A Rate-Distortion Analysis for Composite Sources Under Subsource-Dependent Fidelity Criteria

Jiakun Liu, *Graduate Student Member, IEEE*, H. Vincent Poor, *Life Fellow, IEEE*, lickho Song, *Fellow, IEEE*, and Wenyi Zhang, *Senior Member, IEEE*

Abstract—A composite source, consisting of multiple subsources and a memoryless switch, outputs one symbol at a time from the subsource selected by the switch. If some data should be encoded more accurately than other data from an information source, the composite source model is suitable because in this model different distortion constraints can be put on the subsources. In this context, we propose subsource-dependent fidelity criteria for composite sources and use them to formulate a rate-distortion problem. We solve the problem and obtain a singleletter expression for the rate-distortion function. Further rate-distortion analysis characterizes the performance of classify-then-compress (CTC) coding, which is frequently used in practice when subsource-dependent fidelity criteria are considered. Our analysis shows that CTC coding generally has performance loss relative to optimal coding, even if the classification is perfect. We also identify the cause of the performance loss, that is, class labels have to be reproduced in CTC coding. Last but not least, we show that the performance loss is negligible for asymptotically small distortion if CTC coding is appropriately designed and some mild conditions are satisfied.

Index Terms—Composite source, fidelity criterion, image processing, label-based code, quantization, rate distortion theory, source coding, speech processing.

I. Introduction

T is a common practice in rate-distortion (RD) theory [1]–[5] to model an information source as a stochastic process $\{X_i\}_{i=1}^{\infty}$. Each random variable X_i is called a source symbol or just a symbol. Symbols of many real-world sources can be naturally divided into a few classes. For example, a pixel in a digital image may be in the foreground or background [6], and a sample in a piece of speech signal may belong to a voiced

Fig. 1. A composite source with L subsources.

phoneme, an unvoiced phoneme, or a period of silence [7]. Symbols in different classes usually have different statistical characteristics and are produced by different physical mechanisms. Thus, it is not unreasonable to think of them as being produced by different subsources, as done in the composite source model (see, for example, [3, Section 6.1]). Besides the subsources, a composite source contains a conceptual switch, whose position may vary with time. As shown in Fig. 1, the source outputs a symbol produced by Subsource S, which is selected by the switch. We refer to S as the state of the composite source. A composite source is modeled as a stochastic process $\{(S_i, X_i)\}_{i=1}^{\infty}$ of state-symbol pairs, where $\{S_i\}_{i=1}^{\infty}$ take values in a common finite set, say $\{1, 2, \dots, L\}$.

In lossy compression of composite sources, we may wish to reproduce the symbols from some subsources more accurately than the symbols from other subsources. For example, an obscure foreground has a larger impact on the quality of an image than an obscure background does. Thus, the distortion constraint on the background can be loosened when we have to compress the image into fewer bits. Similarly, a sample of an unvoiced phoneme is more important than a sample of a silence period, and therefore the fidelity of the former sample should be guaranteed first in low-rate coding of speech. This idea applies to general information sources and has been implemented in some source coding techniques such as JPEG, where pixels in regions of interest (ROIs) are coded with higher quality [8].

In this paper, we propose a new type of fidelity criteria, called subsource-dependent fidelity criteria, that impose different distortion constraints on the subsources. We study an RD problem based on the criteria and obtain a single-letter expression for the RD function. The classical fidelity criterion can be viewed as a special case of the proposed criteria.

Subsource-dependent fidelity criteria reflect the need to treat subsources of a composite source differently, and a technique widely adopted to fulfill the need is classify-then-compress (CTC) coding, i.e. dividing the source symbols into a few classes and then compressing the classes separately. See Section I-A for examples. Here the idea behind CTC coding is that if most symbols in a class are produced by the same subsource, then the class can be compressed according to distortion constraints on the subsource. In this paper, we fix an arbitrary classifier and design the coding of the individual classes for good CTC coding performance. The optimal performance is characterized by another RD function. Comparison of the RD functions provides interesting insights, including:

- CTC coding in general has performance loss relative to RD-optimal coding, even if the classification is perfect;
- The cause of the performance loss is that class labels have to be reproduced in CTC coding, while separate compression of source symbols in different classes in CTC coding does not cause performance loss; and
- The performance loss of CTC coding is negligible for asymptotically small distortion if the coding is appropriately designed and some mild conditions are satisfied.

A difficulty in the analysis of CTC coding is how to establish a mathematical model for CTC coding, which we address by using variable-length codes. A key tool in our proofs is a generalization of the conditional RD function [9], [10] to subsource-dependent fidelity criteria, which may be of independent interest.

This paper is organized as follows. In the remaining part of this section we introduce related works and our notation. In Section II, we propose subsource-dependent fidelity criteria and present other definitions that will be used in the following sections. In Section III, we present our main results, including coding theorems and analysis on CTC coding. Section IV outlines the proofs of the coding theorems and Section V concludes the paper. Detailed proofs are given in the appendices.

A. Related Works

The first theoretical studies of the lossy compression problem were by Shannon [1], [2]. Later many variants

of the problem were considered. Many variants involve some side information, which is usually a correlated source. For example, if both the encoder and the decoder know the side information, the problem becomes Gray's conditional RD problem [9], [10]. If only the decoder knows the side information, the problem becomes the one studied by Wyner and Ziv in [11]. If the side information is chosen by some adversary, the problem becomes Berger's source coding game [3, Section 6.1.2] [12]. The side information can also influence distortion measures [13], [14]. Another important variant of the lossy compression problem is the indirect RD problem [3, Section 3.5] [15]–[17], where the encoder observes noisy versions of source symbols instead of source symbols themselves. In our work, the encoder and decoder cannot observe states of composite sources directly, which affect how distortion measures are applied to source symbols.

The composite source model was studied as early as in [3, Section 6.1], where the state of a composite source could vary statistically or be controlled by an adversary. For a composite source with a statistically varying state, both the encoder and the decoder could have different knowledge of the switch position, and this led to different RD functions. Each of the RD functions was shown to equal the RD function of an appropriately chosen information source without a state. If the state is controlled by an adversary, the problem is modeled as the source coding game.

The composite source model turns out to be very versatile. Firstly, information sources with uncertain statistical characteristics can be viewed as mixtures of different sources, i.e. composite sources [3, Section 6.1.2] [12], [18]. Secondly, some complex information sources can be decomposed into simpler subsources and regarded as composite sources to facilitate analysis. For example, some sources that are neither discrete nor continuous can be decomposed into discrete and continuous components so that the behavior of their RD functions at asymptotically small distortions can be characterized [19], [20]. Sparse sources can be viewed as composite sources whose subsources tend to output signals with different magnitudes [21]. A topic beyond our scope here is that non-ergodic sources can be considered as mixtures of ergodic ones [22].

The composite source model is also a good model for many real-world sources such as speech, images, and videos [7], [23]–[25]. Two classes of composite source models, i.e. hidden Markov and Gaussian mixture models [26], have been widely adopted in the analysis and processing of real-world sources. In our work, each composite source is assumed to have a finite number of subsources. As pointed out in [3] and in [22], a gen-

eralized composite source can have uncountably many subsources, and the state of such a source is a continuous variable. Generative machine learning models with latent variables, such as generative adversarial networks [27], variational autoencoders [28], and diffusion models [29], can be viewed as generalized composite sources, with latent variables viewed as source states.

Although RD problems on composite sources have been studied extensively, existing RD analysis does not consider the need to treat subsources of a composite source differently. Such consideration is important to lossy source coding, and especially to lossy source coding in semantic communications [30]. In a series of recent works [31]–[37], inference is made on hidden states of information sources, which are regarded as the meaning or semantics of the sources. In our work, states can represent the importance of the corresponding output data. By putting subsource-dependent fidelity criteria on only the important data, we can provide another interpretation of semantic communications.

CTC coding is widely adopted in situations where subsource-dependent fidelity criteria are relevant. For speech signals, almost every successful coder uses different modes for different parts of the signals [23], [25], [38]. For digital images, the pixels in ROIs, such as the ROIs in JPEG, comprise a class encoded with higher quality and the other pixels comprise a class encoded with lower quality. In remote video analytics systems, relevant and irrelevant pixels usually have to be compressed with different quality levels so that the video transmission bandwidth can be reduced to an acceptable level (see, for example, [39] and references therein). CTC coding is also adopted for other purposes. For example, information sources can be modeled as composite sources with Gaussian subsources. This model enables designs of robust CTC quantizers with low computational complexity and variable rates [40]–[42]. In spite of its wide applications, information-theoretical evaluation of CTC coding based on subsource-dependent fidelity criteria is absent up to now.

B. Notation

The set of real numbers is denoted by \mathbb{R} . For $a,b\in\mathbb{R}\cup\{-\infty,\infty\}$, (a:b] denotes the set of integers n satisfying $a< n\leq b$, and (b] denotes a shorthand for (0:b]. Similarly, [a:b) denotes the set of integers n satisfying $a\leq n< b$, and [b] denotes a shorthand for [0:b). Thus, $[1:\infty)$ denotes the set of positive integers, and $[\infty)$ denotes the set of non-negative integers. The infimum of the empty set \emptyset is considered as ∞ .

For a set $J=\{i_1,i_2,\cdots,i_k\}$ of integers such that $i_1< i_2<\cdots< i_k$, we let x_J denote

the sequence $(x_{i_1}, x_{i_2}, \dots, x_{i_k})$. Thus, $x_{(n]}$ is the sequence (x_1, x_2, \dots, x_n) . This sequence is also written as $\{x_i\}_{i=1}^n$ or as the boldface letter x. The length of a sequence x is denoted by |x|. For two sequences x and y, xy denotes their concatenation. For any set A, the class of all finite sequences composed of the elements of A, including the empty sequence, is denoted by A^* .

We write $X \leftrightarrow Y \leftrightarrow Z$ if X, Y, and Z are random variables and form a Markov chain. All entropies and mutual information are in units of bits.

II. DEFINITIONS

A. Subsource-Dependent Fidelity Criteria

Let \mathcal{S} , \mathcal{X} , and $\hat{\mathcal{X}}$ be sets, and \mathcal{S} be finite. Suppose random pairs (S_1, X_1) , (S_2, X_2) , \cdots are independent and identically distributed (i.i.d.) and take values in $\mathcal{S} \times \mathcal{X}$. We refer to $\{(S_i, X_i)\}_{i=1}^{\infty}$ as a memoryless composite source. For $i \in [1 : \infty)$, X_i is an output symbol and is thought to be produced by Subsource S_i . Let $\{s_i\}_{i=1}^n \in \mathcal{S}^n$ and $\{x_i\}_{i=1}^n \in \mathcal{X}^n$ be realizations of $\{S_i\}_{i=1}^n$ and $\{X_i\}_{i=1}^n$, respectively. Suppose $\{x_i\}_{i=1}^n$ is reproduced as $\{\hat{x}_i\}_{i=1}^n \in \hat{\mathcal{X}}^n$.

A classical fidelity criterion requires

$$\frac{1}{n} \sum_{i=1}^{n} d(x_i, \hat{x}_i) \le \delta, \tag{1}$$

where $\delta \in [0,\infty)$ and d is a distortion measure on $\mathcal{X} \times \hat{\mathcal{X}}$, i.e. a function from $\mathcal{X} \times \hat{\mathcal{X}}$ to $[0,\infty)$. For $x \in \mathcal{X}$ and $\hat{x} \in \hat{\mathcal{X}}$, $d(x,\hat{x})$ is the distortion level of \hat{x} as a reproduction of x. The larger $d(x,\hat{x})$, the lower the fidelity. Unlike (1), the subsource-dependent fidelity criterion involves the state sequence $s_{(n]}$ and a subset \mathcal{S}_* of \mathcal{S} , in addition to $x_{(n]}$, $\hat{x}_{(n]}$, d, and d. We say $s_{(n]}$, $x_{(n]}$, and $\hat{x}_{(n]}$ meet the fidelity criterion $(d, \mathcal{S}_*, \delta)$ if

$$\sum_{i \in (n], s_i \in \mathcal{S}_*} (d(x_i, \hat{x}_i) - \delta) \le 0.$$
 (2)

When the number $m = |\{i \in (n] | s_i \in \mathcal{S}_*\}|$ of terms satisfying $s_i \in \mathcal{S}_*$ is non-zero, (2) can be written as

$$\frac{1}{m} \sum_{i \in (n], s_i \in \mathcal{S}_*} d(x_i, \hat{x}_i) \le \delta, \tag{3}$$

implying that the average distortion of the symbols from the subsources in \mathcal{S}_* does not exceed δ . If $\mathcal{S}_* = \mathcal{S}$, the fidelity criterion $(d, \mathcal{S}_*, \delta)$ is equivalent to the classical fidelity criterion. If $\mathcal{S}_* \neq \mathcal{S}$, the criterion $(d, \mathcal{S}_*, \delta)$ measures fidelity of the symbols from the subsources in \mathcal{S}_* .

