ABSTRACT

Context. The Pyramid Wavefront Sensor (PyWFS) provides with the needed sensitivity for demanding future adaptive optics (AO) instruments. However, the PyWFS is highly nonlinear and requires the use of beam modulation to successfully close an AO loop under varying atmospheric turbulence conditions, at the expense of a loss in sensitivity.

Aims. This work aims to train, analyse, and compare the use of deep neural networks (NNs) as non-linear estimators for the nonmodulated PyWFS, identifying the most suitable NN architecture for reliable closed-loop AO.

Methods. We develop a novel training strategy for NNs that seeks to accommodate for changes in residual statistics between open and closed-loop, plus the addition of noise for robustness purposes. Through simulations, we test and compare several deep NNs, from classical to new convolutional neural networks (CNNs), plus a state-of-the-art transformer neural network (TNN, Global Context Visual Transformer, GCViT), first in open-loop and then in closed-loop. By identifying and properly retraining the most adequate deep neural net, we test its simulated performance first in open-loop and then for closing an AO loop at a variety of noise and turbulence conditions. We finally test the trained NN ability to close a real AO loop for an optical bench.

Results. Using open-loop simulated data, we observe that a TNN (GCViT) largely surpasses any CNN in estimation accuracy in a wide range of turbulence conditions. Moreover, the TNN performs better in simulated closed-loop than CNNs, avoiding estimation issues at the pupil borders. When closing the loop at strong turbulence and low noise, the TNN using non-modulated PyWFS data is able to close the loop similar to a PyWFS with $12\lambda/D$ of modulation. When raising the noise only the TNN is able to close the loop, while the standard linear reconstructor would fail, even when introducing modulation. Using the GCViT, we close a real AO loop in the optical bench achieving a Strehl ratio between 0.28 and 0.77 for turbulence conditions ranging from 6cm to 20cm, respectively. Conclusions. Through a variety of simulated and experimental results, we demonstrate that a Transformer Neural Network is the most suitable architecture to extend the dynamic range without sacrificing sensitivity for a non-modulated PyWFS. It opens the path for using non-modulated Pyramid WFSs under an unprecedented range of atmospheric and noise conditions.

Key words. Adaptive Optics – Wavefront Sensing – Pyramid Wavefront Sensor – Deep Learning – Neural Networks

I. Introduction

The world will see the arrival of Extremely Large Telescopes (ELTs)-with primary mirrors larger than 25 meters of diameter-within the next ten years. However, atmospheric turbulence affects light propagation, acting as a dynamic phase mask that introduces aberrations to the optical path, finally diminishing the ability of current large telescopes, as well as future ELTs, to properly focus light at the diffraction limit. Adaptive Optics (AO, Roddier 1999) can assist modern telescopes to overcome atmospheric turbulence, firstly by measuring/estimating the wavefront fluctuations coming from reference sources, and then optically compensating for the aberrations before reaching the science instruments. Over the past 25-years, AO has revolutionized astronomy by providing the highest achievable image quality for ground-based observatories, becoming a fundamental component in the upcoming ELTs from first light (Hippler 2019).

Wavefront sensors (WFSs) are the core of modern AO systems. Basically, a WFS needs to perform measurements, quickly enough (often within a millisecond), to infer the dynamic phase aberrations present in the wavefront passing through the atmosphere on its way to the telescope. Thus, an AO loop can use

a deformable mirror to compensate for the atmospheric turbulence in real-time. Within the known WFSs, the Pyramid Wavefront Sensor (PyWFS, Ragazzoni 1996) exhibits relevant performance advantages-e.g. high sensitivity, large spatial frequencies and less noise propagation (Fauvarque et al. 2016; Chambouleyron, V. et al. 2023)-reasons why it has been successfully implemented in current large telescopes (LBT, Esposito et al. 2010, Subaru, Guyon et al. 2020, and Keck, Mawet et al. 2022) and it is being considered for the next generation ELT instruments (HARMONI, Neichel et al. 2022 and MICADO, Clénet et al. 2022).

