Leverage Multi-source Traffic Demand Data Fusion with Transformer Model for Urban Parking Prediction

Yin Huang[#], Yongqi Dong[#], Student Member, IEEE, Youhua Tang, and Li Li, Fellow, IEEE

Abstract—The escalation in urban private car ownership has worsened the urban parking predicament, necessitating effective parking availability prediction for urban planning and management. However, the existing prediction methods suffer from low prediction accuracy with the lack of spatial-temporal correlation features related to parking volume, and neglect of flow patterns and correlations between similar parking lots within certain areas. To address these challenges, this study proposes a parking availability prediction framework integrating spatial-temporal deep learning with multi-source data fusion, encompassing traffic demand data from multiple sources (e.g., metro, bus, taxi services), and parking lot data. The framework is based on the Transformer as the spatial-temporal deep learning model and leverages K-means clustering to establish parking cluster zones, extracting and integrating traffic demand characteristics from various transportation modes (i.e., metro, bus, online ride-hailing, and taxi) connected to parking lots. Real-world empirical data was used to verify the effectiveness of the proposed method compared with different machine learning, deep learning, and traditional statistical models for predicting parking availability. Experimental results reveal that, with the proposed pipeline, the developed Transformer model outperforms other models in terms of various metrics, e.g., Mean Squared Error (MSE), Mean Absolute Error (MAE), and Mean Absolute Percentage Error (MAPE). By fusing multi-source demanding data with spatial-temporal deep learning techniques, this approach offers the potential to develop parking availability prediction systems that furnish more accurate and timely information to both drivers and urban planners, thereby fostering more efficient and sustainable urban mobility.

I. INTRODUCTION

With rapid urbanization and the significant increase in private vehicle ownership, the challenge of urban parking has

emerged as a critical concern in metropolitan areas. Parking inaccessibility not only leads to longer driving times but also exacerbates urban traffic congestion, driver frustration, and environmental pollution [1]. The challenge of finding parking spaces, especially during peak periods, is not solely due to the scarcity of parking spots but also largely attributed to the lack of predictive analytics on parking availability. Parking dynamics, which involve the constant turnover of vehicles entering and exiting parking spaces, directly impact the availability of parking spots. Precise prediction of parking availability empowers city authorities and drivers to make informed decisions, optimize the utilization of parking resources, and effectively alleviate traffic congestion.

To estimate and predict parking availability, some pioneering studies have been developed. For example, Caliskan et al. proposed a continuous-time Markov chain based model to predict future parking lot availability [2]. Drawing from real-time data, Rajabioun and Loannou devised a spatiotemporal autoregressive model tailored for forecasting parking availability [3]. Attributed to the inherent instability of parking sensors and the dynamic changes in parking lots, the predictive accuracy of these sensor-based parking studies remains suboptimal. Furthermore, with the proliferation of smart parking guidance and information systems (PGIS), some researchers began to focus on analyzing and predicting parking behavior. Through accurate prediction of parking behavior, PGIS can effectively guide drivers to reach vacant parking spaces in a shorter time [4].

Methodologies for parking prediction can be broadly categorized into two groups: knowledge-based methods and data-driven approaches. The knowledge-based approach typically relies on extensive prior knowledge and complex underlying assumptions, making it suitable for simple problems with strong regularities. However, parking availability prediction is a complex issue influenced by numerous factors, rendering knowledge-based methods unsatisfactory. Regarding data-driven parking prediction methods, three major phases have been experienced: statistical learning, machine learning (ML), and deep learning (DL). In short-term parking prediction, traditional statistical learning techniques like Kalman filters [1], Autoregressive Integrated Moving Average (ARIMA) [5], and Historical Average (HA) [6] have demonstrated strong performance. However, for long-term forecasts, typical statistical approaches struggle to achieve high prediction accuracy due to spatial-temporal fluctuations and parking system complexity. To address the spatial-temporal variability and complex dynamics of parking, a number of studies turned to ML techniques. For example, Feng et al. employed ML algorithms, such as linear regression (LR), decision tree (DT), and random forest (RF), to analyze and predict parking behavior, with the RF model demonstrating the highest accuracy [7]. Some other studies have also compared the performance of algorithms such as support vector machine (SVM), K-nearest neighbors (KNN) and artificial neural networks (ANN) in parking prediction [8]. These traditional ML algorithms require extensive hyperparameter tuning and training, struggle with processing large volumes of data, and are prone to regional overfitting.