We will consider a family $\{(d_{\lambda}, \mathcal{S}_{\lambda}, D(\lambda))\}_{\lambda \in \Lambda}$ of fidelity criteria indexed by a finite set Λ , where for $\lambda \in \Lambda$, d_{λ} is a distortion measure on $\mathcal{X} \times \hat{\mathcal{X}}$, \mathcal{S}_{λ} is a subset of \mathcal{S} , and $D(\lambda) \in [0, \infty)$ is a distortion level. For

example, we can let $\Lambda = S$ and $S_{\lambda} = {\lambda}$ for $\lambda \in \Lambda$. Then the fidelity criteria $\{(d_{\lambda}, \mathcal{S}_{\lambda}, D(\lambda))\}_{\lambda \in \Lambda}$ require that the average distortion of symbols from Subsource sdoes not exceed D(s), for all $s \in \mathcal{S}$. We can define $\{S_{\lambda}\}_{{\lambda}\in\Lambda}$ in a more flexible fashion to describe many other fidelity requirements.

B. Variable-Length Codes and CTC Coding

The number of symbols in a class in CTC coding is usually random. Hence, we use variable-length codes in our analysis of CTC coding. We also use variable-length codes to describe other results for uniformity.

Definition 1: An $(\mathcal{X}, \mathcal{X})$ -variable-length code is a pair (f,φ) of functions $f:\mathcal{X}^* \to \{0,1\}^*$ and $\varphi:\{0,1\}^* \to \{0,1\}^*$ $\hat{\mathcal{X}}^*$ satisfying $|\varphi(f(\boldsymbol{x}))| = |\boldsymbol{x}|$ for all $\boldsymbol{x} \in \mathcal{X}^*$.

Definition 2: An $(\mathcal{X}, \mathcal{X})$ -variable-length code is referred to as an \mathcal{X} -lossless code if $\varphi(f(x)) = x$ for all $oldsymbol{x} \in \mathcal{X}^*$.

In the $(\mathcal{X}, \hat{\mathcal{X}})$ -variable-length code (f, φ) , f describes how an encoder maps the sequence x of source symbols to the bit string f(x), and φ describes how a decoder maps the bit string f(x) to the sequence $\varphi(f(x))$ of reproduced symbols. A key requirement is that the reproduced sequence $\varphi(f(x))$ has the same length as the original sequence x of source symbols.

CTC codes are variable-length codes that accomplish CTC coding. Before defining CTC codes formally, let us consider an example of CTC coding. Let L be a positive integer, $\mathcal{U} = (L]$, and $c: \mathcal{X} \to \mathcal{U}$ be a classifier that assigns the label c(x) to each $x \in \mathcal{X}$. Define $u_i = c(x_i)$ for $i \in (n]$ and $J(u) = \{i \in (n] | u_i = u\}$ for $u \in \mathcal{U}$. An encoder encodes $u_{(n)}$ as a bit string $\hat{b} = \hat{f}(u_{(n)})$ using a \mathcal{U} -lossless code $(\tilde{f}, \tilde{\varphi})$. The encoder also encodes the sequence $x_{J(u)}$ of the symbols in Class u as a bit string $b_u = f_u(x_{J(u)})$ using an $(\mathcal{X}, \hat{\mathcal{X}})$ -variable-length code (f_u, φ_u) . The encoder then outputs the concatenated bit string $bb_1b_2\cdots b_L$. A decoder recovers b, b_1, b_2, \cdots , \boldsymbol{b}_L from the concatenated bit string, reproduces $u_{(n)}$ as $\tilde{\varphi}(\hat{\boldsymbol{b}})$, and reproduces $x_{J(u)}$ as $\varphi_u(\boldsymbol{b}_u)$ for all $u \in \mathcal{U}$. Because $(\tilde{f}, \tilde{\varphi})$ is lossless, $\tilde{\varphi}(\tilde{b})$ equals $u_{(n)}$. The decoder replaces the u's in $u_{(n)}$ with $\varphi_u(\boldsymbol{b}_u)$ for all $u \in \mathcal{U}$ to get $\{\hat{x}_i\}_{i=1}^n$ as the reproduced $x_{(n)}$. The process for L=2is shown in Fig. 2. We can see $\hat{x}_{J(u)} = \varphi_u(f_u(x_{J(u)}))$ for $u \in \mathcal{U}$.

CTC coding can be implemented in ways different from that shown in Fig. 2. For example, we can insert a bit string b_u before b_u to indicate which symbols in $x_{(n)}$ are in Class u, as shown in Fig. 3. Then the bit string b representing labels can be omitted. It is not difficult to think of other implementations of CTC coding. CTC coding has the following characteristics no matter how it is implemented:

- 1) The sequence $u_{(n)}$ of labels can be correctly recovered from the transmitted bit string; and
- 2) The classes are compressed separately, that is, $\hat{x}_{J(u)} = \varphi_u(f_u(x_{J(u)}))$ for all $x_{(n)}$ and u.

We use these characteristics to define CTC codes. In general, the label set \mathcal{U} need not be (L], and can be an arbitrary finite set.

Definition 3: An $(\mathcal{X}, \hat{\mathcal{X}})$ -variable-length code (f, φ) is referred to as an $(\mathcal{X}, \hat{\mathcal{X}}, \mathcal{U}, c)$ -CTC code if there exist functions $\psi: \{0,1\}^* \to \mathcal{U}^*$ and $g: \mathcal{X}^* \times \mathcal{U} \to \hat{\mathcal{X}}^*$ such

- 1) $\psi(f(x_{(n)})) = \{c(x_i)\}_{i=1}^n \text{ for all } n \in [\infty) \text{ and }$ $\{x_i\}_{i=1}^n \in \mathcal{X}^n$; and
- 2) If $n \in [\infty)$ and $\{\hat{x}_i\}_{i=1}^n = \varphi(f(\{x_i\}_{i=1}^n))$, then $\hat{x}_{J(u)} = g(x_{J(u)}, u)$ for all $u \in \mathcal{U}$, where J(u) = $\{i \in (n) | c(x_i) = u\}.$

For $u \in \mathcal{U}$, $g(\cdot, u)$ describes how the symbols in Class u are encoded and decoded, like $\varphi_u(f_u(\cdot))$ in Fig. 2.

The CTC code illustrated in Fig. 2 can be viewed as the combination of two codes: One compresses the labels losslessly, and the other compresses the source symbols based on their labels. We refer to the latter code as a label-based code.

Definition 4: An $(\mathcal{X}, \hat{\mathcal{X}}, \mathcal{U})$ -label-based code is a pair (f,φ) of functions $f:\mathcal{X}^*\times\mathcal{U}^*\to\{0,1\}^*$ and $\varphi:$ $\{0,1\}^* \times \mathcal{U}^* \to \hat{\mathcal{X}}^*$ satisfying $|\varphi(f(\boldsymbol{x},\boldsymbol{u}),\boldsymbol{u})| = n$ for all $n \in [\infty)$, $\boldsymbol{x} \in \mathcal{X}^n$, and $\boldsymbol{u} \in \mathcal{U}^n$.

In Definition 4, we require the original sequence x, the reproduced sequence $\varphi(f(\boldsymbol{x},\boldsymbol{u}),\boldsymbol{u})$, and the label sequence u to have the same length, because every source symbol has a label.

C. RD Functions

Let (S, X) be a random pair such that (S, X), $(S_1, X_1), (S_2, X_2), \cdots$ are identically distributed. Define $\bar{\Lambda} = \{\lambda \in \Lambda | \Pr[S \in \mathcal{S}_{\lambda}] > 0 \}$. For an arbitrary family $\{D(\lambda)\}_{\lambda \in \Lambda}$ of distortion levels, let

$$R^*(D) = \inf_{\hat{X} \in \Xi(D)} I(X; \hat{X}), \tag{4}$$

$$R^{*}(D) = \inf_{\hat{X} \in \Xi(D)} I(X; \hat{X}), \tag{4}$$

$$R^{C}(D) = \inf_{\hat{X} \in \Xi(D)} I(X; \hat{X}, c(X)), \tag{5}$$

and

$$R^{G}(D) = \inf_{\hat{X} \in \Xi(D)} I(X; \hat{X} | c(X)), \tag{6}$$

where $\Xi(D)$ is the set of random variables \hat{X} satisfying $S \leftrightarrow X \leftrightarrow \hat{X}$ and $E[d_{\lambda}(X,\hat{X})|S \in \mathcal{S}_{\lambda}] \leq D(\lambda)$ for all $\lambda \in \bar{\Lambda}$. Equation (4) defines the RD function R^* of (S, X) for $\{(d_{\lambda}, S_{\lambda})\}_{{\lambda} \in \Lambda}$. Equation (5) defines the RD function $R^{\mathbb{C}}$ of (S, X) for $\{(d_{\lambda}, S_{\lambda})\}_{{\lambda} \in \Lambda}$ and $(\mathcal{X}, \hat{\mathcal{X}}, \mathcal{U}, c)$ -CTC codes. Equation (6) defines the RD

Fig. 2. An example of CTC coding.

function $R^{\rm G}$ of (S,X) for $\{(d_\lambda,\mathcal{S}_\lambda)\}_{\lambda\in\Lambda}$ given c(X). In the next section, we will see that R^* , $R^{\rm C}$, and $R^{\rm G}$ characterize the optimal performance of $(\mathcal{X},\hat{\mathcal{X}})$ -variable-length codes, $(\mathcal{X},\hat{\mathcal{X}},\mathcal{U},c)$ -CTC codes, and $(\mathcal{X},\hat{\mathcal{X}},\mathcal{U})$ -label-based codes, respectively.

III. MAIN RESULTS

A. Coding Theorems

Fix $R \in [0, \infty)$ and a family $\{D(\lambda)\}_{\lambda \in \Lambda}$ of distortion levels. An $(\mathcal{X}, \hat{\mathcal{X}})$ -variable-length code is said to achieve (R, D) for (S, X) and $\{(d_{\lambda}, \mathcal{S}_{\lambda})\}_{\lambda \in \Lambda}$ if

$$\lim_{n \to \infty} \Pr[(S_{(n]}, X_{(n]}) \in F_{\epsilon}] = 1 \tag{7}$$

for all $\epsilon \in (0, \infty)$, where F_{ϵ} is the set of $(s, x) \in \mathcal{S}^* \times \mathcal{X}^*$ such that $|f(x)| \leq |x|R$ and such that s, x, and $\varphi(f(x))$ meet the fidelity criterion $(d_{\lambda}, \mathcal{S}_{\lambda}, D(\lambda) + \epsilon)$ for all $\lambda \in \Lambda$. Define $U_i = c(X_i)$ for $i \in [1 : \infty)$. An $(\mathcal{X}, \hat{\mathcal{X}}, \mathcal{U})$ -label-based code is said to achieve (R, D) for (S, X) and $\{(d_{\lambda}, \mathcal{S}_{\lambda})\}_{\lambda \in \Lambda}$ given c(X) if

$$\lim_{n \to \infty} \Pr[(S_{(n]}, X_{(n]}, U_{(n]}) \in G_{\epsilon}] = 1$$
 (8)

for all $\epsilon \in (0, \infty)$, where G_{ϵ} is the set of $(s, x, u) \in \mathcal{S}^* \times \mathcal{X}^* \times \mathcal{U}^*$ such that $|f(x, u)| \leq |x|R$ and such that s, x, and $\varphi(f(x, u), u)$ meet the fidelity criterion $(d_{\lambda}, \mathcal{S}_{\lambda}, D(\lambda) + \epsilon)$ for all $\lambda \in \Lambda$.

The following coding theorems are valid when \mathcal{X} and $\hat{\mathcal{X}}$ are finite. They may be generalized to abstract sources, but with some additional technical conditions [3], [43].

Theorem 1: If $R > R^*(D)$, then there exists an $(\mathcal{X}, \hat{\mathcal{X}})$ -variable-length code (f, φ) achieving (R, D) for (S, X) and $\{(d_{\lambda}, \mathcal{S}_{\lambda})\}_{{\lambda} \in \Lambda}$, and satisfying

$$\limsup_{n \to \infty} \frac{1}{n} \max_{\boldsymbol{x} \in \mathcal{X}^n} |f(\boldsymbol{x})| < R. \tag{9}$$

Conversely, if an $(\mathcal{X}, \hat{\mathcal{X}})$ -variable-length code (f, φ) achieves (R, D) for (S, X) and $\{(d_{\lambda}, \mathcal{S}_{\lambda})\}_{\lambda \in \Lambda}$, then $R \geq R^*(D)$.

