \to \infty$ ,  $U_i(q_i) \to A \sum_{j \in C_i} q_{ij}$ ; (ii) if  $\eta \to 1$ ,  $U_i(q_i) \to (A/\prod_{j \in C_i} \beta_{ij}^{\beta_{ij}}) \prod_{j \in C_i} q_{ij}^{\beta_{ij}}$ ; and (iii) if  $\eta \to 0$ ,  $U_i(q_i) \to A \min_{j \in C_i} \{q_{ij}/\beta_{ij}\}$ .

<span id="page-20-0"></span>**Proposition 5** (Identification of revenue diversion ratios under CES preference). Under Assumptions  $6, 8,$  $6, 8,$  $6, 8,$  and  $9$ , the revenue diversion ratios across all pair of products of the merging firms are identified.

Proposition  $5$  is powerful since it only requires data from the merging parties.<sup>[30](#page-20-1)</sup> For example, the researcher may use merging firms' transaction data (e.g., credit card or loyalty program data) to estimate the fraction of the budget each consumer (or a group of consumers) spends on the merging parties' products [\(Hosken and Tenn,](#page-37-11) [2016\)](#page-37-11). Alternatively, one may use simple consumer surveys to solicit information on the total budget consumers allocate to the relevant products and their expenditures on the merging firms' products [\(Reynolds and Walters,](#page-38-13) [2008\)](#page-38-13). If there is a single representative agent, then Proposition [5](#page-20-0) only requires the total market size and the merging firms' revenues for each of their products; my first empirical application in Section [6](#page-23-0) exploits this result.

Another advantage of assuming CES preference is that it allows the analyst to measure revenue diversion ratios using second-choice data.<sup>[31](#page-20-2)</sup> Proposition [6](#page-20-3) justifies studying intertemporal variations in revenues following a removal of a product when the analyst is unable to observe competitors' revenues, which are inputs to revenue shares calculation.

<span id="page-20-3"></span>**Proposition 6** (Identification from second choice data). Under Assumption [8,](#page-18-2) the revenue diversion ratio from product j to product k following a removal of product j is equal to the revenue diversion ratio derived from a marginal increase in product j's price.

The tractability of models featuring CES has been more heavily exploited in the trade literature (see, e.g., [Dekle et al.](#page-37-16) [\(2007\)](#page-37-16)). However, as with logit demand, CES demand function permits analytic tractability but imposes a restrictive substitution pattern as the cross price elasticity  $\epsilon_{ki}$ only depends on index j but not k [\(Nevo,](#page-38-14) [2011;](#page-38-14) [Berry and Haile,](#page-36-12) [2021\)](#page-36-12). Thus, choosing CES demand function may be inappropriate if the analyst's objective is to explain micro data and discover rich substitution patterns. A mixed CES specification has more plausible range of elasticities and thus can yield more realistic average predicted price effects (Björnerstedt and Verboven, [2016\)](#page-36-6) but is

<span id="page-20-1"></span> $30$ Similar intuition applies with a nested logit assumption on the expenditure shares. If the expenditure shares  $\alpha_{ij}$ 's follow a nested logit form, it is possible to show that the diversion ratios between two products only depend on the nesting parameters of their groups, unconditional group shares, and the products' shares within a group; see [Mansley et al.](#page-38-15) [\(2019\)](#page-38-15) or [Conlon and Mortimer](#page-37-9) [\(2021\)](#page-37-9) for a derivation of the derivatives. The nesting parameters, unconditional group shares, and the products' shares within a group can be estimated or calibrated (see, e.g., [Ellickson](#page-37-8) [et al.](#page-37-8) [\(2020\)](#page-37-8)).

<span id="page-20-2"></span> $31\text{\AA}$  quantity diversion ratio analog appears in [Conlon and Mortimer](#page-37-9) [\(2021\)](#page-37-9).

more demanding on data. [Head and Mayer](#page-37-17) [\(2023\)](#page-37-17) provides simulation evidence that CES demand specification can provide close approximations to the predictions of more complex BLP-type demand models for measuring aggregate outcomes.

## <span id="page-21-0"></span>5 Merger Simulation with CES Utility

I show that merger simulation is feasible without price data when consumers have CES preferences. Specifically, although it is impossible to predict the post-merger prices  $p_j^{\text{post}}$  $j^{\text{post}}$  or the difference in preand post-merger prices  $\Delta p_j = p_j^{\text{post}} - p_j^{\text{pre}}$  $j^{\text{pre}}$ , it is possible to predict the percentage change in price relative to the pre-merger equilibrium  $\ddot{p}_j = (p_j^{\text{post}} - p_j^{\text{pre}})$  $j<sup>pre</sup>$ )/ $p_j<sup>pre</sup>$ .<sup>[32](#page-21-1)</sup> Thus, the proposed methodology allows the analyst to make statements such as "in the post-merger equilibrium, the price of product j will be  $10\%$  higher than the pre-merger equilibrium."

Since a merger changes the ownership structure and possibly the marginal costs of the merging firms, it shifts the merging firms' first-order condition to

$$
-\epsilon_{jj}^{-1} - m_j + (1 + \epsilon_{jj}^{-1}) \sum_{l \in \mathcal{J}_A \setminus j} m_l D_{j \to l}^R + (1 + \epsilon_{jj}^{-1}) \sum_{k \in \mathcal{J}_B} m_k D_{j \to k}^R = 0,
$$

while the first-order conditions of the non-merging firms remain as

$$
-\epsilon_{jj}^{-1} - m_j + (1 + \epsilon_{jj}^{-1}) \sum_{l \in \mathcal{J}_F \setminus j} m_l D_{j \to l}^R = 0.
$$

The key idea is to find  $(\ddot{p}_j)_{j\in\mathcal{J}}$  that solves the above first-order conditions. The following lemma shows how the post-merger objects are related to an arbitrary vector of  $(\ddot{p}_j)_{j\in\mathcal{J}}$ .

<span id="page-21-2"></span>**Lemma [8](#page-18-2)** (Merger simulation under CES utility). Suppose Assumption 8 holds. Let  $\ddot{p}$  be an

<span id="page-21-1"></span><sup>&</sup>lt;sup>32</sup>Note that the meaning of  $\ddot{p} = (\ddot{p}_j)_{j \in \mathcal{J}}$  remains identical to that appeared under the first-order approach. The first-order approach imposes  $\ddot{p}_j = 0$  for the non-merging firms, while merger simulations directly calculate the postmerger equilibrium price using the profit-maximization conditions of all firms in the market.

arbitrary vector of  $\ddot{p}_j = (p_j^{post} - p_j^{pre})$  $j^{pre})/p_j^{pre}$ . For all consumer i and product j,

$$
u_{ij}^{post} = u_{ij}^{pre} + (1 - \eta) \log(1 + \ddot{p}_j),
$$
  
\n
$$
\alpha_{ij}^{post} = \frac{\exp(u_{ij}^{post})}{\sum_{k \in C_i} \exp(u_{ik}^{post})},
$$
  
\n
$$
e_{ij}^{post} = \alpha_{ij}^{post} B_i,
$$
  
\n
$$
R_j^{post} = \int_{i \in S_j} e_{ij}^{post} d\mu,
$$
  
\n
$$
\epsilon_{jj}^{Root} = \frac{1 - \eta}{R_j^{post}} \int_{i \in S_j} (\partial \alpha_{ij}^{post} / \partial u_{ij}^{post}) B_i d\mu,
$$
  
\n
$$
\epsilon_{jj}^{post} = \epsilon_{jj}^{R,post} - 1,
$$
  
\n
$$
D_{j \to l}^{R,post} = -\frac{\int_{i \in S_l} (\partial \alpha_{il}^{post} / \partial u_{ij}^{post}) B_i d\mu}{\int_{i \in S_j} (\partial \alpha_{ij}^{post} / \partial u_{ij}^{post}) B_i d\mu},
$$
  
\n
$$
m_j^{post} = 1 - (1 - m_j^{pre}) \left( \frac{1 + \ddot{c}_j}{1 + \ddot{p}_j} \right).
$$

Lemma [8](#page-21-2) clarifies how the percentage deviation in price  $(\ddot{p}_j)_{j\in\mathcal{J}}$  cascades to the objects that appears in the post-merger first-order conditions. The following assumptions are sufficient to calculate the vector  $(\ddot{p}_j)_{j\in\mathcal{J}}$  that solves the post-merger first-order conditions.