The PyWFS places the apex of a pyramidal 4-sided prism at the PSF plane (focal plane) of the incoming wavefront, finally reimaging 4 different version of the pupil projected onto a detector array. Then, the slopes of the wavefront can be easily estimated from the measured image, although the PyWFS finally offers a very limited dynamic range where its response is still linear (Vérinaud 2004; Burvall et al. 2006), despite its superb sensitivity. In practical scenarios, and as suggested in the seminal work done by Ragazzoni (1996), the inherent non-linearity of the Py-WFS can be counteracted by circularly modulating the incoming beam over the apex of the pyramid, which homogenize the illumination of the four sides of the prism. Although the linearity is improved, beam modulation comes with a detrimental effect on the sensitivity, plus the need for additional fast and expensive optomechanical elements. The non-linearity of the PyWFS becomes evident when using linear matrix-based reconstruction models (Korkiakoski et al. 2007). Despite there are several efforts in the literature to use non-linear least-squares methods– which are often iterative–such as in Frazin (2018); Shatokhina et al. (2020); Hutterer et al. (2023), there are also alternative approaches that exploit the compensation of the optical gains (OG) based on the turbulence statistics (Deo, V. et al. 2019; Chambouleyron, V. et al. 2020). Nevertheless, OG compensation is actually only a first order approximation of the non-linearities (Deo, V. et al. 2019), being particularly hard to handle for the non-modulated PyWFS case.

Nowadays, neural networks (NNs), and more particularly deep neural networks-that make use of a larger amount of hidden layers and intricate interconnections, are a great asset to solve a variety of hard, non-linear problems in imaging such as detection, classification and inference (LeCun et al. 2015). This is no different for WFSs, where in Nishizaki et al. (2019) they demonstrated that any imaging system can be turned into an image-based WFS by appropriately training a convolutional neural network (CNN) to infer the incoming wavefront Zernike modal approximation. Since then, deep learning has been applied to improve the estimation performance of focalplane WFSs (Orban de Xivry et al. 2021), Shack-Hartmann WFSs (DuBose et al. 2020), phase diversity-based WFSs (Andersen et al. 2020), Lyot-based WFSs (Allan et al. 2020), and also the PyWFS (Landman & Haffert 2020), where they use a CNN jointly with the linear estimator to improve the PyWFS linearity. Recently, Wong et al. (2023) demonstrated the ability of a three-layer fully connected neural network to estimate loworder modes from a PyWFS with and without modulation, while Archinuk et al. (2023) used a simple CNN to estimate the first 400 modes from the non-modulated PyWFS. Since AO is a two stage process-wavefront sensing and wavefront control-we can also use deep NNs not only to improve the accuracy of the wavefront estimation of the WFS, but also the performance of the closed-loop AO system, as proposed in Nousiainen et al. (2021) and Pou et al. (2022), where they use reinforcement learning.

Most of the deep learning WFSs have been adapting conventional deep neural nets originally developed for computer vision applications, such as Xception (Chollet 2017), VGG-Net (Simonyan & Zisserman 2014), or ResNet (He et al. 2016), while in Vera et al. (2021) the authors crafted an original deep neural net (WFNET) for image-based WFSs. Nevertheless, there is a new generation of CNNs-ConvNeXt and ConvNeXt v2 (Liu et al. 2022; Woo et al. 2023)-that are delivering impressive performance in classification tasks. Moreover, there is a new class of deep neural nets, called Transformers Neural Networks (TNN), that are overcoming the performance of classical CNNs for a variety of vision applications, being the Visual Transformer ViT (Dosovitskiy et al. 2020), and the Global Context Visual Transformer GCViT (Hatamizadeh et al. 2022), the current state-ofthe-art. Instead of convolutions, TNNs such as the GCViT can find correlations between image patches and their influence on the target outputs. Nevertheless, the main disadvantage of most modern CNNs and TNNs is that they often require massive amount of data for training, although they can be efficiently retrained without requiring to start from scratch.