Theorem 2: If $R > R^{\mathbf{C}}(D)$, then there exists an $(\mathcal{X}, \hat{\mathcal{X}}, \mathcal{U}, c)$ -CTC code achieving (R, D) for (S, X) and $\{(d_{\lambda}, \mathcal{S}_{\lambda})\}_{\lambda \in \Lambda}$. Conversely, if an $(\mathcal{X}, \hat{\mathcal{X}})$ -variable-length code (f, φ) achieves (R, D) for (S, X) and $\{(d_{\lambda}, \mathcal{S}_{\lambda})\}_{\lambda \in \Lambda}$, ψ is a function from $\{0, 1\}^*$ to \mathcal{U}^* , and $\psi(f(X_{(n)})) = U_{(n)}$ with probability one for all $n \in [\infty)$, then $R \geq R^{\mathbf{C}}(D)$.

Theorem 3: If $R > R^{\mathrm{G}}(D)$, then there exist an $(\mathcal{X},\hat{\mathcal{X}},\mathcal{U})$ -label-based code (f,φ) and a function $g:\mathcal{X}^*\times\mathcal{U}\to\hat{\mathcal{X}}^*$ such that

- 1) (f, φ) achieves (R, D) for (S, X) and $\{(d_{\lambda}, \mathcal{S}_{\lambda})\}_{{\lambda} \in \Lambda}$ given c(X); and
- 2) If $n \in [\infty)$ and

$$\{\hat{x}_i\}_{i=1}^n = \varphi(f(\{x_i\}_{i=1}^n, \{u_i\}_{i=1}^n), \{u_i\}_{i=1}^n),$$
(10)

then $\hat{x}_{J(u)} = g(x_{J(u)}, u)$ for all $u \in \mathcal{U}$, where $J(u) = \{i \in (n | | u_i = u)\}.$

Conversely, if there exists an $(\mathcal{X}, \hat{\mathcal{X}}, \mathcal{U})$ -label-based code (f, φ) achieving (R, D) for (S, X) and $\{(d_{\lambda}, \mathcal{S}_{\lambda})\}_{\lambda \in \Lambda}$ given c(X), then $R \geq R^{G}(D)$.

The theorems say that $(\mathcal{X}, \hat{\mathcal{X}})$ -variable-length codes, $(\mathcal{X}, \hat{\mathcal{X}}, \mathcal{U}, c)$ -CTC codes, and $(\mathcal{X}, \hat{\mathcal{X}}, \mathcal{U})$ -label-based codes need rates no less than $R^*(D)$, $R^{\mathbb{C}}(D)$, and $R^{G}(D)$, respectively, for the fidelity criteria $\{(d_{\lambda}, \mathcal{S}_{\lambda}, D(\lambda))\}_{\lambda \in \Lambda}$. The converse part of Theorem 2 does not need the condition that (f, φ) is an $(\mathcal{X}, \hat{\mathcal{X}}, \mathcal{U}, c)$ -CTC code. It only needs the condition that class labels $U_{(n)}$ can be correctly recovered from the transmitted bit string $f(X_{(n)})$, i.e. the first characteristic of CTC codes (see the paragraph preceding Definition 3). Hence, an $(\mathcal{X}, \mathcal{X}, \mathcal{U}, c)$ -CTC code cannot perform better even if it is allowed to compress symbols in different classes jointly. In other words, the performance loss of CTC coding relative to RD-optimal coding is not due to separate compression of source symbols in different classes. The performance loss is because class labels have to be reproduced in CTC coding. The existence of the function g in the direct part of Theorem 3 means that (f,φ) compresses symbols in different classes separately. Hence, separate compression does not cause performance loss for label-based codes either.

 $^1{\rm This}$ means that (7) holds for all $\epsilon\in(0,\infty),$ because any CTC code is a variable-length code.

B. Properties of RD Functions

For an arbitrary random variable \hat{X} , we have

$$I(X; \hat{X}|c(X)) + I(c(X); \hat{X}) = I(X; \hat{X}),$$
 (11)

$$I(X; \hat{X}) + H(c(X)|\hat{X}) = I(X; \hat{X}, c(X)),$$
 (12)

and

$$I(X; \hat{X}|c(X)) + H(c(X)) = I(X; \hat{X}, c(X)),$$
 (13)

leading to the following corollary.

Corollary 1: For every family $\{D(\lambda)\}_{\lambda \in \Lambda}$ of distortion levels, $R^{\mathrm{G}}(D) \leq R^*(D) \leq R^{\mathrm{C}}(D) = R^{\mathrm{G}}(D) + H(c(X))$.

The identity $R^{\rm C}(D)=R^{\rm G}(D)+H(c(X))$ has a straightforward interpretation that CTC codes need to compress labels in addition to source symbols.

Corollary 2: Define distortion measures $\{\hat{d}_{\lambda}\}_{\lambda\in\bar{\Lambda}}$ on $\mathcal{X}\times\hat{\mathcal{X}}$ by

$$\hat{d}_{\lambda}(x,\hat{x}) = \frac{\Pr[S \in \mathcal{S}_{\lambda}|X=x]}{\Pr[S \in \mathcal{S}_{\lambda}]} d_{\lambda}(x,\hat{x}). \tag{14}$$

Then for every $\{D(\lambda)\}_{\lambda \in \Lambda}$,

$$R^*(D) = \inf_{\hat{X} \in \hat{\Xi}(D)} I(X; \hat{X}), \tag{15}$$

where $\hat{\Xi}(D)$ is the set of random variables \hat{X} satisfying $E[\hat{d}_{\lambda}(X,\hat{X})] \leq D(\lambda)$ for all $\lambda \in \bar{\Lambda}$.

We can prove Corollary 2 by noting that

$$E[\hat{d}_{\lambda}(X,\hat{X})] = E[d_{\lambda}(X,\hat{X})|S \in \mathcal{S}_{\lambda}] \tag{16}$$

for all $\lambda \in \bar{\Lambda}$ and random variables \hat{X} satisfying $S \leftrightarrow X \leftrightarrow \hat{X}$. Note that the right-hand side of (15) is the classical RD function of X for the distortion measures $\{\hat{d}_{\lambda}\}_{\lambda \in \bar{\Lambda}}$. By the monotonicity and convexity of the right-hand side of (15) with respect to $\{D(\lambda)\}_{\lambda \in \Lambda}$, R^* is non-increasing and convex. If \mathcal{X} and $\hat{\mathcal{X}}$ are finite, we can compute R^* numerically using the Blahut-Arimoto algorithm [44], [45].

We can use the total expectation formula to prove the following corollary.

Corollary 3: Let $\Lambda = \mathcal{S}, d$ be a distortion measure on $\mathcal{X} \times \hat{\mathcal{X}}$, and R^{O} be the classical RD function of X for d. Suppose $d_{\lambda} = d$ and $\mathcal{S}_{\lambda} = \{\lambda\}$ for all $\lambda \in \Lambda$. Then for every $\delta \in [0, \infty)$ we have

$$R^{\mathcal{O}}(\delta) = \inf_{D \in A(\delta)} R^*(D), \tag{17}$$

where $A(\delta)$ is the set of $\{D(\lambda)\}_{\lambda \in \Lambda}$ satisfying

$$\sum_{s \in \mathcal{S}} \Pr[S = s] D(s) \le \delta. \tag{18}$$

Fig. 4. The relation between $R^{\rm O}$ and R^* in Example 1. Each curve shows the relation between D(0) and $R^*(D)$ under the constraint $\Pr[S=0]D(0)+\Pr[S=1]D(1)=\delta$.

Example 1: Let
$$S = \mathcal{X} = \hat{\mathcal{X}} = \Lambda = \{0, 1\},\$$

$$\begin{bmatrix} \Pr[S=0,X=0] & \Pr[S=0,X=1] \\ \Pr[S=1,X=0] & \Pr[S=1,X=1] \end{bmatrix} = \begin{bmatrix} 0.1 & 0.4 \\ 0.3 & 0.2 \end{bmatrix}, \tag{19}$$

 $S_0 = \{0\}, S_1 = \{1\}, \text{ and } d_0 = d_1 = d, \text{ where } d \text{ is the Hamming distortion measure on } \mathcal{X} \times \hat{\mathcal{X}} \text{ defined by}$

$$d(x,\hat{x}) = \begin{cases} 0, & x = \hat{x}, \\ 1, & x \neq \hat{x}. \end{cases}$$
 (20)

Fig. 4 shows the relation between $R^{\rm O}$ in Corollary 3 and R^* . We can see

1) Subject to

$$Pr[S = 0]D(0) + Pr[S = 1]D(1) = 0.25,$$
 (21)

 $R^*(D)$ is minimized when D(0) is approximately 0.2:

- 2) The minimum $R^*(D)$ subject to (21) equals $R^{\rm O}(0.25)$; and
- 3) $R^*(D) > R^{O}(0.25)$ when (21) and D(0) = 0.25 hold, i.e. when D(0) = D(1) = 0.25.

Analogous facts can be seen for $\delta=0.1$ and for $\delta=0.4$. The second observation confirms Corollary 3. The third observation is more interesting. If D(0)=D(1)=0.25, then $R^*(D)$ is the minimum rate we need to ensure that the distortion level of each subsource does not exceed 0.25. We need the rate $R^{\rm O}(0.25)$ to ensure that the average distortion of all symbols output by the composite source does not exceed 0.25. It is not difficult to understand the fact $R^*(D)>R^{\rm O}(0.25)$: If the distortion level of each subsource does not exceed 0.25, then the average distortion does not exceed 0.25, but not vice versa. Hence, fidelity criteria on individual subsources can be stricter than the classical fidelity criteria that the average distortion of all symbols does not exceed a certain distortion level.

Corollary 4: Let $\tilde{\Lambda} = \Lambda \cup \{\tilde{\lambda}\}$, where $\tilde{\lambda} \notin \Lambda$. Define distortion measures $\{\tilde{d}_{\lambda}\}_{\lambda \in \tilde{\Lambda}}$ on $\mathcal{X} \times (\hat{\mathcal{X}} \times \mathcal{U})$ by

$$\tilde{d}_{\lambda}(x,(\hat{x},u)) = \begin{cases} d_{\lambda}(x,\hat{x}), & \lambda \in \Lambda, \\ 0, & \lambda = \tilde{\lambda}, c(x) = u, \\ 1, & \lambda = \tilde{\lambda}, c(x) \neq u. \end{cases}$$
 (22)

Let $\tilde{\mathcal{S}}_{\tilde{\lambda}} = \mathcal{S}$ and $\tilde{\mathcal{S}}_{\lambda} = \mathcal{S}_{\lambda}$ for all $\lambda \in \Lambda$. Then for every $\{D(\lambda)\}_{\lambda \in \Lambda}$, we have $R^{\mathrm{C}}(D) = \tilde{R}(\tilde{D})$, where \tilde{R} is the RD function of (S,X) for $\{(\tilde{d}_{\lambda},\tilde{\mathcal{S}}_{\lambda})\}_{\lambda \in \tilde{\Lambda}}$, $\tilde{D}(\tilde{\lambda}) = 0$, and $\tilde{D}(\lambda) = D(\lambda)$ for all $\lambda \in \Lambda$.

We can prove Corollary 4 by noting that

$$E[\tilde{d}_{\tilde{\lambda}}(X,(\hat{X},U))|S \in \tilde{\mathcal{S}}_{\tilde{\lambda}}] \le \tilde{D}(\tilde{\lambda}) \tag{23}$$

is equivalent to $\Pr[c(X) = U] = 1$. By Corollaries 1, 2, and 4, R^* , $R^{\rm C}$, and $R^{\rm G}$ have properties similar to those of classical RD functions, as shown in the following corollary.

Corollary 5: The RD functions R^* , $R^{\rm C}$, and $R^{\rm G}$ are non-increasing and convex.

The following theorem can be viewed as a generalization of a property of the conditional RD function [9], [10].