In recent years, deep learning techniques have emerged as prominent methods in parking prediction research. For instance, Qiu et al. combined recurrent neural networks (RNN) and genetic algorithms to develop an effective parking space forecasting model [9]. Shao et al. introduced a unique framework for predicting parking space availability and duration using the Long Short-Term Memory (LSTM) neural network, which outperformed traditional models with superior performance [10]. To compensate for the spatial-temporal correlation between parking lots, Ghosal et al. developed a deep learning model for parking availability prediction that incorporates a convolutional neural network (CNN) and a stacked LSTM autoencoder [11]. Given that parking networks are typically built in non-Euclidean space, some graph-based parking prediction algorithms have also been developed, e.g., Gong et al. adapted a spatial-aware Graph Convolutional Network framework (GCN) to forecast parking availability [12]. Additionally, to enhance temporal dependence, Xiao et al. devised a Hybrid Spatial-Temporal Graph Convolutional Network (HST-GCN) model for forecasting on-street parking availability [13]. These aforementioned parking prediction researches concentrate on intricate model architecture, resulting in higher prediction accuracy but also consuming significant processing resources.

Even though factors like the weather, holidays, and parking zones have been considered, the model still finds it challenging to learn the unstable parking dynamics [14]. A common oversight is neglecting the close correlation between parking availability and the attributes of the parking zone, as well as the dynamic traffic and trip demand in the associated area during the target time periods. To address these issues, this study developed a spatial-temporal DL framework for parking availability prediction by fusing multi-source heterogeneous demanding data. Specifically, this study considered the spatial-temporal correlation among parking lots with similar characteristics within certain areas and constructed the "parking cluster zone" using the K-means clustering. Within the radiation area of the parking lot, travel records of metros, buses, online ride-hailing, and taxis related to the parking cluster zone were integrated to build a set of associated demanding-related features. This study developed a spatial-temporal DL model based on Transformer with the attention mechanism, and compared it with various other baseline models including traditional statistical models (e.g., HA and ARIMA), traditional ML (e.g., DT and SVR), ensemble ML (e.g., RF and XGBoost), and other DL models (e.g., gated recurrent unit model (GRU) and LSTM neural networks). To test and evaluate the model performance, realworld empirical data from Chengdu, China in September 2021

were utilized for experiments. The results reveal that the proposed spatial-temporal DL framework outperforms stateof-the-art benchmarks in parking availability prediction.

In short, the main contributions of this paper lie in:

•For the first time, multi-source heterogeneous travel demanding data is aggregated and integrated to serve as the important spatial-temporal feature for the parking availability prediction.

•A clustering-based method is adopted to establish parking cluster zones identifying parking lots with similar characteristics within certain urban areas. The spatial-temporal parking dynamics and correlations among related parking lots within the identified parking cluster zones are excavated.

• A spatial-temporal Transformer model is designed and customized. Together with various baseline models, the model performances are evaluated using real-world empirical data.

II. METHODOLOGY

A. Demanding Features Integration

1) Parking cluster zone

The parking cluster zone is defined as the area where travelers engage in various trip-related activities after parking their vehicles. The dynamic behavior of vehicles entering and exiting a parking lot is directly correlated with the demand characteristics of the surrounding area.