We believe that a good wavefront estimator/reconstructor will necessarily lead to a good AO performance. Therefore, this work aims to study and analyse the use of deep neural nets as a non-linear estimator for the non-modulated PyWFS, enabling reliable open-loop and closed-loop adaptive optics performance. For that, we will test and compare the ability of several conventional and newest neural network architectures to handle the Py-WFS non-linearity, developing appropriate training strategies to accommodate for changes in residual statistics between open and closed-loop. By choosing and properly training the most adequate deep neural net for the task, we believe we can demonstrate the ability to extend the dynamic range of the non-modulated PyWFS without sacrificing sensitivity, enabling closed-loop operations at a variety of noise and turbulence conditions without requiring beam modulation anymore.

2. Methodology

In this section we describe the methods used for: (1) the simulation of the PyWFS forward model under a variety of turbulence and noise conditions, (2) the training of the deep neural networks using open-loop data, (3) the retraining strategy for closed-loop scenarios, (4) the metrics to quantifying the performance of the different NN estimators, and (5) the configuration of the experimental setup.

2.1. Simulation framework

We use the OOMAO toolbox (Conan & Correia 2014), written in Matlab, to generate the incoming aberrated wavefronts and simulate the propagation through the PyWFS up to the detector plane. The phase map dataset is generated with a spatial resolution of 268 × 268 pixels for a 1.5m aperture telescope working at $\lambda = 550nm$ with an r_0 distribution ranging from 1cm to 20cm (distributed in discrete steps of 2cm after 2cm), leading to an effective D/r_0 range between 7.5 and 150. It is important to note that as D/r0 increases, the turbulence becomes stronger. For every phase map, we retrieve the first 209 Zernike coefficients, ignoring piston, which are considered as the groundtruth for estimation purposes. After propagating each phase map for an incoming Magnitude 0 light source in the V-band using OOMAO, we store the intensity image I projected on the WFS detector of size 268×268 pixels with an exposure time of 1 sec without considering noise. The diameter of each subpupil at the simulated WFS detector span 68 pixels. In total, the open-loop phase map dataset is comprised of 210,000 uncorrelated samples (phase map, Zernikes and PyWFS image) obtained from random turbulence realizations given the selected D/r_0 level.

Additionally, we also simulated phase map sequences (using two layers moving at 5 and 10m/s sampled at 250Hz) of 1,000 samples for different turbulence strengths and several levels of modulation for the PyWFS, at $0\lambda/D$ (non-modulated), $3\lambda/D$, $5\lambda/D$, and $12\lambda/D$. These sequences are aimed for closed-loop testing.

2.2. Magnitude and noise

We added noise to the intensity image I on demand as required either by the training or testing stage. By fixing the telescope size to 1.5m, we first scale the image to a proportional photon flux depending on the magnitude of the star (Mag) and the exposure time (T_e) such that

$$\mathbf{I}_{ref} = \mathbf{I} \cdot 10^{-0.4 \cdot \mathrm{Mag}} \cdot T_e. \tag{1}$$

Then, we apply Poisson noise to the scaled measurement I_{ref} leading to the noisy image I_{noise} , enabling the calculation of the

effective signal-to-noise ratio (SNR) defined as

$$SNR = \frac{\sigma(I_{ref})}{\sigma(I_{ref} - I_{noise})}.$$
(2)

Figure 1 displays the example of three images measured by the PyWFS for different star magnitudes at a fixed exposure time, with the respective associated SNR. We can observe a clear degradation of the image as the photon flux diminishes. Before being used with the linear or NN estimators, the noisy PyWFS measurement is always normalized. Throughout the article, we only refer to the SNR level of the measurements when dealing with noise.

Fig. 1. Non-modulated PyWFS measurement for different star magnitudes at a fixed exposure leading to different effective SNR levels.

2.3. Neural network training

We selected four deep neural network architectures as non-linear estimators for the non-modulated PyWFS. Xception (Nishizaki et al. 2019), WFNet (Vera et al. 2021), ConvNext (Liu et al. 2022), and GCVit (Hatamizadeh et al. 2022), are implemented in PyTorch and adapted to perform regression at the last layer to provide simultaneous estimations for the first 209 Zernike modes (without piston).