<span id="page-22-1"></span><span id="page-22-0"></span>Assumption 10 (Merger simulation under CES utility).

D

- 1. The analyst observes  $m_i^{pre}$  $j^{pre}$  for all product  $j \in \mathcal{J}$ .
- <span id="page-22-2"></span>2. The analyst observes  $u_{ij}^{pre}$  for all consumer  $i \in \mathcal{I}$  and product  $j \in \mathcal{J}$ .
- <span id="page-22-3"></span>3. The analyst knows the elasticity of substitution parameter  $\eta$ .

<span id="page-22-4"></span>**Proposition 7** (Merger simulation). Under Assumptions [3,](#page-7-4) [8](#page-18-2) and [10,](#page-22-0) the percentage price changes from the pre-merger equilibrium to the post-merger equilibrium for all products in the market are identified.

I conclude the section briefly discussing Assumption [10.](#page-22-0) First, Assumption [10.](#page-22-0)[1](#page-22-1) requires the analyst to observe the margins of all products in the market; it is stronger than Assumption [1,](#page-7-1) which only requires the analyst to observe the margins of the merging firms' products. Second, Assumption [10.](#page-22-0)[2](#page-22-2) can be achieved by applying the Hotz-Miller inversion under Assumption [7,](#page-17-3) which

requires observing the expenditure shares of consumers for all products and knowing the distribution of the idiosyncratic random utility shocks. Finally, Assumption [10.](#page-22-0)[3](#page-22-3) requires the analyst to estimate the elasticity of substitution parameter  $\eta$ , which can be achieved using the following result.

<span id="page-23-3"></span>Lemma 9 (Identification of the elasticity of substitution parameter). Suppose Assumption [8](#page-18-2) holds. For any pair of products  $k, j \in \mathcal{J}$ ,

<span id="page-23-1"></span>
$$
\epsilon_{kj}^R = \frac{1 - \eta}{R_k} \int_{i \in \mathcal{S}_k} \frac{\partial \alpha_{ik}}{\partial u_{ij}} B_i d\mu \tag{20}
$$

Equation [\(20\)](#page-23-1) is derived by partially differentiating the equation  $R_k = \int_{i \in S_k} e_{ik} d\mu$  with respect to  $p_j$ , and then multiplying both sides by  $p_j/R_k$ . Since the analyst can identify the own-price elasticities of revenue with pre-merger margins and revenue diversion ratios (see Lemmas [1](#page-6-0) and [2\)](#page-9-6), and the revenue diversion ratios are identified if the Hotz-Miller inversion is applicable (see Proposition [4\)](#page-18-3), the parameter  $\eta$  can be (over-)identified.

## <span id="page-23-0"></span>6 Empirical Application I: Staples/Office Depot (2016)

As a simple empirical example, I apply my framework to evaluate the proposed merger of Staples and Office Depot, which was eventually blocked in 2016. I show that, had the merger been consummated, it would have resulted in a loss of \$143 million in consumer surplus annually.

#### 6.1 Background

Staples and Office Depot are the two largest suppliers of office supplies and services in the United States. On February 4, 2015, Staples entered into a \$6.3 billion merger agreement with Office Depot. On December 9, 2015, the Federal Trade Commission (FTC) sued to block the merger over concerns that it would significantly reduce competition nationwide in the market for consumable office supplies sold to large business customers.<sup>[33](#page-23-2)</sup> On May 10, 2016, a federal judge granted the FTC's preliminary injunction to block the merger. The parties subsequently announced that they would abandon the deal.

<span id="page-23-2"></span> $33$ The FTC defined large business customers as those that purchased at least \$500,000 worth of consumable office supplies during 2014 [\(United States District Court for the District of Columbia,](#page-39-15) [2016\)](#page-39-15).

The claimed market constitutes a cluster market for consumable office supplies that are not substitutes for each other (e.g., pens, file folders, Post-it notes, binder clips, papers, etc.). Defining the market as a cluster market was justified as "market shares and competitive conditions are likely to be similar for the distribution of pens to large customers and the distribution of binder clips to large customers" [\(Shapiro,](#page-39-16) [2016\)](#page-39-16), to which the court agreed. Obtaining reliable price data for many items that enter the cluster market or computing the relevant price indices is challenging. I show that with the proposed methodology, I can easily calculate the merger price effects, welfare effects, and compensating marginal cost reductions.

## 6.2 Model

I assume that the competition in the consumable office supplies markets for large B-to-B customers can be approximated by the standard Bertrand Nash framework. However, the market has features of multiple models, especially bargaining and auction models, since competition for large B-to-B customers often occurs through formal or informal bidding processes for core products.<sup>[34](#page-24-0)</sup> To focus on demonstrating how the proposed methodology can be applied in a real-world example, I abstract away from detailed institutional features and assume that competition in posted price is a reasonable approximation. I assume a single representative consumer with CES preference, which allows me to use the market shares to compute the revenue diversion ratios via the proportionalto-share formula.

#### 6.3 Data

Since I cannot access the confidential data used in the investigation, I use publicly available documents to infer the parties' revenues, margins, and shares. Based on the publicly available case materials, I infer the total market size in 2014 to be  $B = $2.05$  billion and the revenue shares of Staples and Office Depot to be  $\alpha_{\rm SP} = 47.3\%$  and  $\alpha_{\rm OD} = 31.6\%$ , respectively.<sup>[35](#page-24-1)</sup> Based on the

<span id="page-24-0"></span><sup>&</sup>lt;sup>34</sup>See the FTC's proposed findings of fact submitted to the court, available at [https://www.ftc.gov/system/](https://www.ftc.gov/system/files/documents/cases/160420staplesfindings.pdf) [files/documents/cases/160420staplesfindings.pdf](https://www.ftc.gov/system/files/documents/cases/160420staplesfindings.pdf). Specifically, for core products, large B-to-B customers solicit pricing and service information from prospective office supplies vendors through requests for proposals or similar processes. For non-core products, large B-to-B customers generally pay a flat percentage discount off published prices. Large B-to-B customers' contracts for consumable office supplies contain additional financial incentives beyond low pricing, such as volume-based rebates or signing bonuses.

<span id="page-24-1"></span><sup>35</sup>I use the presentation material prepared by the FTC's economic expert Carl Shapiro (see pp.23-27 of [Shapiro](#page-39-16) [\(2016\)](#page-39-16)). The information is also available from the Memorandum Opinion on FTC v. Staples, Inc. and Office Depot, Inc. [\(United States District Court for the District of Columbia,](#page-39-15) [2016\)](#page-39-15).

companies' 10-K documents for fiscal year 2014, I infer Staples' and Office Depot's margins to be  $m_{\text{SP}} = 25.8\%$  and  $m_{\text{OD}} = 23.4\%$ , respectively.<sup>[36](#page-25-0)</sup>

## 6.4 Results

#### Gross Upward Pricing Pressure Indices and Consumer Harm

I estimate the annual consumer harm as follows. The margins imply own-price elasticities of  $\epsilon_{\rm SP, SP} = -3.875$  and  $\epsilon_{\rm OD, OD} = -4.273$ . The market shares imply revenue diversion ratios of  $D_{\rm SP\rightarrow OD}^R = 59.9\%$  and  $D_{\rm OD\rightarrow SP}^R = 69.1\%.$  The gross upward pricing pressure indices, in the absence of cost efficiency credits, are  $GUPPI_{SP} = 10.4\%$  and  $GUPPI_{OD} = 13.7\%$ . The estimated annual harm to consumers is \$143 million.

#### Compensating Marginal Cost Reductions

Holding prices fixed at the pre-merger level, the post-merger margins required to generate marginal cost reductions necessary to offset upward pricing incentives are  $m_{\rm SP}^1 = 47.3\%$  and  $m_{\rm OD}^1 = 48.5\%$ . The post-merger margins imply that Staples and Office Depot need 29.1% and 32.7% reductions in marginal costs to offset upward pricing incentives.