To investigate parking availability more efficiently, we utilized K-means clustering to group similar parking lots within certain areas together. As shown in Fig. 1, each "x" point represents a parking lot; different colors represent distinct parking lot clusters; and " \blacktriangle " signifies the cluster's center. Considering the layout of city streets, this study employs the Minkowski distance to compute the necessary buffer zone and then apply spatial concatenation to obtain the relevant parking cluster zones. Four typical examples of parking cluster zones are illustrated by the irregular polygons with boundary dashed lines framing relevant parking lots.

Figure 1. The distribution of the parking lots and parking cluster zone.

2) Spatial-temporal demanding feature integration

In the early urban traffic prediction theories, researchers usually pre-determined the volume of trip generation and attraction within a given region before trip distribution and traffic modal split analysis. However, with the advancement of comprehensive transportation integration and the widespread adoption of information and communications technologies (ICT), data-driven fusion research between heterogeneous modes of transportation has emerged as an effective approach to address the challenge of dynamic demanding estimation. Recognizing their potential interchangeability in offering travel services akin to private cars, this study selected four distinct travel modes for spatial-temporal demand feature fusion: metro, bus, online ride-hailing, and taxi.

Figure 2. Fusion of demand characteristics within parking cluster zone

As illustrated in Fig. 2, upon extracting travel trip data from these four modes of transportation, the origin (O) and destination (D) of each trip can be identified. If either the origin (O) or destination (D) of a certain trip falls within the boundary of the parking cluster zone, the multi-modal travel trip is then associated with that specific parking cluster zone. In this study, the volume of such multi-modal travel trips is fused to demonstrate the spatial-temporal demanding characteristics of the parking cluster zones. Consequently, this demand characteristic encapsulates both spatial and temporal aspects related to parking dynamics.

B. Transformer Model

Transformer, as illustrated in Fig. 3, is a DL model architecture based on attention mechanisms, with encoding and decoding components at its core [15]. Each encoder and decoder consists of a multilayer self-attention mechanism and a feed-forward neural network. In comparison to CNN or RNN, the self-attention mechanism enables the Transformer model to prioritize the importance of different inputs, capturing longrange dependencies in the data more efficiently. Therefore, Transformer has been effectively applied in various domains, including natural language processing (NLP), computer vision (CV), and long-term time series forecasting (LTSF).

1) Positional Encoding

Positional encoding is a crucial component in Transformer architectures, addressing the absence of sequential information inherently present in the data. Unlike RNNs, which naturally capture sequence order through recurrent connections, Transformers lack this inherent ability. Therefore, positional encoding is introduced to provide the model with information about the position of tokens within the input sequence. In Transformer-based models, positional encoding is added to the input embeddings before feeding them into the model. Vanilla positional encoding is typically implemented using sinusoidal functions, allowing the model to learn and distinguish between tokens based on their position in the sequence. Mathematically, the positional encoding function for position *pos* and dimension *i* is defined as follows:

$$PE(pos, 2i) = sin(\frac{pos}{10000^{\frac{2i}{d_{model}}}})$$
(1)

$$PE(pos, 2i+1) = cos(\frac{pos}{10000^{\frac{2i}{d_{model}}}})$$
(2)

where PE is short for positional encoding, d_{model} represents the dimensionality of the input embeddings.

Figure 3. Transformer framework for time series forecasting

In time series forecasting tasks, encoding temporal information is crucial for capturing inherent patterns and dependencies. Timestamp encoding represents converting timestamps into a format that can be effectively used by ML models. One common method is to use *sine* and *cosine* functions to encode time of day, day of the week, month, etc.

With "*timestamp*" as its associated timestamp and "*T*" representing the maximum value of the time feature (e.g., maximum hour in a day, maximum day in a week), the timestamp encoding can be computed as follows:

$$PE(timestamp, f)_{sin} = sin\left(timestamp \times \frac{2\pi}{T}\right) \quad (3)$$

$$PE(timestamp, f)_{cos} = cos\left(timestamp \times \frac{2\pi}{T}\right) \quad (4)$$

where $f \in \{hour, day, week, month\}$ represents the periodic feature of the input embeddings.