Since all implemented NNs accept the same input image size from the PyWFS and deliver estimates of the Zernike coefficients with same number of coefficients as well, then all NNs are trained and tested with the exact same portions of the simulated dataset, which is divided into 75% for training and 25% for testing. All training sessions were performed in PyTorch by using 8 NVIDIA Quadro RTX5000 GPUs. From several preliminary tests on the NNs, we realized that the choice of a proper range of values for the learning rate and a suitable loss function heavily depend on the strength and amount of Zernikes modes to be estimated, which are also related to the turbulence strength. A loss function is an error metric that is computed between the estimated output values of the NN (in this case a vector of Zernike coefficients \hat{z}) and the vector of ground-truth values (z) used for training. The most common loss functions are the mean square error (MSE) and the mean absolute error (MAE), defined as

MSE =
$$\frac{1}{N} \sum_{N} (z - \hat{z})^2$$
 and MAE = $\frac{1}{N} \sum_{N} |z - \hat{z}|$, (3)

where *N* is the number of coefficients. On the other hand, the learning rate is the weight given to the calculated loss function that is back-propagated to update the NN hidden parameters at every training iteration. For instance, mixing a large learning rate (larger than 10^{-5}) with the MAE loss function allows a correct training of low-order, high-amplitude Zernikes modes. In contrast, mixing a small learning rate ($\approx 10^{-6}$ or less) with

the MSE improves the training of high-order, low-amplitude Zernikes modes.

Therefore, we generated a two-step training strategy for open-loop wavefronts, creating two training datasets with different distributions for the Zernike modes, as seen in Figure 2. The first training uses a limited dataset with the range between $D/r_0 = 25$ and 150, a starting learning rate of 10^{-5} , and MAE as the loss, which emphasizes a boost in the linearity response of the non-modulated PyWFS. Then, in the second stage we retrain the NNs using the whole dataset from $D/r_0 = 7.5$ to 150, a starting learning rate of 10^{-6} , and MSE as the loss, which plays a significant role in preserving the sensitivity of the PyWFS.

Fig. 2. Amplitude distribution for selected Zernike modes for two turbulence training regimes. Full range of $7.5 > D/r_0 > 150$ on the top and high range of $25 > D/r_0 > 150$ on the bottom.

2.4. Closed-loop training

After training the NNs to properly estimate the output from a non-modulated pyramid for a variety of turbulence conditions in open loop, we devise a retraining strategy to prepare for the statistics of the residuals in closed-loop. We propose a two-step approach as depicted in Figure 3. In the first step, we input a phase map from the dataset to the PyWFS and estimate the Zernike coefficients from the chosen NN architecture. Then, we reconstruct the estimated phase out from the Zernike coefficients and compute the phase residual by plain subtraction. In the second step, we input the phase residual to the PyWFS and estimate a new set of Zernike coefficients using the NN. Now we calculate the loss function MAE for the estimated residual coefficients, and update the parameters of the NN with a learning rate of 10^{-6} .

This novel training approach for closed-loop measurements allows to use the simulated wavefronts in the dataset independently, without worrying if they are correlated or not in time. The proposed scheme serves as an effective data augmentation approach, which leads to a higher diversity in the statistics provided for the NN models.

Fig. 3. Neural network closed-loop training strategy. The first stage uses the estimation by the NN from open loop data to compute a residual phase which is used as the input for the second stage. The Zernike coefficients of the residual are used as the ground-truth to compute the loss function used to retrain the NN.

In our initial training using closed-loop data we consider an ideal noiseless case. Nonetheless, when we have to prepare a NN for more realistic scenario, we retrain the NN by randomly selecting a SNR level for the PyWFS measurement (between SNR=0.7 and SNR=7), which tends to improve the robustness of the trained NNs (Bishop 1995).

2.5. Performance metrics

For comparing the open-loop wavefront estimation accuracy between the different NNs in simulations, we use the Root Mean Square Error (RMSE) of the predicted Zernike coefficients as follows,

$$\mathbf{RMSE} = \sqrt{\frac{1}{N} \sum (z - \hat{z})^2},\tag{4}$$

where z corresponds to the ground truth Zernike coefficients extracted from the incoming wavefront ϕi , \hat{z} are the Zernike coefficients estimated by the NN, and N is the number of Zernike coefficients.