#### Merger Simulation

Suppose that Staples and Office Depot are the only players in the market and that all other products are included in the outside option. The mean utilities of a representative consumer that rationalize the pre-merger market shares of Staples and Office Depot can be computed using  $\log \alpha_k - \log \alpha_0 = u_k$ for  $k = 1, 2$ , which gives  $u_{\text{SP}} = 0.807$  and  $u_{\text{OD}} = 0.404$ . I estimate the elasticity of the substitution parameter to be  $\eta = 6.121$ .<sup>[37](#page-25-1)</sup> Solving the post-merger first-order condition gives  $\ddot{p}_{\rm SP} = 21.7\%$  and  $\ddot{p}_{OD} = 23.7\%$ , which turns out to be substantially larger than those of the first-order approach.<sup>[38](#page-25-2)</sup>

<span id="page-25-0"></span><sup>&</sup>lt;sup>36</sup>Margins in the market for consumable office supplies to large business customers may be quite different from the overall margin reported in 10-K due to a variety of factors specific to the market, e.g., discounts and rebates. According to the companies' 10-K documents, Staples' and Office Depot's 2014 net revenues were \$5.6 billion and \$4.7 billion in the business-to-business channel.

<span id="page-25-1"></span><sup>&</sup>lt;sup>37</sup>Since  $\epsilon_{jj}^R = \frac{1-\eta}{R_j}$ ∂αj  $\frac{\partial \alpha_j}{\partial u_j}B$  and  $\frac{\partial \alpha_j}{\partial u_j} = \alpha_j(1-\alpha_j)$ , there are two equations to identify  $\eta$ , I calculate  $\eta_{\rm SP} = 6.457$  and  $\eta_{\text{OD}} = 5.786$  using each equation and take the average.

<span id="page-25-2"></span><sup>&</sup>lt;sup>38</sup>The large differences in the predicted price effects are likely driven by having two firms with extremely high market shares and the fact that merger simulation accounts for the feedback effects of prices, which are strategic complements.

Analysis with gross upward pricing pressure indices, compensating marginal cost reductions, and merger simulation all point to the same conclusion: The merger between Staples and Office Depot creates substantial merger harm, justifying the FTC's effort to prevent it.

## <span id="page-26-0"></span>7 Empirical Application II: Albertsons/Safeway (2015)

As a more involved empirical example, I consider the merger of Albertsons and Safeway, which was consummated in 2015. The FTC's approval required the divestiture of 168 stores. Quantitative evaluation of the competitive effects behind grocery mergers has been challenging due to the lack of access to or complexity associated with enormous price data. I show that my framework enables straightforward unilateral effects calculation without price data. In particular, I demonstrate how I can estimate revenue diversion ratios from store-level revenue data via a parametric model of consumer expenditure.

## 7.1 Background

In March 2014, AB Acquisition LLC, the parent of the Albertsons supermarket chain, agreed to terms to purchase Safeway for \$9 billion.<sup>[39](#page-26-1)</sup> Albertsons operated 1,075 stores in 28 states under the banners Albertsons, United, Amigos, and Market Street, among others. Safeway owned 1,332 stores in 18 states under the banners Safeway, Vons, Pavilions, Tom Thumb, and Randall's, among others. Upon consummation, the merger was to create the second-largest traditional grocery chain (next to Kroger) by store count and sales in the US, with approximately 2,400 stores. Figure [2](#page-27-0) shows Albertsons and Safeway's footprint in the contiguous US in 2009.

The FTC defined the relevant product market as supermarkets within "hypermarkets."<sup>[40](#page-26-2)</sup> Supermarkets refer to "traditional full-line retail grocery stores that sell, on a large-scale basis, food and non-food products that customers regularly consume at home—including, but not limited to, fresh meat, dairy products, frozen foods, beverages, bakery goods, dry groceries, detergents, and health and beauty products." Hypermarkets include chains such as Walmart Supercenters that sell an array of products not found in traditional supermarkets but also offer goods and services

<span id="page-26-1"></span> $^{39}$ See https://www.ftc.gov/legal-library/browse/cases-proceedings/141-0108-cerberus-institutional-partners-v-lp-a for case proceeding files.

<span id="page-26-2"></span><sup>40</sup>See <https://www.ftc.gov/system/files/documents/cases/150127cereberusfrn.pdf>.

<span id="page-27-0"></span>

Figure 2: Albertsons and Safeway footprint in 2009

available at conventional supermarkets.

The FTC defined the relevant geographic markets as areas that range from a two- to ten-mile radius around each party's supermarkets, where the radius depends on factors such as population density, traffic, and unique market characteristics. The agency identified overlapping territories in Arizona, California, Colorado, Montana, Nevada, Oregon, Texas, Washington, and Wyoming. In late 2014, the FTC settled with the parties with a mandate to divest 168 stores in the overlap markets.<sup>[41](#page-27-1)</sup> Figure [3](#page-27-2) shows the locations of the divested stores.

<span id="page-27-2"></span>

Figure 3: Location of the 168 divested stores

<span id="page-27-1"></span><sup>41</sup>See <https://www.ftc.gov/system/files/documents/cases/150127cereberusdo.pdf> for the store list.

## 7.2 Data

I use the 2009 cross-section of AC Nielsen's (currently known as The Nielsen Company) Trade Dimensions TDLinx data for information on grocery stores' locations, sales, and characteristics in the US.[42](#page-28-0)[43](#page-28-1) To generate conservative competitive effects estimates, I include a wide range of firms as potential competitors. Specifically, I include all grocery stores with selling space above 7,000 square feet but exclude military commissaries; my sample includes traditional supermarkets, supercenters, wholesale clubs, natural/gourmet stores, limited assortment stores, and warehouses. Since I cannot access confidential store-level margin data, I uniformly apply a relative margin of 0.27 to all stores based on the merging parties' 2014 10-K reports.<sup>[44](#page-28-2)</sup> Finally, I obtain census tractlevel demographic information including income, proportion of population with college degree or higher, black population, and urbanicity.<sup>[45](#page-28-3)</sup> Table [1](#page-29-0) reports the summary statistics.<sup>[46](#page-28-4)</sup>

#### 7.3 Empirical Specification

I assume that each firm is an owner of multiple stores and competes by setting a uni-dimensional price at each store. Each store corresponds to a "product" in the standard Bertrand-Nash framework. Price  $p_j$  of store j is interpreted as the unobserved price index. I estimate the gross upward pricing pressure indices of the merging parties' stores before and after the merger. I do not credit merger-specific efficiency (i.e., I set  $\ddot{c}_j = 0$ ). Thus, the GUPPI at each store j is given by

$$
GUPPI_j = (1 + \epsilon_{jj}^{-1}) \sum_{k \in \mathcal{J}_B} m_k D_{j \to k}^R,
$$

<span id="page-28-0"></span><sup>&</sup>lt;sup>42</sup> AC Nielsen's Trade Dimensions data estimates weekly sales volume using a proprietary algorithm. Also see [Cho](#page-36-13) [et al.](#page-36-13) [\(2019\)](#page-36-13) for a further discussion on the property of the data.

<span id="page-28-1"></span><sup>&</sup>lt;sup>43</sup>Year 2009 is the closest year before 2014 for which I can access the Trade Dimensions data. In 2013, Super-Value Inc. sold Albertsons, Acme, Jewel-Osco, Shaw's and Start Market banners to Cerberus' AB Acquision, the parent company of Albertsons Inc. To mimic the Albertsons/Safeway merger investigation started in 2014, I assume the Albertsons company owns all the above-mentioned banners, which my 2009 Trade Dimensions data encode as SuperValu-owned.

<span id="page-28-2"></span> $44$ The merging parties' 10-K documents report similar values for company-wide gross margins. See, for example, Safeway's 10-K report for fiscal year 2014, available at [https://www.sec.gov/Archives/edgar/data/86144/](https://www.sec.gov/Archives/edgar/data/86144/000008614415000004/swy-1315x10k.htm) [000008614415000004/swy-1315x10k.htm](https://www.sec.gov/Archives/edgar/data/86144/000008614415000004/swy-1315x10k.htm).

<span id="page-28-3"></span><sup>&</sup>lt;sup>45</sup>I download the data from the IPUMS National Historical Geographic Information System (NHGIS) database [\(Manson et al.,](#page-38-16) [2023\)](#page-38-16), which is publicly accessible. Urbanicity is defined as a fraction of people living in censusdesignated urban areas.

<span id="page-28-4"></span><sup>&</sup>lt;sup>46</sup>I refer the readers to [Ellickson et al.](#page-37-8) [\(2020\)](#page-37-8) for more details on the grocery industry landscape.