2) Multi-Head Attention

The attention mechanism is a fundamental component in Transformer-based sequence-to-sequence models. It enables

the model to focus on various segments of the input sequence while generating an output sequence, thereby effectively capturing long-range dependencies. With Query-Key-Value (QKV) interior design, the scaled dot-product attention used in Transformer is given by

Attention(Q, K, V) = soft max(
$$\frac{QK^T}{\sqrt{d_k}}$$
)V (5)

where Q, K, and V are vector representations of the query, key, and value, respectively, and d_k is the dimensionality of the key. Q, K, and V are calculated by linearly converting the input sequence.

In multi-head attention, the query, key, and value matrices are divided into multiple heads, each with its own set of parameters. Then, attention is computed independently for each head, and the results are concatenated and linearized. With h attention heads, the multi-head attention mechanism is formulated as follows:

$$MHAttn(Q, K, V) = Concat(head_1, \cdots, head_H)W^0$$
(6)

where $head_i = Attention(QW_i^Q, KW_i^K, VW_i^V)$, and W_i^Q, W_i^K, W_i^V , and W^O are learnable parameters.

3) Feed Forward Network

In the Transformer model, the Feedforward Neural Network (FFN) is connected to each attention layer. The feedforward network is a fully connected module, defined as

$$FFN(H') = ReLU(H'W_1 + b_1)W_2 + b_2$$
(7)

where H' is outputs of the previous layer, $W_1 \in \mathbb{R}$, $W_2 \in \mathbb{R}$, $b_1 \in \mathbb{R}$, $b_2 \in \mathbb{R}$, are trainable parameters.

C. Temporal LTSF Model: NLinear

The growing complexity of architecture in (long-term) time series prediction models naturally demands increased computational capacity during iterative model training. LTSF-Linear, a linear model with lower computational complexity designed for LTSF tasks, features direct multi-step prediction via linear regression plus activation function (as illustrated in Fig. 4). Despite its simple model architecture, LTSF-Linear surprisingly outperforms other complex deep learning models on some real-world datasets [16]. Therefore, LTSF-Linear is often used as a baseline model for time series prediction tasks.

Figure 4. Linear models for time series forecasting (adapted from [16])

NLinear, a variation of the LTSF-Linear model, represents an advanced linear time series forecasting approach specifically designed to address the distribution shift problem that is common in time series data [16]. To ensure robust predictions, the NLinear model eliminates the sequence's final value from the history data and normalizes the inputs to mitigate the effects of distributional differences between the training and test datasets. Furthermore, it ensures that readding the initial subtraction restores the model's output to the original data distribution. NLinear achieved competitive performance in various LTSF tasks thus it is selected as the typical baseline for representative of the temporal DL model.

III. EXPERIMENTS AND RESULTS COMPARISON

A. Data Description and Processing

This study utilized parking records from 127 parking lots in Chengdu, Sichuan Province, China. For each parking record, one could obtain the vehicle's arrival time, departure time, date, and total number of parking spots in the relevant parking lot. The data collection spanned one month, from September 1 to September 30, 2021, and contained in total of 2,875,320 parking records during the 30 days. These 127 parking lots were clustered into 24 parking cluster zones based on factors such as spatial distribution and in/outflow. Additionally, travel trip records (including metro, bus, online ride-hailing, and taxi) within these 24 parking cluster zones were also gathered. Note that, for practical limits (no card swipes are necessary to exit the bus service in the region), the bus OD trip demand data is based solely on boarding card swipe data.