Theorem 4: Define $\bar{\mathcal{U}}=\{u\in\mathcal{U}|\Pr[c(X)=u]>0\}$. For $u\in\bar{\mathcal{U}}$, let P_u be the conditional distribution of (S,X) given c(X)=u, and R_u^* be the RD function defined in Section II-C of a P_u -distributed random pair for $\{(d_\lambda,\mathcal{S}_\lambda)\}_{\lambda\in\Lambda}$. Then for every $\{D(\lambda)\}_{\lambda\in\Lambda}$,

$$R^{\mathrm{G}}(D) = \inf_{\delta \in \Delta(D)} \sum_{u \in \overline{\mathcal{U}}} \Pr[c(X) = u] R_u^*(\delta(\cdot, u)), \quad (24)$$

where $\Delta(D)$ is the set of functions $\delta: \Lambda \times \mathcal{U} \to [0, \infty)$ satisfying

$$\sum_{u \in \overline{\mathcal{U}}} \Pr[S \in \mathcal{S}_{\lambda}, c(X) = u] \delta(\lambda, u) \le \Pr[S \in \mathcal{S}_{\lambda}] D(\lambda)$$

for all $\lambda \in \Lambda$.

If $\mathcal{S}_{\lambda}=\mathcal{S}$ for all $\lambda\in\Lambda$, then R^{G} is a conditional RD function and each R^*_u in Theorem 4 is a classical RD function. Hence, (24) is a generalization of (2.2) in [10] for subsource-dependent fidelity criteria. Theorem 4 also provides an approach to numerical computation of R^{G} , because we can compute R^*_u using the Blahut-Arimoto algorithm, as pointed out in the discussions following Corollary 2.

C. CTC Code Where Labels are Compressed by a Variable-Length Code

We have seen in Section II-B that CTC codes can have different implementations. Our proofs outlined in Section IV-B of Theorems 2 and 3 show that CTC codes

Fig. 5. The RD function R^* in Example 2.

implemented as in Fig. 2 can have the performance characterized by $R^{\rm C}$. The implementation shown in Fig. 2, i.e. the implementation where labels are compressed by a variable-length code, is hence justified. Now we illustrate this by showing the relevant steps of the proofs.

Define $\bar{\mathcal{U}}$ and $\{P_u\}_{u\in\bar{\mathcal{U}}}$ as in Theorem 4. For $u\in\bar{\mathcal{U}}$, let an $(\mathcal{X},\hat{\mathcal{X}})$ -variable-length code (f_u,φ_u) achieves $(R_u,\delta(\cdot,u))$ for a P_u -distributed random pair and $\{(d_\lambda,\mathcal{S}_\lambda)\}_{\lambda\in\Lambda}$. Here $\delta(\cdot,u)$ denotes distortion levels $\{\delta(\lambda,u)\}_{\lambda\in\Lambda}$. Then we can combine the codes $\{(f_u,\varphi_u)\}_{u\in\bar{\mathcal{U}}}$ and a variable-length code that losslessly compresses class labels in the way shown in Fig. 2 to get an $(\mathcal{X},\hat{\mathcal{X}},\mathcal{U},c)$ -CTC code (f,φ) . By Lemmas 2, 3, and 4 stated in Section IV-B, the rate of (f,φ) is approximately

$$H(c(X)) + \sum_{u \in \mathcal{I}} \Pr[c(X) = u] R_u, \qquad (26)$$

and for $\lambda \in \bar{\Lambda}$, the distortion level of (f, φ) corresponding to d_{λ} and \mathcal{S}_{λ} is approximately

$$\sum_{u \in \mathcal{I}} \Pr[c(X) = u | S \in \mathcal{S}_{\lambda}] \delta(\lambda, u). \tag{27}$$

For a family $\{D(\lambda)\}_{\lambda\in\Lambda}$ of distortion levels, we should choose such δ and $\{R_u\}_{u\in\bar{\mathcal{U}}}$ that the approximate distortion level (27) does not exceed $D(\lambda)$ for any λ and that $R_u=R_u^*(\delta(\cdot,u))$ for all $u\in\bar{\mathcal{U}}$. By $R^{\rm C}(D)=R^{\rm G}(D)+H(c(X))$ and Theorem 4, the minimum rate (26) for δ so chosen is $R^{\rm C}(D)$. Hence CTC codes where labels are compressed by a variable-length code can have the performance characterized by $R^{\rm C}$. The performance of other implementations of CTC codes is left for future research.

D. A Case with Perfect Classification

In this section, we study a case where the classification is perfect in that $S \in \mathcal{S}_{\lambda}$ is equivalent to $c(X) = \lambda$

Fig. 6. The gap $R^{C} - R^{*}$ in Example 2.

with probability one for all $\lambda \in \Lambda$. Of course, this is possible only if all $\lambda \in \Lambda$ satisfying $\Pr[S \in \mathcal{S}_{\lambda}] > 0$ are chosen as labels. Insights into connections between CTC codes and general variable-length codes will be gained in the following theorem and example.

Theorem 5: For $\lambda \in \bar{\Lambda}$, let Q_{λ} be the distribution of X given the condition $S \in \mathcal{S}_{\lambda}$ and $R^{(\lambda)}$ be the RD function of a Q_{λ} -distributed random variable for d_{λ} . Fix a family $\{D(\lambda)\}_{\lambda \in \Lambda}$ of distortion levels. If $S \in \mathcal{S}_{\lambda}$ is equivalent to $c(X) = \lambda$ with probability one for all $\lambda \in \Lambda$, then

$$R^{G}(D) = \sum_{\lambda \in \bar{\Lambda}} \Pr[S \in \mathcal{S}_{\lambda}] R^{(\lambda)}(D(\lambda)). \tag{28}$$

If we have $|\bar{\Lambda}|=1$ in addition, then $R^{\rm G}(D)=R^*(D)$. The meaning of (28) is as follows. For $\lambda\in\bar{\Lambda}$, the symbols from the subsources in \mathcal{S}_{λ} account for approximately $\Pr[S\in\mathcal{S}_{\lambda}]$ of all the source symbols, and consequently we need a rate of $\Pr[S\in\mathcal{S}_{\lambda}]R^{(\lambda)}(D(\lambda))$ to describe them.

Example 2: Let $S = \mathcal{X} = \hat{\mathcal{X}} = \{0, 1, 2, 3\}$, S be uniformly distributed over S, S = X with probability one, $\Lambda = \mathcal{U} = \{0, 1\}$, $S_0 = \{0, 1\}$, $S_1 = \{2, 3\}$, c(0) = c(1) = 0, c(2) = c(3) = 1, and

$$d_0(x,\hat{x}) = d_1(x,\hat{x}) = \begin{cases} 0, & x = \hat{x}, \\ 1, & x \neq \hat{x}, \end{cases}$$
(29)

for all $x \in \mathcal{X}$ and $\hat{x} \in \hat{\mathcal{X}}$. The RD function R^* and the gap $R^{\mathrm{C}} - R^*$ are shown in Figs. 5 and 6, respectively.

From (11), (12), and Example 2 we can see $R^{\rm G}(D) < R^*(D) < R^{\rm C}(D)$ unless certain conditions are satisfied. This is true even if the classification is perfect. The strict inequality $R^{\rm G}(D) < R^*(D)$ can be understood by observing that the encoder not only needs to describe source symbols in each class to the decoder, but also needs to inform the decoder the labels of the symbols. On the other hand, $R^*(D) < R^{\rm C}(D) = R^{\rm G}(D) + H(c(X))$ show that compressing the labels

using a lossless code with the rate H(c(X)) is usually a suboptimal way to do this. In the extreme case of $|\bar{\Lambda}|=1,\,R^*(D)$ even equals $R^{\rm G}(D)$. The differences between the reproduced symbols from different classes may be utilized to reduce the additional rate required by label compression. In conclusion, CTC coding can be suboptimal even if the classification is perfect.

E. Comparison of RD Functions

In this section, we will show that the performance loss $R^{C}(D) - R^{*}(D)$ is small under mild conditions. Equation (12) leads to the following corollary.

Corollary 6: Fix $\mu \in \Lambda$ and a family $\{D(\lambda)\}_{\lambda \in \Lambda}$ of distortion levels. Let $D(\mu) > 0$. For $\delta \in [0, \infty)$ and $\lambda \in \Lambda$, let

$$D_{\delta}(\lambda) = \begin{cases} \delta, & \lambda = \mu, \\ D(\lambda), & \lambda \neq \mu. \end{cases}$$
 (30)

If there exists a family $\{\hat{X}_{\delta}\}_{\delta\in(0,D(\mu))}$ of random variables such that

- 1) $\hat{X}_{\delta} \in \Xi(D_{\delta})$ for all $\delta \in (0, D(\mu))$; and
- 2) $I(X; \hat{X}_{\delta}) R^*(D_{\delta})$ and $H(c(X)|\hat{X}_{\delta})$ tend to 0 as $(0, D(\mu)) \ni \delta \to 0$;

then $R^{\mathbb{C}}(D_{\delta}) - R^*(D_{\delta}) \to 0$ as $(0, D(\mu)) \ni \delta \to 0$.

As $\delta \to 0$, $D_\delta(\mu)$ tends to zero while the other distortion levels in $\{D_\delta(\lambda)\}_{\lambda \in \Lambda}$ remain fixed. Hence under the conditions in Corollary 6, the performance loss $R^{\rm C} - R^*$ is negligible for asymptotically small distortion.

The cases where the conditions in Corollary 6 are satisfied are not rare. For example, we can let $\mathcal{X} = \hat{\mathcal{X}}$ and let d_{μ} be a distortion measure that characterizes the closeness or similarity between source symbols and their reproductions, such as the Hamming distortion measure or the squared-error distortion measure. For such a d_{μ} and some common classifier c, a sufficiently small $d_{\mu}(x,\hat{x})$ means that x and \hat{x} tend to have the same label. For $\delta \in (0, D(\mu))$, we let \hat{X}_{δ} be a random variable in $\Xi(D_{\delta})$ satisfying $I(X; \hat{X}_{\delta}) < R^*(D_{\delta}) + \delta$. Further assume that the support set of X equals the conditional support set of X given $S \in \mathcal{S}_{\mu}$. Then for sufficiently small δ , $E[d_{\mu}(X, \hat{X}_{\delta})]$ is small, and consequently $c(X) = c(\hat{X}_{\delta})$ with a high probability. Hence for sufficiently small δ , $H(c(X)|\hat{X}_{\delta})$ is small, and by Corollary 6, we can expect $R^{C}(D_{\delta}) - R^{*}(D_{\delta})$ to be small.

If $D(\lambda)$ is sufficiently large for all $\lambda \in \Lambda$, then $R^{\mathrm{G}}(D) = R^*(D) = 0$. Therefore, $R^*(D)$ can be close to $R^{\mathrm{G}}(D)$ for D having large values and can be close to $R^{\mathrm{C}}(D)$ for D having small values. Or equivalently, the performance loss $R^{\mathrm{C}}(D) - R^*(D)$ of optimal CTC codes is close to 0 for D having small values and is close to H(c(X)) for D having large

Fig. 7. The RD function R^* in Example 3.

values. This can be understood by observing that lossless compression of labels needs a rate of H(c(X)), and that CTC codes need to compress the labels losslessly even if $D(\lambda)$ is large. For D having medium values, we have $0 < R^{\rm C}(D) - R^*(D) < H(c(X))$ by the continuity of R^* and $R^{\rm C}$, which follows from Corollary 5. The performance loss $R^{\rm C}(D) - R^*(D)$ is small if the number $|\mathcal{U}|$ of classes is small.

Example 3: Let S be uniformly distributed over $S = \{0,1\}$, $\mathcal{X} = \hat{\mathcal{X}} = \{n/256 + 1/512 | n \in [256)\}$, $\Lambda = \mathcal{U} = \{0,1\}$, $S_0 = \{0\}$, $S_1 = \{1\}$, and $d_0(x,\hat{x}) = d_1(x,\hat{x}) = (x-\hat{x})^2$ for all $x \in \mathcal{X}$ and $\hat{x} \in \hat{\mathcal{X}}$. Define an 8-bit quantizer $Q : \mathbb{R} \to \mathcal{X}$ by

$$Q(y) = \begin{cases} 1/512, & y < 1/256, \\ \frac{\lfloor 256y \rfloor}{256} + \frac{1}{512}, & \frac{1}{256} \le y < \frac{255}{256}, \\ 511/512, & 255/256 \le y. \end{cases}$$
(31)

Let a random variable Y have the conditional distribution $\mathcal{N}(0.3,0.04)$ given S=0, and have the conditional distribution $\mathcal{N}(0.7,0.04)$ given S=1. Suppose X=Q(Y) with probability one. A reasonable classifier c assigns label 0 to every x<1/2, and assigns label 1 to every $x\geq 1/2$. The RD function R^* is shown in Fig. 7. Fig. 8 shows the gap between R^* and $R^{\rm C}$. The performance loss $R^{\rm C}(D)-R^*(D)$ is close to 1=H(c(X)) when D(0) and D(1) are sufficiently large and is close to 0 when D(0) or D(1) are close to 0. This confirms Corollary 6 and the discussions following it.