<span id="page-29-0"></span>

	Mean	St. Dev.	1st Quartile	Median	3rd Quartile

Table 1: Summary Statistics

 $^{\rm 1}$  Sample consists of census tracts in overlap states.

<sup>2</sup> I define big chains as those with over 100 stores. Medium chains are those with 10 to 100 stores. Small chains are those with 10 or fewer stores.

where B represents the merger counterparty, and the own-price elasticity  $\epsilon_{jj}$  is a known function of margins and revenue diversion ratios as shown in [\(7\)](#page-9-2). Given store-level margin data, the estimation of revenue diversion ratios completes the GUPPI calculation.

I estimate the revenue diversion ratios using a parametric model that follows [Ellickson et al.](#page-37-8) [\(2020\)](#page-37-8). I make the following assumptions. I designate the relevant unit of consumers to be censusdelineated tracts, i.e., I take each tract as a representative consumer of the population residing in the tract. Each representative consumer considers all stores within 10-mile radius, which determines the consideration sets  $\mathcal{C}_i$ . Each representative agent has a nested CES preference. Let the set of nests  $\beta$  include 6 nests: supermarket, supercenter, wholesale club, natural/gourmet, limited assortment, and the outside option. Consumer  $i$ 's budget share spent on store  $j$  in nest  $b$  is

$$
\alpha_{ij} = s_b^i s_{j|b}^i,\tag{21}
$$

where

$$
s_b^i = \left(\frac{\exp(\mu_b I_{i,b})}{\sum_{q \in \mathcal{B}} \exp(\mu_q I_{i,q})}\right),
$$

$$
s_{j|b}^i = \left(\frac{\exp(u_{ij}/\mu_b)}{\sum_{l \in \mathcal{C}_{i,b}} \exp(u_{il}/\mu_b)}\right),
$$

 $\mu_b \in [0,1]$  is the nesting parameter,  $\mathcal{C}_{i,b}$  is the available options in nest b, and  $I_{i,b} \equiv \log \sum_{l \in \mathcal{C}_{i,b}} \exp(u_{i,l}/\mu_b)$ is the inclusive value of nest  $b$ <sup>[47](#page-30-0)</sup>. The outside good forms a distinct nest, and its nesting parameter is normalized to  $\mu_0 = 1$ . I simplify the estimation problem by assuming that  $\mu_b = \mu$  for  $b \in \mathcal{B} \setminus \{0\}$ .<sup>[48](#page-30-1)</sup> The latent utility indices can be projected to the set of observable characteristics as

$$
u_{ij} = x_{ij}^{\top} \theta. \tag{22}
$$

The covariate vector  $x_{ij}$  includes distance from tract to store (in miles), tract characteristics, and store characteristics.<sup>[49](#page-30-2)</sup> Finally, following [Ellickson et al.](#page-37-8)  $(2020)$ , I assume each tract's grocery budget is 13% of its total income.<sup>[50](#page-30-3)</sup> I estimate the utility parameter  $\theta$  by minimizing the distance between the observed store revenues and the model-implied store revenues via nonlinear least squares.<sup>[51](#page-30-4)</sup>

#### 7.4 Estimation Results

#### Utility Parameters

Table [2](#page-31-0) reports the utility parameter estimates from the nonlinear least squares problem. All coefficients have expected signs. For example, consumers dislike traveling far, especially more

<span id="page-30-0"></span><sup>&</sup>lt;sup>47</sup>If  $\mu_b \to 1$  for all nests, the model collapses to the standard logit case. If  $\mu_b \to 0$  for all nests, consumers substitute only within each nest.

<span id="page-30-2"></span><span id="page-30-1"></span> $^{48}$ [Ellickson et al.](#page-37-8) [\(2020\)](#page-37-8)'s results also show that the nesting parameters have similar values.

 $^{49}$ I assume the set of controls is rich enough to absorb the unobserved price terms. I rationalize this assumption by appealing to the findings of [DellaVigna and Gentzkow](#page-37-12) [\(2019\)](#page-37-12) that retail stores' prices tend to be approximately equal across stores within a chain. [Ellickson et al.](#page-37-8) [\(2020\)](#page-37-8) also uses the uniform pricing assumption and control for prices using a rich set of chain fixed effects; I keep my set of controls more parsimonious than theirs for simplicity and tractability.

<span id="page-30-3"></span><sup>&</sup>lt;sup>50</sup>The grocery budget estimate is likely to be conservative. The 2014 Bureau of Labor Statistics Consumer Expenditure Survey reports that consumers spend approximately 12.6% of their pre-tax income on food but only 7.4% on food at home, which may be more relevant for estimating grocery budget.

<span id="page-30-4"></span> $51$ I minimize the sum of squares of the difference between log observed share revenues and log model-implied store revenues. I use the nonlinear least squares package in R.

<span id="page-31-0"></span>when they are in an urban area. Urban residents or richer/higher-educated people have lower grocery expenditures because they can substitute more for outside options such as restaurants or food delivery. Black consumers also spend less on groceries.<sup>[52](#page-31-1)</sup> Consumers spend more in larger stores and at supercenters. Consumers highly value major banners such as Walmart, Costco, H-E-B, Whole Foods, and Trader Joe's.<sup>[53](#page-31-2)</sup> Finally, the nesting parameter  $\mu$  is estimated to be 0.46, which indicates consumers perceive different grocery formats as highly differentiated.<sup>[54](#page-31-3)</sup>

#### Revenue Diversion Ratios

Figure [4](#page-32-0) shows the distribution of revenue diversion ratios implied at the estimated utility parame-

ter.<sup>[55](#page-31-4)</sup> Figure [4a](#page-32-0) reports the distribution of revenue diversion ratios for pairs of stores within 3 miles

<span id="page-31-1"></span> $52$ One explanation is that black neighborhoods have fewer supermarkets; see, e.g., [Bower et al.](#page-36-14) [\(2014\)](#page-36-14) and [Charron-](#page-36-15)Chénier et al. [\(2017\)](#page-36-15). The current framework does not capture the endogeneity of grocery store entries depending on the characteristics of neighborhoods.

<span id="page-31-2"></span><sup>&</sup>lt;sup>53</sup>For parsimony, I include chain fixed-effects for the thirteen biggest grocery chains (by store counts). I assume that big/medium chain indicators can capture most of the price variation elsewhere, which would be true if grocery prices tend to be similar elsewhere. It is straightforward to add extra fixed effect terms.

<span id="page-31-3"></span> $54$ Interestingly, my estimate of the nesting parameter is quite smaller than those found in [Ellickson et al.](#page-37-8) [\(2020\)](#page-37-8), which finds  $\mu \approx 0.75$  using 2006 TDLinx data. Multiple factors, including data years, model specification, and classification of nests, could drive the difference.

<span id="page-31-4"></span><sup>55</sup>I use [Mansley et al.](#page-38-15) [\(2019\)](#page-38-15) to derive the tract-level weights and diversion ratios with nested CES demand.

of each other.<sup>[56](#page-32-1)</sup> The revenue diversion ratios from one store to another tend to be small. However, the total revenue diversion ratio from one store to all surrounding merger counterparty stores can be significantly larger, as Figure [4b](#page-32-0) illustrates. GUPPI statistics enable researchers to summarize how diversions to a network of surrounding stores aggregate, which is crucial for analyzing competition in the grocery industry.

<span id="page-32-0"></span>

(b) Aggregate revenue diversion ratios to merger counterparty stores

Figure 4: Distribution of revenue diversion ratios

#### Gross Upward Pricing Pressure Indices

The FTC-mandated divestiture contributed to a substantial reduction in the GUPPIs. Table [3](#page-33-0) reports the distribution of GUPPIs. Column "Pre" reports the store-level GUPPIs in the predivestiture regime. Column "Post" reports the GUPPIs of the remaining stores after the divesti-ture.<sup>[57](#page-32-2)</sup> Finally, Column "Divested" reports the GUPPIs of the divested stores prior to the merger.

<span id="page-32-2"></span><span id="page-32-1"></span><sup>56</sup>Figures are truncated at 0.25 for presentation.