For data preprocessing, this study employed a multi-step strategy to refine the original dataset by eliminating noise and inconsistencies. Initially, the dropna function was used to discard instances containing NULL or missing values. Subsequently, the data was processed in sets with a 10-minute interval to further reduce noise. To mitigate the impact of lowfrequency noise, a Fourier Transform was applied to the dataset, followed by an inverse Fourier Transform to revert the frequency domain data back to the time domain. After these treatments, 4,032 refined records were obtained from each parking lot, resulting in a total of 512,064 data samples (4,032*127 parking lots). The dataset was divided into two parts: 70% for training and 30% for testing. In the training dataset, data from 90 parking lots in 18 clusters were utilized for training. The training process involves using information from the past 432 time steps as input to predict the parking availability for the subsequent 144th time step. As each time step represents a duration of 10 minutes, the prediction for the subsequent 144th time step is equivalent to forecasting parking availability 24 hours (1 day) later, which is reasonable and holds practical significance in real-world applications. For the test dataset, data from 37 parking lots across 6 clusters were employed.

B. Baseline Models

Apart from the NLinear model, this study considers three types of baseline models: conventional statistical models, ML models (including ensemble learning models), and DL models.

History Average (HA): HA is a straightforward time series forecasting method for short-term forecasting. The

primary idea behind this strategy is that future values will be fairly similar to the average of recent historical values.

- Autoregressive Integrated Moving Average (ARIMA): ARIMA is a statistical model used to extract seasonality and periodicity in time series data by combining moving average and difference operations.
- **Decision Tree (DT)**: DT is a decision-making tool that organizes decisions and their potential outcomes in a tree-like structure [17]. Object properties and values are mapped within the tree, with each leaf node representing a specific object value determined by the path from the root node, and each forked path corresponds to a potential attribute value.
- Support vector regression (SVR): The SVR is a variant of Support Vector Machines (SVM) specifically designed for regression tasks [18]. SVR operates by mapping the input data into a high-dimensional feature space using a nonlinear relationship. Given the input *X*, SVR calculates the predicted value ŷ and introduces a threshold ε to assess the disparity between ŷ and the true value *y*. In this study, a Radical Basis Function, i.e., "*rbf*" is employed as the kernel function for SVR.
- Extreme Gradient Boosting (XGBoost): XGBoost is an aggregated learning approach that enhances prediction performance by constructing a cohesive model of many weak learners via gradient boosting [19].
- **Random Forest (RF):** RF is an integrated learning technique that increases prediction accuracy and generalization by generating several decision trees and aggregating their predictions [20].
- **Gated Recurrent Unit model (GRU):** GRU is a RNN variant that efficiently captures long-term dependencies in sequential data via a gating mechanism [21]. In this study, 5 layers of GRU, each comprising 256 neurons, were employed in the experimental tests.
- Long Short-Term Memory (LSTM): LSTM is another RNN variant designed to handle the problem of longterm dependency and mitigate the issue of vanishing gradients [22]. LSTM processes sequential data and outputs information for a specific window of time steps. A typical LSTM unit is composed of a cell, an input gate, an output gate, and a forget gate. In the experimental test, a 4-layer LSTM neural network was employed, with each layer containing 256 neurons.

C. Evaluation Metric

To better demonstrate the performance of the models, this study incorporates the following evaluation indicators for parking availability prediction.

• Mean Squared Error (MSE):

$$MSE = \frac{1}{N} \sum_{n=1}^{N} (\hat{y}_n - y_n)^2 .$$
 (8)

• Mean Absolute Error (MAE):

$$MAE = \frac{1}{N} \sum_{n=1}^{N} |\hat{y}_n - y_n| \quad .$$
 (9)

Mean Absolute Percentage Error (MAPE):

MAPE =
$$\frac{100\%}{N} \sum_{n=1}^{N} \left| \frac{\hat{y}_{n} - y_{n}}{y_{n}} \right|$$
 (10)

Here, *N* signifies the total number of test samples, while y_n and \hat{y}_n represent the actual and predicted values, respectively. MSE, MAE, and MAPE are three prevalent metrics for predictive analysis. MSE squares the error, making larger error values stand out, and is appropriate for penalizing larger errors. MAE takes the absolute value of the error, providing a more robust measure that reflects the average level of actual error. MAPE focuses on relative errors, making it more comparable for prediction tasks of varying magnitudes.