IV. PROOF SKETCHES OF CODING THEOREMS

A. Theorem 1

A key step in the proof is to define functions $\{d_{\lambda,\delta}\}_{\lambda\in\Lambda,\delta\in\mathbb{R}}$ from $\mathcal{X}\times\hat{\mathcal{X}}\times\mathcal{S}$ to \mathbb{R} by

$$d_{\lambda,\delta}(x,\hat{x},s) = \begin{cases} d_{\lambda}(x,\hat{x}), & s \in \mathcal{S}_{\lambda}, \\ \delta, & s \notin \mathcal{S}_{\lambda}. \end{cases}$$
(32)

Fig. 8. The gap $R^{C} - R^{*}$ in Example 3.

For $\lambda \in \Lambda$ and $\delta \in [0, \infty)$, $d_{\lambda, \delta}$ can be interpreted as a distortion measure on $\mathcal{X} \times \hat{\mathcal{X}}$ dependent on s. For $\lambda \in \Lambda$, $\delta \in [0, \infty)$, $n \in [1 : \infty)$, $\{s_i\}_{i=1}^n \in \mathcal{S}^n$, $\{x_i\}_{i=1}^n \in \mathcal{X}^n$, and $\{\hat{x}_i\}_{i=1}^n \in \hat{\mathcal{X}}^n$, we can verify that

$$\frac{1}{n} \sum_{i=1}^{n} d_{\lambda,\delta}(x_i, \hat{x}_i, s_i) \le \delta \tag{33}$$

is a sufficient and necessary condition for $s_{(n]}, x_{(n]}$, and $\hat{x}_{(n]}$ to meet the fidelity criterion $(d_{\lambda}, \mathcal{S}_{\lambda}, \delta)$. The inequality (33) means that the average of all $d_{\lambda}(x_i, \hat{x}_i)$ satisfying $s_i \in \mathcal{S}_{\lambda}$ does not exceed δ , because $d_{\lambda,\delta}(x_i, \hat{x}_i, s_i) = \delta$ whenever $s_i \notin \mathcal{S}_{\lambda}$. Thus, the problem is reduced to an RD problem where the distortion measures are influenced by some side information unknown to both the encoder and the decoder [13], [14]. In spite of the difference that the distortion measures depend on the distortion level δ , Theorem 1 can be proved using existing results [14] and the following corollary of the definition of $\Xi(D)$.

Corollary 7: Define $d_{\lambda,\delta}: \mathcal{X} \times \hat{\mathcal{X}} \times \mathcal{S} \to \mathbb{R}$ by (32) for $\lambda \in \Lambda$ and $\delta \in \mathbb{R}$. Let $\{D(\lambda)\}_{\lambda \in \Lambda}$ be a family of distortion levels. Then $\Xi(D)$ equals the set of random variables \hat{X} satisfying $S \leftrightarrow X \leftrightarrow \hat{X}$ and $E[d_{\lambda,D(\lambda)}(X,\hat{X},S)] \leq D(\lambda)$ for all $\lambda \in \Lambda$.

Since the existing results are on block codes, we still need to adapt them for variable-length codes. From a sequence of block codes, a variable-length code with almost the same rate can be constructed using the compound representation of positive integers [46]. The compound representation of $j \in [1:\infty)$ is the bit string $\gamma(j)$ obtained by

- 1) Writing j in the binary form $1b_{\lfloor \log_2(j) \rfloor 1} \cdots b_1 b_0$;
- 2) Inserting a 1 after b_0 and 0's after all the other bits in the binary form; and
- 3) Dropping the leading 1 to get the bit string $\gamma(j)$.

For example, the binary form of 5 is 101, and so $\gamma(5) =$ 00011. It is known [46] that

$$|\gamma(j)| = 1 + 2\lfloor \log_2(j) \rfloor \le 1 + 2\log_2(j) \tag{34}$$

for $j \in [1:\infty)$, and that γ is prefix-free, that is, $\gamma(i)$ is not a prefix of $\gamma(j)$ for all $i, j \in [1:\infty)$ when $i \neq j$. The following lemma shows properties of so constructed variable-length codes.

Lemma 1: For $n \in [1 : \infty)$, let $M_n \in [1 : \infty)$, f_n be a function from \mathcal{X}^n to $(M_n]$, and φ_n be a function from $(M_n]$ to $\hat{\mathcal{X}}^n$. If $R \in \mathbb{R}$ and $M_n \leq 2^{nR}$ for all $n \in [1:\infty)$, then there exists an $(\mathcal{X}, \hat{\mathcal{X}})$ -variable-length code (f, φ) satisfying

$$\limsup_{n \to \infty} \frac{1}{n} \max_{\boldsymbol{x} \in \mathcal{X}^n} |f(\boldsymbol{x})| \le R \tag{35}$$

and $\varphi(f(x)) = \varphi_{|x|}(f_{|x|}(x))$ for all non-empty strings

The complete proof of Theorem 1 is given in Appendix D.

B. Theorems 2 and 3

We prove the converse part of Theorem 2 using Theorem 1 and Corollary 4. By assumption, the labels of the source symbols can be correctly recovered from the transmitted bit string $f(X_{(n)})$ in the code (f,φ) . Hence we can use (f,φ) to construct an $(\mathcal{X},\mathcal{X}\times\mathcal{U})$ -variablelength code $(f, \tilde{\varphi})$ that achieves (R, \tilde{D}) for (S, X) and $\{(\tilde{d}_{\lambda}, \tilde{\mathcal{S}}_{\lambda})\}_{\lambda \in \tilde{\Lambda}}$, where \tilde{D} , \tilde{d}_{λ} , and $\tilde{\mathcal{S}}_{\lambda}$ are defined in Corollary 4. By Theorem 1 we have $R \geq \tilde{R}(\tilde{D})$, i.e. $R > R^{\mathcal{C}}(D)$.

It is not difficult to prove the direct part of Theorem 3. We have shown in Section IV-A how the subsourcedependent fidelity criteria can be converted to fidelity criteria considered in [13] and [14]. The conversion can be used here to reduce the problem to an RD problem with the side information expressed as two random variables: S unknown to both the encoder and the decoder, and c(X) known by both the encoder and the decoder. Then we can use existing results [9], [14] to show that the lowest achievable rate is $R^{G}(D)$.

We will go into more detail about an alternative proof of the direct part of Theorem 3 that also serves as a foundation of the analysis in Section III-C. This proof explicitly constructs a variable-length code for each class $u \in \mathcal{U}$ and then combines the variable-length codes to form the desired label-based code. The proof uses the following lemmas.

Lemma 2: Let $n \in [1 : \infty)$, $u \in \mathcal{U}$, P_u be the conditional distribution of (S, X) given c(X) = u, and J be the random set $\{i \in (n] | c(X_i) = u\}$. Define random pairs $\{(T_i, Y_i)\}_{i=1}^{\infty}$ such that

- 1) For every $i \in [1:\infty)$, (T_i, Y_i) has the distribution P_u and is independent of $c(X_i)$; and
- 2) $\{(T_i, Y_i, c(X_i))\}_{i=1}^{\infty}$ is an i.i.d. process.

Then (S_J, X_J) and (T_J, Y_J) are identically distributed. Lemma 3: Let $\{Y_i\}_{i=1}^{\infty}$ be a sequence of i.i.d. random variables taking values in a set \mathcal{Y} . For $n \in [1 : \infty)$, let J(n) be a random subset of a finite subset of $[1:\infty)$ and let J(n) be independent of $\{Y_i\}_{i=1}^{\infty}$. If $\lim_{n\to\infty} \Pr[|J(n)| > k] = 1 \text{ for all } k \in [1 : \infty),$

 $G \subseteq \mathcal{Y}^*$, and $\lim_{k\to\infty} \Pr[Y_{(k)} \in G] = 1$, then

 $\lim_{n\to\infty} \Pr[Y_{J(n)}\in G]=1.$

Lemma 4: Let d be a distortion measure on $\mathcal{X} \times \mathcal{X}$, \mathcal{S}_* be a subset of \mathcal{S} , $\delta \in [0,\infty)$, $\{s_i\}_{i=1}^n \in \mathcal{S}^n$, $\{x_i\}_{i=1}^n \in \mathcal{X}^n, \, \{\hat{x}_i\}_{i=1}^n \in \hat{\mathcal{X}}^n, \, J_* = \{i \in (n] | s_i \in \mathcal{S}_*\},$ and $\{J(u)\}_{u\in\mathcal{U}}$ be a partition of (n]. If $s_{J(u)}, x_{J(u)}$, and $\hat{x}_{J(u)}$ meet the fidelity criterion $(d, \mathcal{S}_*, \delta_u)$ for all $u \in \mathcal{U}$, and $\sum_{u\in\mathcal{U}}|J(u)\cap J_*|\delta_u\leq |J_*|\delta$, then $s_{(n]}, x_{(n]},$ and $\hat{x}_{(n]}$ meet the fidelity criterion $(d, \mathcal{S}_*, \delta)$. If $s_{J(u)}, x_{J(u)}$, and $\hat{x}_{J(u)}$ do not meet the fidelity criterion $(d, \mathcal{S}_*, \delta_u)$ for any $u \in \mathcal{U}$, and $\sum_{u \in \mathcal{U}} |J(u) \cap J_*| \delta_u \ge |J_*| \delta$, then $s_{(n]}, \ x_{(n]}$, and $\hat{x}_{(n]}$ do not meet the fidelity criterion $(d, \mathcal{S}_*, \delta).$

We omit the proofs of the lemmas because they are straightforward. Lemma 2 characterizes the distributions of the symbols in the classes. Lemma 3 helps us deal with the nuance that the number of the source symbols in a class is random. We use Lemma 4 to calculate the distortion levels $\{D(\lambda)\}_{\lambda \in \Lambda}$ of the constructed labelbased code. The direct part of Theorem 3 is proved by showing that the rate of the label-based code is close to $R^{G}(D)$.

Finally, the converse part of Theorem 3 follows from that of Theorem 2, and the direct part of Theorem 2 follows from that of Theorem 3. The reason is that we can get an $(\mathcal{X}, \hat{\mathcal{X}}, \mathcal{U}, c)$ -CTC code by assembling the labelbased code (f,φ) in the direct part of Theorem 3 and a code that compresses class labels losslessly. Formally, we have the following lemma.

Lemma 5: If (f_1, φ_1) is an $(\mathcal{X}, \hat{\mathcal{X}}, \mathcal{U})$ -label-based code, $R_1 \in [0, \infty)$, and

$$\lim_{n \to \infty} \Pr[|f_1(X_{(n]}, U_{(n]})| \le nR_1] = 1, \quad (36)$$

then there exist an $(\mathcal{X}, \hat{\mathcal{X}})$ -variable-length code (f_2, φ_2) and a function $\psi: \{0,1\}^* \to \mathcal{U}^*$ such that

1) For every $R_2 > R_1 + H(c(X))$,

$$\lim_{n \to \infty} \Pr[|f_2(X_{(n)})| \le nR_2] = 1; \quad (37)$$

2) If $n \in [\infty)$, $\{x_i\}_{i=1}^n \in \mathcal{X}^n$, and $u_i = c(x_i)$ for all $i \in (n]$, then $\psi(f_2(x_{(n]})) = u_{(n]}$ and

$$\varphi_2(f_2(x_{(n)})) = \varphi_1(f_1(x_{(n)}, u_{(n)}), u_{(n)}).$$
 (38)

The complete proofs of Theorems 2 and 3 are given in Appendix E.

V. CONCLUSION

In this paper, we have proposed subsource-dependent fidelity criteria for composite sources and solved RD problems based on these criteria. The criteria and hence the results in the paper are useful in situations where some data from an information source should be encoded more accurately than other data from the source. CTC coding is widely used in such situations. It is found in this paper that CTC coding in general has performance loss relative to RD-optimal coding, even if the classification is perfect. On the other hand, the performance loss is small for appropriately designed CTC codes. How to design practical CTC codes is left for future research.

APPENDIX A PROOF OF THEOREM 4

We can verify the following lemmas about Markov chains, and will use them in the proof.