When we switch to closed-loop in simulations, we analyze the standard deviation of the phase map residual σ_{ϕ} . The residual is computed by the difference between the incoming phase ϕ_i and the corresponding update given by the last reconstruction from the last estimated Zernike coefficients.

Also, for the experimental validation, we analyze the system performance by computing the Strehl ratio (SR) given by the ratio between the maximum value of the reconstructed PSF and the maximum value of the equivalent diffraction limited PSF.

2.6. Experimental AO bench

We use the PULPOS AO bench (Tapia et al. 2022) to validate the performance of the PyWFS + GCVIT in closed-loop. The particular branch of PULPOS used to close the AO loop with a PyWFS is shown in Fig. 4. We use a $\lambda = 635nm$ fibercoupled laser source (Thorlabs S1FC635) attached to an airspaced doublet collimator (Thorlabs F810APC-635) and a beam expander (Thorlabs GBE02-A). After a 5 mm diameter aperture

stop (P), the beam passes through a 4f-system with 1X magnification (L1 and L2) before reaching the reflective high-speed spatial light modulator (SLM, Meadowlark HSP1920-488-800-HSP8, 1920×1152 pixels, $9.2 \mu m$ pixel size), where phase maps of 560×560 pixels are projected to emulate the desired turbulence, matching the pupil size relayed at the SLM. Then, a beamsplitter (BS1) redirects the aberrated wavefront through a 0.75X magnification 4f-system (L3 and L4), reaching the L5 lens (400 mm) that focus the beam on the PSF plane where the apex of a zeonex pyramid is located. Then, the L6 lens (200 mm) collimates the four sub-pupils emerging from the pyramid, projected onto a high-speed CMOS camera (Emergent Vision HR-500-S-M, $9\mu m$ pixel size, 1586 fps, 812×620 pixels). The WFS images are cropped at 620×620 pixels, where each of the subpixels span a diameter of 110 pixels. These images are resized to match the subpixel diameter of the pupils used in the simulations before entering the NN estimation. In parallel, we record the PSF that is imaged by a 125mm lens onto the science camera (SC, Emergent Vision HR-500-S-M, 9μ m pixel size), where we extract the Strehl ratio. The SLM and cameras are controlled by a desktop computer loaded with a RTX4000 GPU.

Fig. 4. Schematic of the experimental AO setup using PULPOS to test the PyWFS in open- and closed-loop.

3. Results

In this section, we start by going through the results obtained in open- and closed-loop using simulations of the non-modulated PyWFS estimated with a variety of deep NN options. Then, these results drove the decision of selecting the best performing NN architecture, which is used in the final experimental validation using PULPOS in open- and closed-loop as well.

3.1. Neural network comparison

In our initial test results, we evaluated the performance of several deep NNs trained with identical parameters utilizing the entire dataset range ($r_0 = [1 \rightarrow 20]$ cm). The chosen NNs are three CNNs, Xception, WFNet, and ConvNext, plus one TNN, GCViT. In particular, we trained the lightweight version of the GCViT, which is the GCViT–xxtiny.

In Table 1, we present a summary of the number of parameters, the estimation speed-for the same training computer machine using a single GPU card-and the estimation performance (average fitting error per mode) from noiseless measurements of every tested NN architecture. The number of parameters refers to the number of interconnections (weights) inside each NN, which depends on the number of layers and neurons of each architecture and has great correlation to the size of the NN stored in the GPU memory. However, every architecture has its own intricacies and choice for the number of hidden layers and the inner operators such as linear convolutions and neuron non-linearities that finally affect in different manner the speed of calculus of each NN.

Table 1. Comparison of deep neural networks used for WFS in terms of the number of parameters (# Params), inference speed (Speed), and estimation error (Error). The best result is highlighted within each column.

| NN | # Params (10 ⁶) | Speed (ms) | Error (nm) |
|--------------|-----------------------------|------------|------------------|
| Xception | 22 | 1 | 32.5 ± 7.0 |
| WFNet | 152 | 0.37 | 286.8 ± 28.3 |
| ConvNext | 88 | 1.13 | 102.5 ± 16.3 |
| GCVit-xxtiny | 12 | 1.56 | 25.0 ± 7.2 |

From the results, it is evident that the GCViT achieves the best average performance, meaning that it is able to provide with good estimates in the whole turbulence range. A slightly worse performance is surprisingly achieved by the Xception, despite being an older CNN in contrast with the newer ConvNext. The worst performance was achieved by the WFNet, maybe related to the fact that it was originally developed for undersampled image-based WFS. Interestingly, we can also observe that the error was somehow proportional to the number of parameters of the NNs. Nevertheless, the GCViT seems to be the slowest, despite having fewer parameters. One possible explanation for this is the fact of being a way more intricate and complicated architecture.