Moreover, the model parameter size, represented as Params (M), along with the multiply-accumulate operations, denoted as MACs (G), serve as indicators of the DL models' complexity. The two metrics are frequently utilized to estimate models' computational complexity and real-time capabilities.

D. Results Comparison

Table I summarizes the quantitative performance comparison results for the evaluated models. It displays the mean values of the results across the target 37 parking lots. As demonstrated, the Transformer model outperformed other methods, with the lowest MSE, MAE and MAPE scores. Conventional statistical models like HA and ARIMA and traditional ML models, e.g., DT and SVM, are inadequate in capturing complex spatial-temporal dependencies in parking availability. In comparison, XGBoost and RF algorithms notably improve prediction performance by leveraging larger ensembled model structures and iterative training. However, these ML algorithms do not outperform DL algorithms (GRU, LSTM, Transformer, NLinear, etc.). This may be because ML algorithms' tendency to overfit on the training dataset, resulting in inferior performance on the test dataset. In contrast, DL models can automatically extract useful features and correlations, and they often employ regularization or penalty methods to mitigate overfitting.

TABLE I. PERFORMANCE COMPARISON OF THE MODELS

Algorithms	MSE	MAE	MAPE	MACs (G)	Params (M)
HA	0.2478	0.1748	1.1495		
ARIMA	0.1761	0.1679	0.8785		
DT	0.1477	0.1863	0.7723		
SVR	0.1344	0.1637	0.7465		
XGBoost	0.1162	0.1643	0.7275		
RF	0.1017	0.1473	0.6704		
GRU	0.0924	0.1665	0.6138	0.6876	1.7781
LSTM	0.0745	0.1582	0.6055	0.7216	1.8952
NLinear	0.0703	0.1542	0.5708	0.3185	0.6246
Transformer	0.0626	0.1358	0.5496	1.0644	0.9107

To comprehensively compare the performance of different DL models, computational complexity and real-time capabilities are also taken into account. Among DL methods, traditional RNN models (GRU, LSTM) exhibit competitive performance in parking availability prediction. These algorithms capture temporal dependencies in sequences through gated units, but they also entail a larger number of parameters to be learned, which amounts to 1.8952 (M) for LSTM and 1.7781 (M) for GRU, respectively. Nevertheless, handling long-term sequence correlations remains a challenge for LSTM/GRU algorithms. This is further underscored by the findings of the ablation study depicted in Fig.5.

On the other hand, the improved simple linear DL model, i.e., NLinear, is significantly smaller than LSTM and GRU in terms of MACs and Params. Despite its compact size, NLinear achieves superior performance through direct multi-step prediction. Among all DL models, the top-performing model, i.e., Transformer, demands the most computing resources with 1.0644 (G) MAC operations, yet only comprises 0.9107 (M) parameters. This is attributed to Transformer's self-attention mechanism. which reduces model parameters while amplifying processing complexity. Indeed, the significance of the self-attention mechanism lies in its ability to enable the Transformer model to efficiently utilize the spatial-temporal features, correlations, and dependencies within the integrated spatial-temporal demanding data and relevant parking data. By attending to relevant features across different time steps and parking cluster zones, the Transformer model can capture complex relationships and dependencies, ultimately enhancing its predictive capability. Concerning this, it is worth noting that unlike in [16], where NLinear outperformed Transformer, in this study, Transformer surpassed NLinear due to its efficient utilization of spatial-temporal features and correlations, while NLinear lacks in the spatial aspect.

E. Ablation Study

To investigate the effect of the proposed integrated demand features on the model prediction results, ablation experiments were conducted regarding the utilization of features and regarding different prediction steps. There are four settings for the feature utilization, 1) all the features, i.e., integrated spatial-temporal demanding data and the historical data of all the parking lots within the parking cluster zones; 2) integrated spatial-temporal demanding data plus only the historical data of the target parking lot; 3) only the historical data of all the parking lots within the parking cluster zones without integrated spatial-temporal demanding data; 4) only the historical data of the target parking lot.