<sup>&</sup>lt;sup>57</sup>The table lists the divestiture of 165 stores, which is slightly less than the actual divestiture of 168 stores. This discrepancy of three stores arises from the time gap between my data, collected in 2009, and the year of the merger

Overall, the divestiture significantly decreased the upward pricing pressures at many problematic stores; Figure [5](#page-33-1) shows that the divestiture induced a leftward shift in the GUPPI distribution. The divested stores had relatively high GUPPIs in proportion compared to the overall distribution reported in the first column. Post divestiture, the number of high-GUPPI stores decreases substantially.

<b>GUPPI</b>	Pre	Post	Divested
$0 - 1\%$	430	555	0
$1 - 2\%$	348	440	9
$2 - 3\%$	380	229	35
$3 - 4\%$	195	113	32
$4 - 5\%$	117	66	28
$5\% -$	168	63	61
Total	1,638	1,466	165

<span id="page-33-0"></span>Table 3: Distribution of GUPPIs before and after the divestiture

<span id="page-33-1"></span>

Figure 5: Distribution of GUPPIs pre and post divestiture

#### Welfare Effects of Merger

The estimated annual consumer harm before the divestiture is  $$621$  million.<sup>[58](#page-33-2)</sup> Post-merger, the annual consumer harm reduces to \$383 million.

proposal in 2014.

<span id="page-33-2"></span><sup>&</sup>lt;sup>58</sup>Following [Jaffe and Weyl](#page-38-2) [\(2013\)](#page-38-2), I simply use  $\Delta CS_j \approx -R_j \times GUPPI_j$  to estimate the consumer harm at each store j. The total consumer harm is the sum of store-level consumer harm across all stores.

#### Compensating Cost Efficiencies to Offset Upward Pricing Pressures

The consumer harm remains substantial because I assume no efficiency credit (i.e.,  $\ddot{c}_j = 0$ ). If the merger induces reductions in marginal costs, then the consumer harm will be smaller. In practice, it is common for antitrust authorities to evaluate merger effects after crediting some degree of marginal cost efficiencies. Like [Nocke and Whinston](#page-38-6) [\(2022\)](#page-38-6), I study the antitrust authorities' beliefs in firms' merger-induced marginal cost reductions by estimating the percentage change in marginal costs  $\ddot{c}_j$ 's that offset the upward pricing pressures.<sup>[59](#page-34-0)</sup>

Figure [6](#page-34-1) reports the distribution of cost-efficiency credits required to offset upward pricing pressures at the merging firms' stores before and after the divestiture. The 90th, 95th, and 99th quantiles of the post-divestiture compensating cost efficiencies are 5.2%, 6.6%, and 9.9%. If the FTC hypothetically were to credit cost efficiencies of 5%, 6%, or 7% to all stores, it would predict no price increase at more than 90%, 95%, or 99% of the remaining stores, respectively.

<span id="page-34-1"></span>

Figure 6: Distribution of compensating cost efficiencies pre and post divestiture

#### 7.5 Limitations

My analysis has several limitations. First, the data quality used in this application is more restricted than what would be available during actual merger reviews. For example, the TDLinx data relies heavily on an unknown proprietary imputation method to estimate revenues. In practice, antitrust authorities can request actual store-level sales data or detailed consumer-level transaction data

<span id="page-34-0"></span><sup>&</sup>lt;sup>59</sup>From [\(4\)](#page-8-1), the net gross upward pricing pressure index is  $GUPPI_j = GUPPI_j^{\text{no credit}} + \ddot{c}_j(1 - m_j)$ . Thus, the percentage reduction in marginal cost to offset upward pricing pressure at store j is  $-\ddot{c}_j = GUPPI_j^{\text{no credit}}/(1 - m_j)$ . Note that this measure of compensating cost efficiency slightly differs from [Werden](#page-39-3) [\(1996\)](#page-39-3)'s compensating marginal cost reductions, which account for all firms' optimal pricing equations as in merger simulation.

from firms operating in the overlap markets [\(Hosken and Tenn,](#page-37-11) [2016\)](#page-37-11). Such data would dramatically improve the quality of the revenue diversion ratio estimates and the consumer budget share parameter. Moreover, store-level margin data can refine the estimates further.

Second, my GUPPI estimates can be sensitive to model specifications. My estimates of diversion ratios may be sensitive to the specification of the nesting structure. In practice, the contention between the antitrust authority and the merging parties may revolve around the definition of the relevant antitrust market, which also influences estimates of consumers' overall budget and nesting structures. For example, in *Whole Foods/Wild Oats*, the FTC alleged a market consisting of "premium, natural, and organic supermarkets," which would result in a substantially narrower market than what I use for the current application. Estimating a flexible random coefficient model can improve the quality of the estimates with weaker assumptions but can be challenging without price data.

## <span id="page-35-0"></span>8 Conclusion

Throughout this paper, I have illustrated that a lack of price data is not a barrier to conducting thorough unilateral effects analysis for horizontal mergers. Data on revenues, profit margins, and revenue diversion ratios are sufficient to identify the price and welfare implications of mergers. When supplemented with additional assumptions about consumer demand, revenue diversion ratios become identifiable from cross-sectional data on consumers' expenditures, and merger simulations are feasible. The approach detailed in this study offers broad applicability to various industries in scenarios where access to price data is limited.

I see several avenues for future research. First, it would be interesting to find alternative methods for estimating diversion ratios. My proposed strategy hinges on a homogeneous price responsiveness assumption, which can be quite strong. Developing econometric methods to estimate diversion ratios with weaker assumptions on demand or data will be valuable to antitrust economists. Second, developing alternative methods to obtain reliable pass-through rates will be promising. The advantage of the first-order approach over merger simulation lies in its lighter data requirement. Still, existing research has demonstrated that predictions on merger price effects may not be accurate without information on the demand curvature. A further addition to this topic will help facilitate more accurate merger analysis with low data requirements.

## <span id="page-40-0"></span>A Proofs

## A.1 Proof of Lemma [1](#page-6-0)

#### A.1.1 Proof of Lemma [1.](#page-6-0)[1](#page-6-1)

*Proof.* Recall  $\epsilon_{jj} = \frac{\partial q_j}{\partial n_j}$  $p_j$  $\frac{p_j}{q_j},\;\epsilon_{kj}\;=\;\frac{\partial q_k}{\partial p_j}$  $\frac{p_j}{q_k},\,\,\epsilon_{jj}^R\,=\,\frac{\partial R_j}{\partial p_j}$  $p_j$  $p_j$  $p_j$  $\frac{p_j}{R_j}, \epsilon_{kj}^R = \frac{\partial R_k}{\partial p_j}$  $\frac{p_j}{R_k}$ . Using these objects, it is ∂p<sup>j</sup> ∂p<sup>j</sup>  $\partial p_j$  $\partial p_j$  $\frac{q_k}{q_j}$  and  $D_{j\to k}^R = -\frac{\epsilon_{kj}^R}{\epsilon_{jj}^R}$ straightforward to verify  $D_{j\rightarrow k} = -\frac{\epsilon_{kj}}{\epsilon_{ij}}$  $q_k$  $R_k$  $\Box$  $\frac{R_k}{R_j}.$  $\overline{\epsilon_{jj}}$ 

## A.1.2 Proof of Lemma [1.](#page-6-0)[2](#page-6-2)

*Proof.* From  $R_k = p_k q_k$ ,  $\frac{\partial R_k}{\partial p_k}$  $\frac{\partial R_k}{\partial p_j} = q_j \mathbb{I}_{j=k} + p_k \frac{\partial q_k}{\partial p_j}$  $\frac{\partial q_k}{\partial p_j}$  for arbitrary j and k. Then for arbitrary j and k,

$$
\epsilon_{kj}^{R} = \frac{\partial R_k}{\partial p_j} \frac{p_j}{R_k}
$$
  
=  $\mathbb{I}_{j=k} q_j \frac{p_j}{R_k} + p_k \frac{\partial q_k}{\partial p_j} \frac{p_j}{R_k}$   
=  $\mathbb{I}_{j=k} + \frac{\partial q_k}{\partial p_j} \frac{p_j}{q_k}$   
=  $\mathbb{I}_{j=k} + \epsilon_{kj}$ .