To select the most promising NN candidate for real AO applications, we test the best two performing NNs in closed-loop, the Xception as the CNN candidate and the GCViT as the TNN one. We performed the close loop test under a "frozen" turbulence condition–static phase map at the input–and no noise (SNR= ∞) to analyze their estimation and compensation behavior in ideal conditions. Closed loop results for a turbulence of $D/r_0 = 75$ are depicted in Figure 5, where we can observe that both NNs quickly reduce the residual within a few frames. Nevertheless, at some point the CNN tends to diverge as the TNN approaches the ideal residual value for the estimation of 209 Zernike modes. This problem for the the CNN in closed loop is clearly seen after inspecting the residual phase map, where significant aberrations start to appear at the borders, most likely created by a deficient estimation of the high order modes by the CNN.

We believe this behavior of the CNN must be due to the convolutional nature of the CNN, which may complicate the handling of the phase at the sharp pupil borders. On the other hand, the TNN can identify the portions within the image that are informative, which may explain its superior performance, delivering a spatially homogeneous residual phase map. As a side note, please be aware that it is impossible to close the loop using a linear estimator for the non-modulated PyWFS at this turbulence level.

3.2. Noise response

Once we decided that the GCViT is the most suitable NN architecture for closing the loop with a non-modulated PywFS, we retrained the GCViT with different levels of photon noise equivalent to a range of SNR between 0.7 and 7, randomly applied to the measurements. We compare the GCViT estimation with the

Fig. 5. Closed loop performance in simulations using a constant input phase with two neural networks, a CNN (Xception) and a TNN (GCViT). Top: last frame of the closed-loop residual phase map. Bottom: Evolution of the residual standard deviation, comparing the CNN, TNN and the optimal estimation of 209 Zernike modes.

linear estimation of the non-modulated PyWFS for a turbulence range between $D/r_0 = 7.5$ and $D/r_0 = 150$ in open-loop. Performance results for measurements taken with two noise levels– low noise (SNR=7) and high noise (SNR=0.7)–are presented in Fig. 6. The first observation is that the linear estimation for the non-modulated PyWFS is extremely immune to noise, given its high sensitivity, so the two plots are merged into one.

Fig. 6. Open loop performance comparison in similations for the linear least-squares estimation and the GCViT estimation for a non-modulated PyWFS at different SNR.

For a high SNR, the GCViT is vastly superior to the linear estimation in the whole turbulence range, clearly improving the linearity of the PyWFS response, particularly within the $D/r_0 = 20 - 60$ range. Although the GCViT estimations are still better than the traditional linear estimation for the PyWFS under low SNR conditions for most of the turbulence range, the linearity advantages are not as high as in the high SNR case. Nevertheless, the estimation for the GCViT can become slightly worse than the linear estimation for the PyWFS for very weak turbulence at $D/r_0 = 7.5$.

3.3. Closed-loop performance

We test the performance of the GCViT trained with noise when closing an AO loop using the non-modulated PyWFS. We compare the closed-loop performance against the PyWFS working at different modulations of $3\lambda/D$, $5\lambda/D$, and $12\lambda/D$, using the traditional linear least-squares estimator. We choose to close the AO loop at weak turbulence conditions of $D/r_0 = 15$ as well as at the worst trained turbulence conditions of $D/r_0 = 150$, where it is impossible to close the loop with the non-modulated PyWFS using linear estimation. In Figure 7 we present the results when closing the AO loop for three different SNR levels: 9.04, 1.41, and 0.57. Note that the lowest SNR level is beyond the training regime used for the GCViT.