Lemma 6: Suppose V,Y, and Z are random variables, B is a set, and $\Pr[Y \in B] > 0$. Let $(\tilde{V},\tilde{Y},\tilde{Z}) \sim \tilde{P},$ where \tilde{P} is the conditional distribution of (V,Y,Z) given $Y \in B$. If $V \leftrightarrow Y \leftrightarrow Z$, then $\tilde{V} \leftrightarrow \tilde{Y} \leftrightarrow \tilde{Z}$.

Lemma 7: Let $\mathcal Q$ be a finite set, and V_q, Y_q , and Z_q be random variables for every $q \in \mathcal Q$. Let a random variable $\mathcal Q$ take values in $\mathcal Q$ and be independent of $\{(V_q,Y_q,Z_q)\}_{q\in\mathcal Q}$. If the support sets of $\{Y_q\}_{q\in\mathcal Q}$ are disjoint, and $V_q\leftrightarrow Y_q\leftrightarrow Z_q$ for all $q\in\mathcal Q$, then $V_Q\leftrightarrow Y_Q\leftrightarrow Z_Q$.

Define functions $\{\chi_{\lambda}\}_{{\lambda}\in\Lambda}$ from Λ to $\{0,1\}$ by

$$\chi_{\lambda}(s) = \begin{cases} 1, & s \in \mathcal{S}_{\lambda}, \\ 0, & s \notin \mathcal{S}_{\lambda}. \end{cases}$$
 (39)

Then $\Xi(D)$ defined in Section II-C equals the set of random variables \hat{X} satisfying $S \leftrightarrow X \leftrightarrow \hat{X}$ and

$$E[\gamma_{\lambda}(S)d_{\lambda}(X,\hat{X})] < \Pr[S \in \mathcal{S}_{\lambda}]D(\lambda)$$
 (40)

for all $\lambda \in \Lambda$. To prove (24), we firstly prove that for every $\hat{X} \in \Xi(D)$, $I(X;\hat{X}|c(X))$ is no less than the right-hand side of (24). We then prove that

$$R^{\mathrm{G}}(D) \le \sum_{u \in \bar{\mathcal{U}}} \Pr[c(X) = u] R_u^*(\delta(\cdot, u)) + \epsilon$$
 (41)

for all $\delta \in \Delta(D)$ and $\epsilon \in (0, \infty)$.

Let $\hat{X} \in \Xi(D)$. For $u \in \bar{\mathcal{U}}$, let Q_u be the conditional distribution of (S, X, \hat{X}) given c(X) = u, and define a random tuple (T_u, Y_u, \hat{Y}_u) independent of c(X) and having the distribution Q_u . Then we have

$$I(X; \hat{X}|c(X)) = \sum_{u \in \bar{\mathcal{U}}} \Pr[c(X) = u] I(Y_u; \hat{Y}_u) \quad (42)$$

and the total expectation formula

$$E[\chi_{\lambda}(S)d_{\lambda}(X,\hat{X})]$$

$$= \sum_{u \in \mathcal{U}} \Pr[c(X) = u] E[\chi_{\lambda}(T_u)d_{\lambda}(Y_u,\hat{Y}_u)] \qquad (43)$$

for all $\lambda \in \Lambda$. For $u \in \overline{\mathcal{U}}$, we have $T_u \leftrightarrow Y_u \leftrightarrow \hat{Y}_u$ by Lemma 6. There exists a function $\delta : \Lambda \times \mathcal{U} \to [0, \infty)$ satisfying

$$E[\chi_{\lambda}(T_u)d_{\lambda}(Y_u, \hat{Y}_u)] = \Pr[T_u \in \mathcal{S}_{\lambda}]\delta(\lambda, u)$$
 (44)

for all $\lambda \in \Lambda$ and $u \in \overline{\mathcal{U}}$: Note that (44) holds true even when $\Pr[T_u \in \mathcal{S}_{\lambda}] = 0$, because the left-hand side of (44) is zero in such a case. Hence

$$I(Y_u; \hat{Y}_u) \ge R_u^*(\delta(\cdot, u)) \tag{45}$$

for all $u \in \overline{\mathcal{U}}$. We can see $\delta \in \Delta(D)$ from (40), (43), and (44). By (42), (45), and $\delta \in \Delta(D)$, we conclude that $I(X; \hat{X}|c(X))$ is no less than the right-hand side of (24).

Let $\delta \in \Delta(D)$ and $\epsilon \in (0,\infty)$. Since (41) is apparent if $R_u^*(\delta(\cdot,u)) = \infty$ for some $u \in \bar{\mathcal{U}}$, we assume $R_u^*(\delta(\cdot,u)) < \infty$ for all $u \in \bar{\mathcal{U}}$. Define a random pair $(T_u,Y_u) \sim P_u$ for every $u \in \bar{\mathcal{U}}$. There exist random variables $\{\hat{Y}_u\}_{u \in \bar{\mathcal{U}}}$ satisfying $T_u \leftrightarrow Y_u \leftrightarrow \hat{Y}_u$,

$$E[\chi_{\lambda}(T_u)d_{\lambda}(Y_u, \hat{Y}_u)] \le \Pr[T_u \in \mathcal{S}_{\lambda}]\delta(\lambda, u),$$
 (46)

and

$$I(Y_u; \hat{Y}_u) < R_u^*(\delta(\cdot, u)) + \epsilon \tag{47}$$

for all $\lambda \in \Lambda$ and $u \in \bar{\mathcal{U}}$. Further define a random variable U independent of $\{(T_u,Y_u,\hat{Y}_u)\}_{u\in\bar{\mathcal{U}}}$ and let U and c(X) be identically distributed. It is not difficult to verify that (S,X,c(X)) and (T_U,Y_U,U) are identically distributed. Consequently, we can define a random variable \hat{X} such that $(S,X,c(X),\hat{X})$ and (T_U,Y_U,U,\hat{Y}_U) are identically distributed. Then (42) still holds, and (43) still holds for all $\lambda \in \Lambda$. For $\lambda \in \Lambda$, (43), (46), and (25) imply (40). By Lemma 7 we have $T_U \leftrightarrow Y_U \leftrightarrow \hat{Y}_U$, which implies $S \leftrightarrow X \leftrightarrow \hat{X}$. Therefore,

$$R^{G}(D) < I(X; \hat{X}|c(X)). \tag{48}$$

The inequality (41) follows from (42), (47), and (48).

APPENDIX B PROOF OF THEOREM 5

We use Theorem 4 to prove (28). Define $\bar{\mathcal{U}}$, $\{P_u\}_{u\in\bar{\mathcal{U}}}$, $\{R_u^*\}_{u\in\bar{\mathcal{U}}}$, and $\Delta(D)$ as in Theorem 4. We can see $\Delta(D)$ is the set of functions $\delta:\Lambda\times\mathcal{U}\to[0,\infty)$ satisfying (25) for all $\lambda\in\bar{\Lambda}$. We have $\Lambda\cap\bar{\mathcal{U}}=\bar{\Lambda}$ because $c(X)=\lambda$ is equivalent to $S\in\mathcal{S}_\lambda$ with probability one for all $\lambda\in\Lambda$. For $\delta:\Lambda\times\mathcal{U}\to[0,\infty)$ and $\lambda\in\bar{\Lambda}$, (25) is equivalent to $\delta(\lambda,\lambda)\leq D(\lambda)$.

Fix $u \in \bar{\mathcal{U}}$ and $\tilde{D}: \Lambda \to [0, \infty)$. Define a random pair $(T, Y) \sim P_u$ and a set $\tilde{\Lambda} = \{\lambda \in \Lambda | \Pr[T \in \mathcal{S}_{\lambda}] > 0\}$. Then

$$R_u^*(\tilde{D}) = \inf_{\hat{Y} \in \tilde{\Xi}(\tilde{D})} I(Y; \hat{Y}), \tag{49}$$

where $\tilde{\Xi}(\tilde{D})$ is the set of random variables \hat{Y} satisfying $T \leftrightarrow Y \leftrightarrow \hat{Y}$ and $E[d_{\lambda}(Y,\hat{Y})|T \in \mathcal{S}_{\lambda}] \leq \tilde{D}(\lambda)$ for all $\lambda \in \tilde{\Lambda}$. Also note

$$\Pr[T \in \mathcal{S}_{\lambda}] = \Pr[c(X) = \lambda | c(X) = u]$$
 (50)

$$= \begin{cases} 1, & \lambda = u, \\ 0, & \lambda \neq u \end{cases}$$
 (51)

for $\lambda \in \Lambda$. If $u \in \bar{\Lambda}$, then $Y \sim Q_u$, $\Pr[T \in \mathcal{S}_u] = 1$, $\tilde{\Lambda} = \{u\}$, and consequently $\tilde{\Xi}(\tilde{D})$ is the set of random variables \hat{Y} satisfying $T \leftrightarrow Y \leftrightarrow \hat{Y}$ and $E[d_u(Y,\hat{Y})] \leq \tilde{D}(u)$. If $u \notin \bar{\Lambda}$, then $u \notin \Lambda$, $\tilde{\Lambda} = \emptyset$, and consequently $\tilde{\Xi}(\tilde{D})$ is the set of random variables \hat{Y} satisfying $T \leftrightarrow Y \leftrightarrow \hat{Y}$. Hence $R_u^*(\tilde{D}) = R^{(u)}(\tilde{D}(u))$ if $u \in \bar{\Lambda}$, and $R_u^*(\tilde{D}) = 0$ otherwise.

Therefore,

$$R^{\mathrm{G}}(D) = \inf_{\delta \in \Delta(D)} \sum_{u \in \bar{\Lambda}} \Pr[c(X) = u] R^{(u)}(\delta(u, u)),$$

and $\Delta(D)$ is the set of functions $\delta: \Lambda \times \mathcal{U} \to [0, \infty)$ satisfying $\delta(\lambda, \lambda) \leq D(\lambda)$ for all $\lambda \in \bar{\Lambda}$. This proves (28).

Now suppose $\bar{\Lambda}$ has only one element λ . Fix $\epsilon \in (0, \infty)$. Then there exists a random variable \hat{X} satisfying $S \leftrightarrow X \leftrightarrow \hat{X}$,

$$E[d_{\lambda}(X, \hat{X})|S \in \mathcal{S}_{\lambda}] < D(\lambda), \tag{53}$$

and

$$R^{G}(D) + \epsilon > I(X; \hat{X}|c(X)). \tag{54}$$

Let \hat{P} be the conditional distribution of \hat{X} given $c(X) = \lambda$. Let a random variable \hat{Y} have the distribution \hat{P} and be independent of (S, X, \hat{X}) . Let a random variable Z equals \hat{X} when $c(X) = \lambda$, and equals \hat{Y} when $c(X) \neq \lambda$. We will show $Z \in \Xi(D)$, which implies an upper bound for $R^*(D)$. Subtracting I(S; X) from both sides of the data processing inequality $I(S; X, \hat{X}, \hat{Y}) \geq I(S; X, Z)$, we get

$$I(S; \hat{X}|X) + I(S; \hat{Y}|X, \hat{X}) \ge I(S; Z|X).$$
 (55)

By the chain rule for mutual information,

$$I(S, X, \hat{X}; \hat{Y}) = I(X, \hat{X}; \hat{Y}) + I(S; \hat{Y}|X, \hat{X}).$$
 (56)

By (55), (56), and the fact

$$I(S; \hat{X}|X) = I(S, X, \hat{X}; \hat{Y}) = I(X, \hat{X}; \hat{Y}) = 0,$$
 (57)

we have $S \leftrightarrow X \leftrightarrow Z$. Also note (53) and

$$E[d_{\lambda}(X,Z)|S \in \mathcal{S}_{\lambda}] = E[d_{\lambda}(X,\hat{X})|S \in \mathcal{S}_{\lambda}]. \quad (58)$$

By definition, we have $Z \in \Xi(D)$, which implies

$$R^*(D) \le I(X; Z). \tag{59}$$

The data processing inequality $I(X;\hat{X},\hat{Y},c(X)) \geq I(X;Z,c(X))$, the chain rule for mutual information, $I(X;\hat{Y})=0$, and $I(X;\hat{X},c(X)|\hat{Y})=I(X;\hat{X},c(X))$ lead to

$$I(X; \hat{X}, c(X)) \ge I(X; Z, c(X)).$$
 (60)

Subtracting I(X; c(X)) from (60), we get

$$I(X; \hat{X}|c(X)) \ge I(X; Z|c(X)). \tag{61}$$

For $u \in \overline{\mathcal{U}}$, Z has the conditional distribution \hat{P} given c(X) = u, no matter $u = \lambda$ or not. Hence c(X) and Z are independent. Since I(c(X); Z) = 0, I(c(X); Z|X) = 0, and I(X; Z|c(X)) + I(c(X); Z) = I(X; Z) + I(c(X); Z|X), we have

$$I(X; Z|c(X)) = I(X; Z). \tag{62}$$

The inequality (54), (59), (61), and (62) lead to $R^{\rm G}(D)+\epsilon>R^*(D)$. Since ϵ can be an arbitrary number in $(0,\infty)$, we have proved $R^{\rm G}(D)\geq R^*(D)$.