#### A.1.3 Proof of Lemma [1.](#page-6-0)[3](#page-6-4)

*Proof.* Finally, by definition,  $R_k = p_k q_k$ , so  $\frac{\partial R_k}{\partial p_j} = \mathbb{I}_{j=k} q_k + p_k \frac{\partial q_k}{\partial p_j}$  $\frac{\partial q_k}{\partial p_j}$  for arbitrary j and k. Then

$$
D_{j\to k}^{R} = -\frac{\mathbb{I}_{j=k}q_k + p_k \frac{\partial q_k}{\partial p_j}}{q_j + p_j \frac{\partial q_j}{\partial p_j}}
$$
  
= 
$$
-\frac{\mathbb{I}_{j=k}(\frac{q_k}{p_j})/(\frac{\partial q_k}{\partial p_j}) + \frac{p_k}{p_j}(\frac{\partial q_k}{\partial p_j})/(\frac{\partial q_j}{\partial p_j})}{(\frac{q_j}{p_j})/(\frac{\partial q_j}{\partial p_j}) + 1}
$$
  
= 
$$
-\frac{\mathbb{I}_{j=k}\epsilon_{kj}^{-1} - (\frac{p_k}{p_j})D_{j\to k}}{\epsilon_{jj}^{-1} + 1}.
$$

Rewriting the last line gives  $(1 + \epsilon_{jj}^{-1})D_{j \to k}^R + \mathbb{I}_{j=k} \epsilon_{kj}^{-1} = D_{j \to k} \frac{p_k}{p_j}$  $\frac{p_k}{p_j}$ . But since  $\mathbb{I}_{j=k} \epsilon_{kj}^{-1} = \mathbb{I}_{j=k} \epsilon_{jj}^{-1}$ , we have  $(1 + \epsilon_{jj}^{-1})D_{j \to k}^R + \mathbb{I}_{j=k} \epsilon_{jj}^{-1} = D_{j \to k} \frac{p_k}{p_j}$  $\frac{p_k}{p_j}.$  $\Box$ 

## A.2 Proof of Lemma [2](#page-9-6)

*Proof.* Recall that firm  $F$ 's first order condition with respect to  $p_j$  can be written as

$$
m_j = -\epsilon_{jj}^{-1} + \sum_{k \in \mathcal{J}_F \backslash j} m_k D_{j \to k} \frac{p_k}{p_j}.
$$
\n(23)

Substituting in  $(1 + \epsilon_{jj}^{-1})D_{j \to k}^R = D_{j \to k} \frac{p_k}{p_j}$  $\frac{p_k}{p_j}$  gives

$$
m_j = -\epsilon_{jj}^{-1} + (1 + \epsilon_{jj}^{-1}) \sum_{k \in \mathcal{J}_F \setminus j} m_k D_{j \to k}^R.
$$
 (24)

.

Solving for  $\epsilon_{jj}$  gives the desired expression [\(7\)](#page-9-2).

## A.3 Proof of Proposition [1](#page-9-5)

Proof. Omitted.

## A.4 Proof of Lemma [3](#page-12-3)

Proof. The changes in consumer surplus and the producer surplus from a price change are

$$
\Delta CS_j \approx -\frac{1}{2}(p_j^1 - p_j^0)(q_j^1 + q_j^0)
$$
  

$$
\Delta PS_j \approx \Delta p_j \times q_j^1 + \Delta q_j \times (p_j^0 - c_j^0) - \Delta c_j \times q_j^1
$$

Since  $q_j^1 \approx q_j^0 + (\partial q_j/\partial p_j)(p_j^1 - p_j^0) = q_j^0(1 + \epsilon_{jj}\ddot{p}_j), \ \Delta q_j \equiv q_j^1 - q_j^0 \approx \epsilon_{jj}q_j^0\ddot{p}_j.$  Moreover,  $-\Delta c_j / p_j^0 = -\ddot{c}_j c_j^0 / p_j^0 = -\ddot{c}_j (1 - m_j^0)$ . Then

$$
\Delta CS_j \approx -\frac{1}{2} \Delta p_j q_j^0 (2 + \epsilon_{jj} \ddot{p}_j)
$$
  
=  $-\ddot{p}_j R_j^0 (1 + \frac{1}{2} \epsilon_{jj} \ddot{p}_j).$ 

Next,

$$
\Delta PS_j \approx \ddot{p}_j R_j^0 (1 + \epsilon_{jj} \ddot{p}_j) + \epsilon_{jj} R_j^0 \ddot{p}_j m_j^0 - \frac{\Delta c_j}{p_j} R_j^0 (1 + \epsilon_{jj} \ddot{p}_j)
$$

 $\Box$ 

But 
$$
\Delta c_j/p_j = \frac{\Delta c_j}{c_j} \frac{c_j}{p_j} = \ddot{c}_j (1 - m_j).
$$

## A.5 Proof of Proposition [2](#page-12-2)

Proof. Omitted.

## A.6 Proof of Lemma [4](#page-13-2)

Proof. Suppose Assumption [5](#page-13-1) holds. In Appendix [B,](#page-46-0) I show that the compensating marginal cost reductions are defined by equations [\(25\)](#page-47-0) and [\(26\)](#page-47-1). Replacing the terms  $D_{j\rightarrow l} \frac{p_l}{n_s}$  $\frac{p_l}{p_j}$  with  $(1+\epsilon_{jj}^{-1})D_{j\to l}^R$  $(Lemma 1)$  $(Lemma 1)$  yields  $(12)$ .  $\Box$ 

#### A.7 Proof of Proposition [3](#page-14-3)

*Proof.* Using the fact that  $(1 + \epsilon_{jj}^{-1})D_{j\to k}^R = \mathbb{I}_{j=k}\epsilon_{kj}^{-1} = D_{j\to k}\frac{p_k}{p_j}$  $\frac{p_k}{p_j}$ , the post-merger first order conditions can be rewritten as

$$
-\epsilon_{jj}^{-1}-m_j^1+(1+\epsilon_{jj}^{-1})\sum_{l\in\mathcal{J}_A\backslash j}m_l^1D_{j\to k}^R+(1+\epsilon_{jj}^{-1})\sum_{k\in\mathcal{J}_B}m_k^1D_{j\to k}^R=0.
$$

Since the own-price elasticities and revenue diversion ratios are identified, the post-merger margins  $\Box$ are identified from the post-merger first-order conditions.

#### A.8 Proof of Lemma [5](#page-16-7)

*Proof.* The revenue diversion ratio from product  $j$  to  $k$ , assuming that Leibniz's rule applies, is

$$
D_{jk}^{R} = -\frac{\int_{i \in S_k} \partial e_{ik} / \partial p_j d\mu}{\int_{i \in S_j} \partial e_{ij} / \partial p_j d\mu}
$$
  
= 
$$
- \int_{i \in S_k} \left( \frac{\partial e_{ik} / \partial p_j}{\int_{i \in S_j} \partial e_{ij} / \partial p_j d\mu} \right) d\mu
$$
  
= 
$$
\int_{i \in S_k} \left( \frac{\partial e_{ij} / \partial p_j}{\int_{i \in S_j} \partial e_{ij} / \partial p_j d\mu} \right) \left( -\frac{\partial e_{ik} / \partial p_j}{\partial e_{ij} / \partial p_j} \right) d\mu,
$$

which is what I wanted to show.

 $\Box$ 

## A.9 Proof of Lemma [6](#page-17-2)

Proof. Under Assumption [6,](#page-16-1)

$$
\frac{\partial e_{ik}}{\partial p_j} = \frac{\partial e_{ik}}{\partial u_{ij}} \frac{\partial u_{ij}}{\partial p_j}.
$$

Since  $\frac{\partial u_{ik}}{\partial p_j}$  is independent of i, it cancels out in the numerators and the denominators of  $w_{ij}$  and  $D_{i,j\rightarrow k}^R$ , yielding the desired expressions.  $\Box$ 

## A.10 Proof of Proposition [4](#page-18-3)

Proof. Omitted.

## A.11 Proof of Proposition [5](#page-20-0)

Proof. Omitted.