The AO loop is closed at the 100th frame. For the strong turbulence case (shown at the top row) we can observe that for a high SNR, all the WFSs are able to close the loop and reach a stable but different residual levels, being the GCViT and the Py-WFS at $12\lambda/D$ using linear estimation the best performing, indicating that they may share an equivalent linear response at that turbulence regime, as corroborated by the very similar residual shape for the very last frame. As the SNR decreases, only the GCViT is able to keep up a similar level of residual as obtained in high SNR conditions, while the PyWFS using linear estimation at different modulations is not successful in closing the loop. Only at the very lowest SNR level, the GCViT shows some slight difficulties for maintaining the expected residual levels achieved for higher SNRs, but without loosing the ability of closing the loop at all. By being able to close the loop at this extreme turbulence regime even at high noise levels, it seems that by using the non-modulated PyWFS measurements the GCViT is able to keep some of the inherent high sensitivity while still dramatically increasing the linearity. The bottom row of Figure 7 reveals the results for a weak turbulence regime, where the GCViT shows a similar behavior, perhaps slightly worse in terms of residual, successfully closing the AO loop as all the modulated PyWFS versions for the high SNR scenario. However, as the SNR is decreased, we can easily note the loss of sensitivity for the PyWFS as modulation is increased at $12\lambda/D$, while the GCViT is able to maintain a stable residual in between of the PyWFS at $3\lambda/D$ and $5\lambda/D$ of modulation for the lowest SNR case.

3.4. Experimental validation

We use the PULPOS (Tapia et al. 2022) AO bench to obtain measurements from the non-modulated PyWFS under controlled, arbitrary phase maps projected onto the SLM display. We start by calibrating the PyWFS and obtaining the interaction matrix by projecting the first pure 209 Zernike modes (without piston) in push and pull using an amplitude of 0.5λ . As a first part of the experimental validation, we test the PyWFS using the same open-loop dataset used in the simulations, although only for $r_0 = [6 \rightarrow 20]$ cm, which are the conditions found at the 1.5m telescope at the Observatoire de Haute-Provence (OHP) that is currently running PAPYRUS (Muslimov et al. 2021): an adaptive optics instrument based on a PyWFS. We present the performance results for the classical linear estimation method and the GCViT in Figure 8, comparing both the use of simulated measurements and the experimental PyWFS data obtained at PULPOS. Please note that the GCViT has solely be trained using simulated data.

We can notice from the plots in Fig. 8 that the GCViT estimation using experimental data vastly outperforms the classical least-squares estimation, as predicted by the simulations. Despite some general offset in both cases, the experimental estimations follow the overall trend and standard deviation obtained when using the simulated measurements. The linearity offered by the GCViT estimations using the non-modulated PywFS are superior to what is being offered by the linear estimation methods. On top of that, we may even consider that the sensitivity offered by the GCViT is also better, considering the superior performance at low turbulence levels and that measurements are noisy since the CMOS camera being used for the PyWFS is not a scientificgrade camera.

As the second part of the experimental validation, we use the trained GCViT to close an AO loop using PULPOS with the non-modulated PyWFS. We estimate the 209 Zernike modes on-the-fly using a NVIDIA RTX4000 GPU. As a deformable mirror, we use the same SLM where we project the aberrated turbulence phase maps in open loop, now displaying the compensated phase maps given by the chosen control law applied to the estimations provided by the GCViT. Although the simulated phase map sequence used for closed-loop is sampled at 250Hz, we close the AO loop in PULPOS at 10Hz, as we are working on a realtime control upgrade. We choose to close the loop at three representative turbulence conditions with r_0 at 6, 10, and 20 cms, equivalent to a D/r_0 of 25, 15, and 7.5 at OHP, respectively. Results displaying the evolution of the Strehl ratio-computed from the instantaneous PSFs captured by the scientific camera in PULPOS-for different turbulence conditions are shown at the top of Figure 9, where we close the loop at the 100th frame. We can clearly observe that by using the GCViT we are able to close the AO loop in all situations, and that the loop is stable. As a side note, we can hardly close the loop at $D/r_0 = 7.5$ when using linear estimation with the non-modulated pyramid in the AO bench, explaining why these results are not even presented here.