Table II summarizes the prediction results of the top 2 models, i.e., NLiner and Transformer, under different feature settings. A comparison between feature settings 1 and 2 indicates that including historical information of similar parking lots within the parking cluster zone enhances the accuracy of parking availability prediction for the target parking lot. Moreover, comparing the results of setting 1 versus 3 and setting 2 versus 4, highlights the significant improvement in prediction accuracy when incorporating the designed integrated spatial-temporal demand feature. Additionally, comparing the results of settings 3 versus 4

suggests that when using only the historical data from the parking lots, it is wise to utilize only the historical data of the target parking lot. Further examination is needed to understand why adding historical information from similar parking lots within the parking cluster zone without adding the integrated demand feature worsens the prediction under this setting. Overall, the integration of multi-source heterogeneous demand data significantly contributes to parking availability forecasting.

To evaluate the model performance for different prediction steps, Fig. 5 displays the prediction results of various algorithms validated on the test dataset with different time step settings. Traditional ensemble ML models (RF and XGboost), as well as classical RNN models (GRU and LSTM), suffer from error accumulation with increasing prediction time steps, leading to diminished performance in long time series prediction. Conversely, the Transformer and NLinear models demonstrate proficiency in learning long-term dependencies, enabling them to perform well for both short and long-term step prediction.

TABLE II. PREDICTION RESULTS OF DIFFERENT FEATURE SETTINGS

Features	NLi	near	Transformer		
settings	MSE	MAE	MSE	MAE	
1	0.0713	0.1597	0.0626	0.1358	
2	0.0764	0.1435	0.0832	0.1581	
3	0.1808	0.2624	0.1697	0.2304	
4	0.1647	0.2447	0.1452	0.1785

IV. CONCLUSION

In the era of rapid urbanization, resolving parking issues is critical to alleviating urban traffic congestion and improving traffic operation efficiency. With the booming Internet of Things (IoT), Information and Communications Technology (ICT), as well as Artificial Intelligence (AI) technologies, it is possible to develop parking availability prediction systems. Although there are existing studies that have considered different machine learning (ML) and deep learning (DL) models for parking prediction, most of these studies are based on ineffective feature design with only ego parking lots data, which fails to capture effective spatial-temporal influencing factors. To address the gap and to improve the prediction accuracy of urban parking availability, this study designs a pipeline that integrates spatial-temporal Transformer-based deep learning with integrated spatial-temporal demanding data fused from multi-sources (i.e., metro, bus, online ride-hailing, and taxi services data, as well as parking lot data). The proposed method leverages K-means clustering to establish parking cluster zones grouping relevant parking lots together and extracting and integrating traffic demand characteristics from various transportation modes within the target parking cluster zone. Real-world empirical data was employed to verify the effectiveness of the proposed method.

Through extensive experiments, the performance of various traditional statistical models (HA, ARIMA), ML models (DT, SVR), ensemble learning models (RF, XGBoost), and DL models (GRU, LSTM, Nlinear, Transformer) on parking availability prediction is evaluated. The results demonstrate that DL algorithms significantly outperform traditional ML algorithms and statistical methods. More specifically, the Transformer-based model customized in this study achieved the highest performance, yielding the lowest Mean Squared Error (MSE), Mean Absolute Error (MAE), and Mean Absolute Percentage Error (MAPE). The ablation study regarding different feature utilization settings demonstrates the efficacy of the proposed integrated spatial-temporal demanding feature and the utilization of the designed parking cluster zone to group similar parking lots together. Furthermore, the ablation study regarding different prediction steps verifies the proficiency of Transformer and NLinear models in learning long-term dependencies for delivering good performance in both short and long-term step prediction. This study can improve parking prediction systems, offering more accurate information to drivers and urban planners, thus enhancing urban mobility efficiency and sustainability.