Therefore, $R^{\mathrm{G}}(D) = R^*(D)$ if $|\bar{\Lambda}| = 1$.

APPENDIX C PROOFS OF LEMMAS

A. Lemma 1

For $n \in [1:\infty)$, since $M_n \leq 2^{\lceil nR \rceil}$, there exist functions $\alpha_n : (M_n] \to \{0,1\}^{\lceil nR \rceil}$ and $\beta_n : \{0,1\}^{\lceil nR \rceil} \to (M_n]$ satisfying $\beta_n(\alpha_n(m)) = m$ for all $m \in (M_n]$. Define $f: \mathcal{X}^* \to \{0,1\}^*$ by

$$f(\mathbf{x}) = \begin{cases} \text{the empty string,} & |\mathbf{x}| = 0, \\ \gamma(|\mathbf{x}|)\alpha_{|\mathbf{x}|}(f_{|\mathbf{x}|}(\mathbf{x})), & |\mathbf{x}| > 0, \end{cases}$$
(63)

where $\gamma(|x|)$ is the compound representation of |x| (see Section IV-A). Since γ is prefix-free, there exists a function $\varphi:\{0,1\}^*\to\hat{\mathcal{X}}^*$ that maps the empty string to the empty string and satisfies $\varphi(\gamma(n)b)=\varphi_n(\beta_n(b))$ for all $n\in[1:\infty)$ and $b\in\{0,1\}^{\lceil nR\rceil}$. We can see $\varphi(f(x))=\varphi_{|x|}(f_{|x|}(x))$ for all non-empty strings $x\in\mathcal{X}^*$. Also note that $\varphi(f(\text{the empty string}))$ is the empty string. Therefore, (f,φ) is an $(\mathcal{X},\hat{\mathcal{X}})$ -variable-length code. For $n\in[1:\infty)$ and $x\in\mathcal{X}^n$, we have $|\gamma(n)|\leq 1+2\log_2(n), |\alpha_n(f_n(x))|< nR+1$, and consequently $|f(x)|<2+2\log_2(n)+nR$. This proves (35).

B. Lemma 5

By basic information theory results, there exists a \mathcal{U} -lossless code $(f_{\rm L}, \varphi_{\rm L})$ such that

$$\lim_{n \to \infty} \Pr[|f_{\mathcal{L}}(U_{(n)})| \le nR_{\mathcal{L}}] = 1 \tag{64}$$

for all $R_L > H(c(X))$. For $n \in [\infty)$ and $\{x_i\}_{i=1}^n \in \mathcal{X}^n$, let

$$f_2(x_{(n]}) = \gamma(|f_L(u_{(n]})| + 1)f_L(u_{(n]})f_1(x_{(n]}, u_{(n]}),$$
(65)

where γ denotes the compound representation introduced in Section IV-A, and $u_i = c(x_i)$ for all $i \in (n]$. Define $\varphi_2 : \{0,1\}^* \to \hat{\mathcal{X}}^*$ and $\psi : \{0,1\}^* \to \mathcal{U}^*$ such that

$$\varphi_2(\gamma(l+1)b_{(m)}) = \varphi_1(b_{(l:m)}, \varphi_L(b_{(l)}))$$
 (66)

and $\psi(\gamma(l+1)b_{(m]})=\varphi_{\mathbf{L}}(b_{(l]})$ hold for all $l\in [\infty), m\in [l:\infty)$, and $\{b_i\}_{i=1}^m\in \{0,1\}^m$. This is possible because γ is prefix-free. If $n\in [\infty), \{x_i\}_{i=1}^n\in \mathcal{X}^n$, and $u_i=c(x_i)$ for all $i\in (n]$, then we can verify $\psi(f_2(x_{(n]}))=u_{(n]}$ and (38).

Fix $R_2 > R_1 + H(c(X))$. Then there exists a value $R_{\rm L}$ satisfying $R_{\rm L} > H(c(X))$ and $R_1 + R_{\rm L} < R_2$. Equation (37) follows from (34), (36), (64), (65), and $R_1 + R_{\rm L} < R_2$.

APPENDIX D PROOF OF THEOREM 1

A. Direct Part

Let $R > R^*(D)$. Define functions $\{d_{\lambda,\delta}\}_{\lambda \in \Lambda, \delta \in \mathbb{R}}$ by (32).

By Proposition 1 in [14] and Corollary 7, there exist sequences $\{M_n\}_{n=1}^{\infty}$, $\{f_n\}_{n=1}^{\infty}$, and $\{\varphi_n\}_{n=1}^{\infty}$ such that

- 1) For every $n \in [1 : \infty)$, $M_n \leq 2^{nR^*(D)}$ is a positive integer, f_n is a function from \mathcal{X}^n to $(M_n]$, and φ_n is a function from $(M_n]$ to $\hat{\mathcal{X}}^n$; and
- 2) For every $\lambda \in \Lambda$ and $\epsilon \in (0, \infty)$, the probability that

$$\frac{1}{n}\sum_{i=1}^{n}d_{\lambda,D(\lambda)}(X_{i},\hat{X}_{n,i},S_{i}) \le D(\lambda) + \epsilon \quad (67)$$

tends to 1 as $n \to \infty$, where $\hat{X}_{n,i}$ is defined by $\{\hat{X}_{n,i}\}_{i=1}^n = \varphi_n(f_n(X_{(n]}))$.

By Lemma 1, there exists an $(\mathcal{X}, \hat{\mathcal{X}})$ -variable-length code (f, φ) satisfying (9) and $\varphi(f(\boldsymbol{x})) = \varphi_{|\boldsymbol{x}|}(f_{|\boldsymbol{x}|}(\boldsymbol{x}))$ for all non-empty strings $\boldsymbol{x} \in \mathcal{X}^*$. Hence there exists $n_1 \in [1:\infty)$ such that $|f(\boldsymbol{x})| \leq nR$ for all integers $n > n_1$ and $\boldsymbol{x} \in \mathcal{X}^n$. We then have

$$\lim_{n \to \infty} \Pr[|f(X_{(n)})| \le nR] = 1. \tag{68}$$

We now analyze the distortion of (f,φ) . Fix $\lambda \in \bar{\Lambda}$ and $\epsilon \in (0,\infty)$. Since $\Pr[S \in \mathcal{S}_{\lambda}] > 0$, the probability that

$$\frac{1}{n} \sum_{i=1}^{n} d_{\lambda, D(\lambda)}(X_i, \hat{X}_{n,i}, S_i) \le D(\lambda) + \frac{\epsilon}{2} \Pr[S \in \mathcal{S}_{\lambda}]$$
(69)

tends to 1 as $n \to \infty$. Define a function $\chi_{\lambda} : \mathcal{S} \to \{0,1\}$ by (39). Then

$$d_{\lambda,D(\lambda)+\epsilon}(X_i, \hat{X}_{n,i}, S_i) = d_{\lambda,D(\lambda)}(X_i, \hat{X}_{n,i}, S_i) + \epsilon - \epsilon \chi_{\lambda}(S_i)$$
(70)

with probability one for all integers n and i satisfying $0 < i \le n$. By the law of large numbers, the probability that

$$\frac{1}{n} \sum_{i=1}^{n} \chi_{\lambda}(S_i) \ge \frac{1}{2} \Pr[S \in \mathcal{S}_{\lambda}] \tag{71}$$

tends to 1 as $n \to \infty$. If (70) holds for all $i \in (n]$ with $n \in [1 : \infty)$, (69) holds, and (71) holds, then we have

$$\frac{1}{n} \sum_{i=1}^{n} d_{\lambda, D(\lambda) + \epsilon}(X_i, \hat{X}_{n,i}, S_i) \le D(\lambda) + \epsilon, \quad (72)$$

which implies that $S_{(n]}$, $X_{(n]}$, and $\varphi(f(X_{(n]}))$ meet the fidelity criterion $(d_{\lambda}, \mathcal{S}_{\lambda}, D(\lambda) + \epsilon)$. Therefore, the probability with which $S_{(n]}$, $X_{(n]}$, and $\varphi(f(X_{(n]}))$ meet the fidelity criterion $(d_{\lambda}, \mathcal{S}_{\lambda}, D(\lambda) + \epsilon)$ tends to 1 as $n \to \infty$.

For $\lambda \in \Lambda \setminus \bar{\Lambda}$, $\epsilon \in (0, \infty)$, and $n \in [1 : \infty)$, because $S_i \notin \mathcal{S}_{\lambda}$ with probability one for all $i \in (n]$, the probability with which $S_{(n]}, X_{(n]}$, and $\varphi(f(X_{(n]}))$ meet the fidelity criterion $(d_{\lambda}, \mathcal{S}_{\lambda}, D(\lambda) + \epsilon)$ is 1. In conclusion, this probability tends to 1 as $n \to \infty$ for all $\lambda \in \Lambda$ and $\epsilon \in (0, \infty)$. This fact and (68) lead to the conclusion that (f, φ) achieves (R, D) for (S, X) and $\{(d_{\lambda}, \mathcal{S}_{\lambda})\}_{\lambda \in \Lambda}$.

B. Converse Part

Suppose an $(\mathcal{X}, \hat{\mathcal{X}})$ -variable-length code (f, φ) achieves (R, D) for (S, X) and $\{(d_{\lambda}, \mathcal{S}_{\lambda})\}_{\lambda \in \Lambda}$.

We firstly fix an arbitrary $n \in [1:\infty)$ and define a block code. Let M_n be the number of the bit strings in $f(\mathcal{X}^n)$ whose length does not exceed nR. There exists functions $f_n: \mathcal{X}^n \to (M_n]$ and $\varphi_n: (M_n] \to \hat{\mathcal{X}}^n$ such that for every $x \in \mathcal{X}^n$, if $|f(x)| \leq nR$, then $\varphi_n(f_n(x)) = \varphi(f(x))$. Since

$$M_n \le \sum_{l=0}^{\lfloor nR \rfloor} 2^l = 2^{\lfloor nR \rfloor + 1} - 1 \le 2^{nR + 1},$$
 (73)

the rate $\log_2(M_n)/n$ of the block code (f_n, φ_n) does not exceed R + 1/n.

Now we analyze the distortion of the block codes. Fix $\lambda \in \Lambda$ and $\epsilon \in (0, \infty)$. For $n \in [1 : \infty)$, define the following sets:

- F_n the set of $(s, x) \in S^n \times \mathcal{X}^n$ such that s, x, and $\varphi(f(x))$ meet the fidelity criterion $(d_\lambda, S_\lambda, D(\lambda) + \epsilon)$; and
- G_n the set of $(\{s_i\}_{i=1}^n, \{x_i\}_{i=1}^n) \in \mathcal{S}^n \times \mathcal{X}^n$ such that $\{\hat{x}_i\}_{i=1}^n = \varphi_n(f_n(x_{(n)}))$ satisfies

$$\frac{1}{n} \sum_{i=1}^{n} d_{\lambda, D(\lambda)}(x_i, \hat{x}_i, s_i) \le D(\lambda) + \epsilon. \tag{74}$$

For $n \in [1:\infty)$ and $(\{s_i\}_{i=1}^n, \{x_i\}_{i=1}^n)$, if $(s_{(n]}, x_{(n]}) \in F_n$, $|f(x_{(n]})| \le nR$, and $\{\hat{x}_i\}_{i=1}^n = \varphi_n(f_n(x_{(n]}))$, then we have $\{\hat{x}_i\}_{i=1}^n = \varphi(f(x_{(n)}))$,

$$\frac{1}{n} \sum_{i=1}^{n} d_{\lambda, D(\lambda) + \epsilon}(x_i, \hat{x}_i, s_i) \le D(\lambda) + \epsilon, \tag{75}$$

and consequently $(s_{(n]}, x_{(n]}) \in G_n$ by the discussions in Section IV-A and the fact that

$$d_{\lambda,D(\lambda)}(x,\hat{x},s) \le d_{\lambda,D(\lambda)+\epsilon}(x,\hat{x},s) \tag{76}$$

for all $x \in \mathcal{X}$, $\hat{x} \in \hat{\mathcal{X}}$, and $s \in \mathcal{S}$. Hence for $n \in [1:\infty)$, we have $(S_{(n]}, X_{(n]}) \in G_n$ whenever $(S_{(n]}, X_{(n]}) \in F_n$ and $|f(X_{(n]})| \leq nR$. Also note that $\Pr[(S_{(n]}, X_{(n]}) \in F_n]$ and $\Pr[|f(X_{(n]})| \leq nR]$ tend to 1 as $n \to \infty$. Therefore

$$\lim_{n \to \infty} \Pr[(S_{(n]}, X_{(n]}) \in G_n] = 1.$$
 (77)

The inequality $R \geq R^*(D)$ follows from Proposition 1 in [14] and Corollary 7.