We display at the bottom of Fig. 9 the PSFs and respective central horizontal line profiles, integrated between frames 100 and 300, as obtained by the GCViT in closed-loop for different turbulence conditions, corresponding to an average SR of 0.28, 0.56, and 0.77 for an r_o of 6cm, 10*cm*, and 20cm, respectively.

4. Conclusions

In this work we presented a comparative analysis of using deep neural networks as non-linear estimators for the non-modulated PyWFS. We trained, tested and compared several conventional and state-of-the-art neural network architectures to handle the PyWFS non-linearity, where Convolutional Neural Networks have been the widest used architecture for WFS applications, so far. We developed a novel training strategy that combines the use of open and closed-loop data, as well as the addition of noise for robustness purposes. Through simulations, we have found that a state-of-the-art Transformer Neural Network, in this case the GCViT, is the most suitable NN architecture for closed-loop AO operation, avoiding systematic phase estimation problems at the pupil borders caused by the convolutional nature of CNNs.

When testing in open-loop, the GCViT is able to dramatically extend the dynamic range of the non-modulated PyWFS in contrast with the traditional linear estimation methods at a variety of noise conditions, although there is a clear loss in performance at very high noise levels. However, when testing in a simulated AO scenario at the worst turbulence conditions, we have found that the GCViT is able to close a stable AO loop similar to a modulated PyWFS at $12\lambda/D$ at a high SNR level. Moreover, the GCViT showed to be very robust to noise, since it was the only estimator able to reliably close the AO loop for mid to low SNRs for strong turbulence conditions. When deal-

Fig. 7. (Movie online) Closed loop residual phase evolution using simulated data at $D/r_0 = 150$ (top column) and $D/r_0 = 15$ (bottom row), comparing the linear least-squares estimation for the PyWFS at different modulation levels (M=3,5 and $12\lambda/D$) against the GCViT estimation for the non-modulated PyWFS (M=0). The AO loop is closed at frame 100 using a proportional controller with gain k = 0.5. From left to right: results for different SNR levels. At the top of each plot: residual phase for the different estimation methods at frame 250.

ing with weak turbulence, the GCViT was able to close the loop for the whole range of SNR, with a performance similar to the PyWFS with $5\lambda/D$ of modulation. These results were experimentally validated in the PULPOS AO bench, where the GCViT was able to consistently close the AO loop for turbulence ranging from 6cm to 20cm, achieving an integrated Strehl ratio at the scientific camera between 0.28 and 0.77, respectively.

In conclusion, we demonstrated that a TNN such as the GCViT can be properly trained and become suitable as a nonlinear estimator for a non-modulated PyWFS. By dramatically extending the dynamic range of the non-modulated PyWFS without sacrificing sensitivity, the GCViT can be used in real AO scenarios, being robust to noise and varying turbulence conditions, paving the way for further testing in real observing conditions, which is out of the scope for this work. The fact that the proposed NN has been trained entirely offline is interesting. The

Top: Evolution of the strehl ratio for different turbulence conditions. Bottom: Integrated PSFs in closed-loop (PSF_{CL}) with their respective horizontal line profiles.

presented experimental results showed that the trained TNN actually possesses a certain degree of flexibility to accommodate for statistical variations. Nevertheless, we believe that retraining using real data may be necessary in some cases, which will be validated through on-sky experiments at OHP using the PA-PYRUS instrument (Chambouleyron et al. 2022), scheduled for mid 2024. As prospective work, we can mention that the results obtained at $D/r_0 = 150$ are very encouraging to scale and extend our research towards ELTs-meaning orders-of-magnitude more Zernike modes and larger D/r_0 turbulence ranges-which can also benefit from the design and use of modern optical preconditioners (Guzmán et al. 2024) to improve even further the dynamic range of the non-modulated PyWFS. Moreover, we may extend our work to detect differential piston modes between the ELT segments (petal modes) using the non-modulated pyramid (Levraud et al. 2022), while also adapting the GCViT for improving the wavefront estimation performance of an even more sensitive WFS such as the Zernike WFS (Cisse et al. 2022).