## A.12 Proof of Proposition [6](#page-20-3)

*Proof.* Let  $v_{ij} \equiv \exp(u_{ij})$ . The revenue of product k before the removal of product j is  $R_k^{\text{pre}} =$  $\int_{i \in \mathcal{S}_k} \alpha_{ik}^{\text{pre}} B_i d\mu$  where  $\alpha_{ij}^{\text{pre}} = \frac{v_{ik}}{\sum_{l \in \mathcal{C}_i} v_{il}}$ . After removing product j, the revenue of product k becomes  $R_k^{\text{post}} = \int_{i \in \mathcal{S}_k} \alpha_{ik}^{\text{post}} B_i d\mu$  with  $\alpha_{ik}^{\text{post}} = \frac{v_{ik}}{\sum_{l \in \mathcal{C}_i \setminus j} v_{il}}$ . The revenue diversion ratio associated with a removal of product  $j$  is

$$
D_{jk}^{\text{2nd}} = -\frac{R_k^{\text{post}} - R_k^{\text{pre}}}{0 - R_j^{\text{pre}}}
$$
  
= 
$$
\frac{\int_{i \in S_k} (\alpha_{ik}^{\text{post}} - \alpha_{ik}^{\text{pre}}) B_i d\mu}{\int_{i \in S_j} \alpha_{ij}^{\text{pre}} B_i d\mu}
$$
  
= 
$$
\int_{i \in S_k} \left( \frac{\alpha_{ij}^{\text{pre}} B_i}{\int_{i \in S_j} \alpha_{ij}^{\text{pre}} B_i d\mu} \right) \left( \frac{\alpha_{ik}^{\text{post}} - \alpha_{ik}^{\text{pre}}}{\alpha_{ij}^{\text{pre}}} \right) d\mu.
$$

 $\Box$ 

Thus, it is sufficient to verify that  $\frac{\alpha_{ik}^{\text{post}} - \alpha_{ik}^{\text{pre}}}{\alpha_{ij}^{\text{pre}}} = \frac{\alpha_{ik}^{\text{pre}}}{1 - \alpha_{ij}^{\text{pre}}}$ . Observe

$$
\frac{\alpha_{ik}^{\text{post}} - \alpha_{ik}^{\text{pre}}}{\alpha_{ij}^{\text{pre}}} = \frac{\frac{v_{ik}}{\sum_{l \in C_i \setminus j} v_{il}} - \frac{v_{ik}}{\sum_{l \in C_i} v_{il}}}{\frac{v_{ij}}{\sum_{l \in C_i} v_{il}}}
$$
\n
$$
= \frac{\left(\frac{\sum_{l \in C_i} v_{il}}{\sum_{l \in C_i \setminus j} v_{il}}\right) v_{ik} - v_{ik}}{v_{ij}}
$$
\n
$$
= \frac{v_{ik}}{v_{ij}} \left(\frac{v_{ij}}{\sum_{l \in C_i \setminus j} v_{il}}\right)
$$
\n
$$
= \frac{\frac{v_{ik}}{\sum_{l \in C_i} v_{il}}}{1 - \frac{v_{ij}}{\sum_{l \in C_i} v_{il}}},
$$

which is the desired expression.

## A.13 Proof of Lemma [7](#page-19-1)

*Proof.* I omit the derivation of the multinomial logit functional form for  $\alpha_{ij}$  as it is standard. Under Assumption [8,](#page-18-2) since  $\frac{\partial \alpha_{ik}}{\partial u_{ij}} = \alpha_{ik} (\mathbb{I}_{j=k} - \alpha_{ij}) \mathbb{I}_{j,k \in \mathcal{C}_i}$ , I can simplify the expression to [\(15\)](#page-16-0) with

$$
w_{ij} = \frac{\alpha_{ij}(1 - \alpha_{ij})B_i}{\sum_{\tilde{i}\in S_j} \alpha_{\tilde{i}j}(1 - \alpha_{\tilde{i}j})B_{\tilde{i}}},
$$

$$
D_{ijk}^R = \frac{\alpha_{ik}}{1 - \alpha_{ij}},
$$

which is what I wanted to show.

## A.14 Proof of Lemma [8](#page-21-2)

*Proof.* Given that the latent utility function is specified as  $u_{ij} = \log \beta_{ij} + (1 - \eta) \log p_j$ , since  $p_j^{\text{post}} \equiv$  $p_i^{\text{pre}}$  $j_j^{\text{pre}}(1+\ddot{p}_j)$ , the pre- and post-merger latent utilities are related as  $u_{ij}^{\text{post}} = u_{ij}^{\text{pre}} + (1-\eta) \log(1+\ddot{p}_j)$ . Thus, if  $u_{ij}^{\text{pre}}$  and  $\eta$  are identified,  $u_{ij}^{\text{post}}$  is a known function of  $\ddot{p}_j$ . It follows that for arbitrary  $\ddot{p}$ ,

45

 $\Box$ 

 $u_{ij}^{\text{post}}, \, \alpha_{ij}^{\text{post}}, \, e_{ij}^{\text{post}}, \, R_j^{\text{post}}$  $j_j^{\text{post}}$  can be computed for all i and j. Furthermore, since

$$
\epsilon_{jj}^{R} = \frac{1 - \eta}{R_j} \sum_{i \in S_j} \frac{\partial \alpha_{ij}}{\partial u_{ij}} B_i,
$$

$$
D_{jl}^{R} = -\frac{\sum_{i \in S_l} \frac{\partial \alpha_{il}}{\partial u_{ij}} B_i}{\sum_{i \in S_j} \frac{\partial \alpha_{ij}}{\partial u_{ij}} B_i},
$$

 $\epsilon_{jj}^{R, \text{post}}$  and  $D_{j \to k}^{R, \text{post}}$  $\mu_{j\rightarrow k}^{R, \text{post}}$  can be computed for arbitrary j and k. Finally, assuming that the marginal cost does not change,

$$
m_j^{\text{post}} = \frac{p_j^{\text{post}} - c_j^{\text{pre}}}{p_j^{\text{post}}} = 1 - \frac{1}{1 + \ddot{p}_j} (1 - m_j^{\text{pre}}).
$$

Thus, each  $m_i^{\text{post}}$  $j^{\text{post}}$  is also a function of  $\ddot{p}_j$ .

## A.15 Proof of Proposition [7](#page-22-4)

Proof. Omitted.

## A.16 Proof of Lemma [9](#page-23-3)

*Proof.* Since  $R_k = \int_{i \in S_k} e_{ik} d\mu$ , and  $e_{ik} = \alpha_{ik} B_i$ ,

$$
\frac{\partial R_k}{\partial p_j} = \int_{i \in S_k} \frac{\partial e_{ik}}{\partial p_j} d\mu
$$
  
= 
$$
\int_{i \in S_k} \frac{\partial \alpha_{ik}}{\partial u_{ij}} \frac{\partial u_{ij}}{\partial p_j} B_i d\mu
$$
  
= 
$$
\frac{1 - \eta}{p_j} \int_{i \in S_k} \frac{\partial \alpha_{ik}}{\partial u_{ij}} B_i d\mu,
$$

where the last equality follows from the CES utility assumption  $\partial u_{ij}/\partial p_j = (1 - \eta)/p_j$ . Multiplying both sides by  $(p_j/R_k)$  gives

$$
\epsilon_{kj}^R = \frac{1-\eta}{R_k} \int_{i \in \mathcal{S}_k} \frac{\partial \alpha_{ik}}{\partial u_{ij}} B_i d\mu.
$$

 $\Box$ 

 $\Box$ 

## <span id="page-46-0"></span>B Review of Unilateral Effects Analysis

In this section, I review the derivation of firms' profit maximization conditions, gross upward pricing pressure indices, and compensating marginal cost reductions.

## B.1 Firm's Problem

The multiproduct firms engage in a Bertrand-Nash pricing game. Each firm  $F \in \mathcal{F}$  maximizes its total profit  $\sum_{j\in\mathcal{J}_F}\pi_j$  with respect to a vector of prices  $(p_j)_{j\in\mathcal{J}_F}$ . The first-order condition with respect to  $p_j$  is

$$
q_j + (p_j - c_j) \frac{\partial q_j}{\partial p_j} + \sum_{l \in \mathcal{J}_F \setminus j} (p_l - c_l) \frac{\partial q_l}{\partial p_j} = 0.
$$

Normalizing the above to be quasilinear in the marginal cost gives

$$
-p_j \epsilon_{jj}^{-1} - (p_j - c_j) + \sum_{l \in \mathcal{J}_F \setminus j} (p_l - c_l) D_{j \to l} = 0,
$$

where  $\epsilon_{jj} \equiv \frac{\partial q_j}{\partial p_j}$  $\overline{\partial p_j}$  $p_j$  $\frac{p_j}{q_j}$  is the own-price elasticity of demand, and  $D_{j\to l} \equiv -\frac{\partial q_l/\partial p_j}{\partial q_j/\partial p_j}$  $\frac{\partial q_i}{\partial q_j/\partial p_j}$  is the quantity diversion ratio from product j to product  $l^{60}$  $l^{60}$  $l^{60}$  Further dividing the FOC by  $p_j$  normalizes the first-order conditions to be quasilinear in margins and gives [\(1\)](#page-5-2):

$$
-\epsilon_{jj}^{-1} - m_j + \sum_{l \in \mathcal{J}_F \backslash j} m_l D_{j \to l} \frac{p_l}{p_j} = 0.
$$

#### B.2 Upward Pricing Pressure

Consider a merger between two firms A and B. The upward pricing pressure associated with product  $j$  of firm  $A$  is defined as

$$
UPP_j \equiv \Delta c_j + \sum_{k \in \mathcal{J}_B} (p_k - c_k) D_{j \to k},
$$

<span id="page-46-1"></span><sup>&</sup>lt;sup>60</sup>Rearranging the first-order conditions gives the optimal markup equation  $p_j(1+\epsilon_{jj}^{-1}) = c_j + \sum_{l \in \mathcal{J}_F \setminus j} (p_l - c_l)D_{j \to l}$ , which in turn implies that  $(1+\epsilon_{jj}^{-1}) > 0$ , or, equivalently,  $\epsilon_{jj} < -1$ , i.e., in a Bertrand-Nash equilibrium, firms always price at the elastic region of demand.

where  $\Delta c_j = c_j^{\text{post}} - c_j^{\text{pre}} < 0$  represents the reduction in marginal cost due to merger-specific efficiencies; those of firm B are defined symmetrically.<sup>[61](#page-47-2)</sup> The gross upward pricing pressure index is obtained by normalizing upward pricing pressure by price, i.e.,  $GUPPI_j \equiv UPP_j/p_j$  and can be rewritten as

$$
GUPPI_j = \ddot{c}_j(1 - m_j) + \sum_{k \in \mathcal{J}_B} m_k D_{j \to k} \frac{p_k}{p_j},
$$

where  $\ddot{c}_j \equiv \Delta c_j/c_j^{\text{pre}} \in (-1,0)$  represents the percentage decrease in marginal cost from the premerger equilibrium.

## B.3 Compensating Marginal Cost Reduction

Compensating marginal cost reductions (CMCR) are defined as the percentage decrease in the merging parties' costs that would leave the pre-merger prices unchanged after the merger. [Werden](#page-39-3)  $(1996)$  shows that CMCRs are identified when prices, margins, and diversion ratios are observed.<sup>[62](#page-47-3)</sup> Specifically, under Assumption [5,](#page-13-1) the compensating marginal cost reductions (defined in percentage change relative to pre-merger levels) are

<span id="page-47-0"></span>
$$
\ddot{c}_j = \frac{m_j^0 - m_j^1}{1 - m_j^0}.\tag{25}
$$

The post-merger margins are defined by the post-merger first-order conditions

<span id="page-47-1"></span>
$$
-\epsilon_{jj}^{-1} + \sum_{l \in \mathcal{J}_A} m_l^1 D_{j \to l} \frac{p_l}{p_j} + \sum_{k \in \mathcal{J}_B} m_k^1 D_{j \to k} \frac{p_k}{p_j} = 0.
$$
 (26)

Finding post-merger margins amounts to solve a linear system of equations.

To see that [\(25\)](#page-47-0) holds, note that, since  $p_j^1 = p_j^0$ ,

$$
m_j^0 - m_j^1 = \frac{1}{p_j^0}((p_j^0 - c_j^0) - (p_j^0 - c_j^1)) = \frac{\Delta c_j}{p_j^0}.
$$

Then

$$
\frac{m_j^0-m_j^1}{1-m_j^0}=\frac{\frac{\Delta c_j}{p_j}}{\frac{p_j^0}{p_j^0}-\frac{p_j^0-c_j^0}{p_j^0}}=\frac{\Delta c_j/p_j^0}{c_j^0/p_j^0}=\frac{\Delta c_j}{c_j^0}=\ddot{c}_j.
$$

<span id="page-47-2"></span> $61$ I occasionally omit the superscript "pre" when it is clear the object is that of the pre-merger equilibrium.

<span id="page-47-3"></span> $62$ [Werden](#page-39-3) [\(1996\)](#page-39-3) derives the expressions for a single-product firms case.

# <span id="page-48-0"></span>C Identification of Compensating Variation Under CES Preferences

It is possible to show that the compensating variation associated with a price increase is identified under the CES utility assumption. In the previous sections, I showed that consumer surplus variations can be approximated. When the utility function takes a CES form, it is possible to derive an exact formula for compensating variation associated with a vector of simultaneous price changes.

Let  $V_i(p, B_i)$  be consumer i's indirect utility at price p and budget  $B_i$ . The compensating variation for consumer i associated with a price increase from  $p^0$  to  $p^1$  is defined as  $CV_i \in \mathbb{R}$  that solves  $V_i(p^0, B_i) = V_i(p^1, B_i - CV_i)$ . The total compensating variation is  $CV = \int_{i \in \mathcal{I}} CV_i d\mu$ . Under the CES utility assumption, the compensating variation admits a closed-form expression.

**Lemma 10** (Compensating variation under CES utility). Suppose Assumption [8](#page-18-2) holds. Let  $P_i(u_i) \equiv$  $\left(\sum_{k\in\mathcal{C}_i} \exp(u_{ik})\right)^{\frac{1}{\eta-1}}$ . For each consumer i, the compensating variation associated with a price change from  $p^0$  to  $p^1$  is

$$
CV_i = B_i \left( 1 - \frac{P_i(u_i^0)}{P_i(u_i^1)} \right) \tag{27}
$$

where  $u_i^0 = u_i(p^0)$  and  $u_i^1 = u_i(p^1)$ . Furthermore,  $u_{ij}^1 = u_{ij}^0 + (1 - \eta) \log(1 + \ddot{p}_j)$ .

Proof. Consumer i's indirect utility function is

$$
V_i(p, B_i) = AP_i^{\beta, \eta}(p)B_i
$$
\n(28)

 $\left(\frac{1-\eta}{k}\right)^{\frac{1}{\eta-1}}$ . Solving for  $CV_i$  gives the desired expression.  $p^{\beta,\eta}_i(p)\equiv \Bigl( \sum_{k\in\mathcal{C}_i}\beta_{ik}p_k^{1-\eta}$ where  $P_i^{\beta,\eta}$  $\Box$ 

Given a vector of percentage price increases  $\ddot{p}$ , the analyst can compute the compensating variation of each consumer if the analyst observes the consumer's budget and pre-merger mean utilities, and the price coefficient.

**Proposition [8](#page-18-2)** (Identification of compensating variation). Suppose Assumptions [6,](#page-16-1) [7](#page-17-3) and 8 hold. Then the compensating variation of each consumer associated with the the merger price effects is identified.

## <span id="page-49-0"></span>D Accuracy of Upward Pricing Pressure

To predict merger price effects using upward pricing pressure, I have assumed that

<span id="page-49-1"></span>
$$
\Delta p_j \approx UPP_j. \tag{29}
$$

In a companion paper [\(Koh,](#page-38-17) [2024\)](#page-38-17), I repeat the simulation exercise in [Miller et al.](#page-38-3) [\(2017\)](#page-38-3) and examine whether [\(29\)](#page-49-1) is reasonable. [Miller et al.](#page-38-3) [\(2017\)](#page-38-3) does not study the case of CES demand.

<span id="page-49-2"></span>

Figure 7: Accuracy of UPP

I report the simulation results in Figure [7.](#page-49-2) First, Figure [7-](#page-49-2)(a) shows that upward pricing pressure accurately predicts merger price effects in the case of logit demand. The result is also consistent with [Miller et al.](#page-38-3) [\(2017\)](#page-38-3) (see their Figure 2). Next, Figure [7-](#page-49-2)(b) shows the simulation results with CES demand. It shows that upward pricing pressure underpredicts merger price effects. Thus, using upward pricing pressures as proxies for merger price effects would yield conservative predictions.