$\begin{array}{c} \text{Appendix E} \\ \text{Proof of Theorems 2 and 3} \end{array}$

In Section IV-B we have seen that the converse part of Theorem 2 implies that of Theorem 3. Also, the direct part of Theorem 3 implies that of Theorem 2. Therefore, we only need to prove the converse part of Theorem 2 and the direct part of Theorem 3.

A. Converse Part of Theorem 2

Suppose an $(\mathcal{X}, \hat{\mathcal{X}})$ -variable-length code (f, φ) achieves (R, D) for (S, X) and $\{(d_{\lambda}, \mathcal{S}_{\lambda})\}_{\lambda \in \Lambda}$, ψ is a function from $\{0, 1\}^*$ to \mathcal{U}^* , and $\psi(f(X_{(n]})) = U_{(n]}$ with probability one for all $n \in [\infty)$.

Define $\tilde{\lambda}$, $\tilde{\Lambda}$, $\{\tilde{d}_{\lambda}\}_{\lambda \in \tilde{\Lambda}}$, $\{\tilde{\mathcal{S}}_{\lambda}\}_{\lambda \in \tilde{\Lambda}}$, \tilde{R} , and \tilde{D} as in Corollary 4. For $\boldsymbol{b} \in \{0,1\}^*$, let $\tilde{\varphi}(\boldsymbol{b}) = \{(\hat{x}_i,\hat{u}_i)\}_{i=1}^n$, where $\{\hat{x}_i\}_{i=1}^n = \varphi(\boldsymbol{b})$ and $\{\hat{u}_i\}_{i=1}^n = \psi(\boldsymbol{b})$.

Fix $\epsilon \in (0, \infty)$. For $\lambda \in \Lambda$ and $n \in [\infty)$, let $p_{\lambda,n}$ denote the probability with which $S_{(n]}$, $X_{(n]}$, and $\varphi(f(X_{(n]}))$ meet the fidelity criterion $(d_{\lambda}, \mathcal{S}_{\lambda}, D(\lambda) + \epsilon)$.

For $\lambda \in \tilde{\Lambda}$ and $n \in [\infty)$, let $\tilde{p}_{\lambda,n}$ denote the probability with which $S_{(n]}, X_{(n]}$, and $\tilde{\varphi}(f(X_{(n)}))$ meet the fidelity criterion $(\tilde{d}_{\lambda}, \tilde{S}_{\lambda}, \tilde{D}(\lambda) + \epsilon)$. Then for $\lambda \in \Lambda$, $\tilde{p}_{\lambda,n} = p_{\lambda,n} \to 1$ as $n \to \infty$. For $n \in [\infty)$, because $\psi(f(X_{(n)})) = U_{(n)}$ with probability one, $\tilde{p}_{\tilde{\lambda},n} = 1$. In short, $\tilde{p}_{\lambda,n} \to 1$ as $n \to \infty$ for all $\lambda \in \tilde{\Lambda}$.

Also note that $\Pr[|f(X_{(n)})| \leq nR] \to 1$ as $n \to \infty$. Therefore, the $(\mathcal{X}, \hat{\mathcal{X}} \times \mathcal{U})$ -variable-length code $(f, \tilde{\varphi})$ achieves (R, \tilde{D}) for (S, X) and $\{(\tilde{d}_{\lambda}, \tilde{\mathcal{S}}_{\lambda})\}_{\lambda \in \tilde{\Lambda}}$. By the converse part of Theorem 1, we have $R \geq \tilde{R}(\tilde{D})$, i.e. $R > R^{\mathrm{C}}(D)$.

B. Direct Part of Theorem 3

Suppose $R > R^{G}(D)$.

Define $\bar{\mathcal{U}}$, $\{P_u\}_{u\in\bar{\mathcal{U}}}$, and $\{R_u^*\}_{u\in\bar{\mathcal{U}}}$ as in Theorem 4. By Theorem 4, there exists a function $\delta:\Lambda\times\mathcal{U}\to[0,\infty)$ satisfying $\sum_{u\in\bar{\mathcal{U}}}\Pr[c(X)=u]R_u^*(\delta(\cdot,u))< R$ and (25) for all $\lambda\in\Lambda$. Then there exist $\{q_u\}_{u\in\mathcal{U}}$ and $\{R_u\}_{u\in\mathcal{U}}$ satisfying

$$\sum_{u \in \bar{\mathcal{U}}} q_u R_u < R,\tag{78}$$

 $\begin{array}{lll} \Pr[c(X) = u] &< q_u, \text{ and } R_u^*(\delta(\cdot,u)) &< R_u \text{ for all } u \in \bar{\mathcal{U}}. \text{ For } u \in \bar{\mathcal{U}}, \text{ by the direct part of Theorem 1, there exists an } (\mathcal{X},\hat{\mathcal{X}})\text{-variable-length code } (f_u,\varphi_u) \text{ achieving } (R_u,\delta(\cdot,u)) \text{ for a } P_u\text{-distributed random pair (see Theorem 4) and } \{(d_\lambda,\mathcal{S}_\lambda)\}_{\lambda\in\Lambda}. \text{ For } u \in \mathcal{U}\setminus\bar{\mathcal{U}}, \text{ define } f_u:\mathcal{X}^*\to\{0,1\}^* \text{ by } f_u(x)=\gamma(|x|+1), \text{ and let } \varphi_u:\{0,1\}^*\to\hat{\mathcal{X}}^* \text{ satisfy } \varphi_u(\gamma(k+1))\in\hat{\mathcal{X}}^k \text{ for all } k\in[\infty), \text{ where } \gamma \text{ is the compound representation introduced in Section IV-A. Then } \{(f_u,\varphi_u)\}_{u\in\mathcal{U}} \text{ are } (\mathcal{X},\hat{\mathcal{X}})\text{-variable-length codes. These variable-length codes will be combined to form the desired label-based code. Let } \mu(i) \text{ denote the } i\text{-th element of the set } \mathcal{U}\text{:} \text{ That is, } \mathcal{U} = \{\mu(1),\mu(2),\cdots,\mu(|\mathcal{U}|)\}. \text{ For } n\in[\infty), \\ \{x_i\}_{i=1}^n\in\mathcal{X}^n, \text{ and } \{u_i\}_{i=1}^n\in\mathcal{U}^n, \text{ let } f(x_{(n]},u_{(n]}) = b_{\mu(1)}b_{\mu(2)}\cdots b_{\mu(|\mathcal{U}|)}, \text{ where } J(u) = \{i\in(n]|u_i=u\} \text{ and } \mathcal{U} \text{ and } \mathcal{U} \text{ for } \mathcal{U} \text{ and } \mathcal{U} \text{ of } \mathcal{U} \text{ and } \mathcal{U} \text{ of } \mathcal{U} \text{ of$

$$\boldsymbol{b}_{u} = \begin{cases} \gamma(|f_{u}(x_{J(u)})| + 1)f_{u}(x_{J(u)}), & u \in \bar{\mathcal{U}}, \\ f_{u}(x_{J(u)}), & u \notin \bar{\mathcal{U}} \end{cases}$$
(79)

for all $u \in \mathcal{U}$. Since γ is prefix-free, the bit strings $\{f_u(x_{J(u)})\}_{u \in \mathcal{U}}$ can be recovered from $f(x_{(n]}, u_{(n]})$. Hence there exists a function $\varphi : \{0,1\}^* \times \mathcal{U}^* \to \hat{\mathcal{X}}^*$ such that

- 1) (f, φ) is an $(\mathcal{X}, \hat{\mathcal{X}}, \mathcal{U})$ -label-based code; and
- 2) If $n \in [\infty)$ and (10) hold, then $\hat{x}_{J(u)} = \varphi_u(f_u(x_{J(u)}))$ for all $u \in \mathcal{U}$, where $J(u) = \{i \in (n] | u_i = u\}$.

Define

$$\{\hat{X}_{i}^{(n)}\}_{i=1}^{n} = \varphi(f(X_{(n]}, U_{(n]}), U_{(n]})$$
 (80)

and $J(n,u)=\{i\in(n]|U_i=u\}$ for $n\in[1:\infty)$ and $u\in\mathcal{U}.$ Then

$$|f(X_{(n]}, U_{(n]})| = \sum_{u \in \mathcal{U} \setminus \bar{\mathcal{U}}} |\gamma(|J(n, u)| + 1)|$$

$$+ \sum_{u \in \bar{\mathcal{U}}} |\gamma(|f_u(X_{J(n, u)})| + 1)| + \sum_{u \in \bar{\mathcal{U}}} |f_u(X_{J(n, u)})|$$
(81)

with probability one for all $n \in [1:\infty)$, and

$$\hat{X}_{J(n,u)}^{(n)} = \varphi_u(f_u(X_{J(n,u)}))$$
 (82)

with probability one for all $n \in [1 : \infty)$ and $u \in \mathcal{U}$.

We now analyze the performance of (f, φ) . Fix $u \in \overline{\mathcal{U}}$ and $\epsilon \in (0, \infty)$. Define random pairs $\{(T_i, Y_i)\}_{i=1}^{\infty}$ as in Lemma 2. Then

$$\lim_{k \to \infty} \Pr[(T_{(k)}, Y_{(k)}) \in F_{u,\epsilon}] = 1, \tag{83}$$

where $F_{u,\epsilon}$ is the set of $(s,x) \in \mathcal{S}^* \times \mathcal{X}^*$ such that $|f_u(x)| \leq |x|R_u$ and that s, x, and $\varphi_u(f_u(x))$ meet the fidelity criterion $(d_\lambda, \mathcal{S}_\lambda, \delta(\lambda, u) + \epsilon)$ for all $\lambda \in \Lambda$. By Lemma 3 we have

$$\lim_{n \to \infty} \Pr[(T_{J(n,u)}, Y_{J(n,u)}) \in F_{u,\epsilon}] = 1.$$
 (84)

By Lemma 2, $(S_{J(n,u)}, X_{J(n,u)})$ and $(T_{J(n,u)}, Y_{J(n,u)})$ are identically distributed for all $n \in [1:\infty)$. Hence

$$\lim_{n \to \infty} \Pr[(S_{J(n,u)}, X_{J(n,u)}) \in F_{u,\epsilon}] = 1.$$
 (85)

By the law of large numbers, the probability of $|J(n,u)| \le nq_u$ also tends to 1 as $n \to \infty$. Hence

$$\lim_{n \to \infty} \Pr[|f_u(X_{J(n,u)})| \le nq_u R_u] = 1.$$
 (86)

Fix $\lambda \in \bar{\Lambda}$ and $\epsilon \in (0, \infty)$. Define $J_n = \{i \in (n] | S_i \in S_{\lambda}\}$ for $n \in [1 : \infty)$. By (25) and the law of large numbers, the probability that

$$\sum_{u \in \mathcal{U}} |J(n, u) \cap J_n| \left(\delta(\lambda, u) + \frac{\epsilon}{2} \right) \le |J_n| (D(\lambda) + \epsilon)$$
(87)

tends to 1 as $n \to \infty$. Also note that, for every $u \in \mathcal{U}$, the probability with which $S_{J(n,u)}$, $X_{J(n,u)}$, and $\varphi_u(f_u(X_{J(n,u)}))$ meet the fidelity criterion $(d_\lambda, \mathcal{S}_\lambda, \delta(\lambda, u) + \epsilon/2)$ tends to 1 as $n \to \infty$. By (80), (82), and Lemma 4, the probability with which $S_{(n]}, X_{(n]}$, and $\varphi(f(X_{(n]}, U_{(n]}), U_{(n]})$ meet the fidelity criterion $(d_\lambda, \mathcal{S}_\lambda, D(\lambda) + \epsilon)$ tends to 1 as $n \to \infty$.

Furthermore, $\lim_{n\to\infty}\Pr[|f(X_{(n]},U_{(n]})|\leq nR]=1$ follows from (34), (78), (81), and (86). Therefore, (f,φ) achieves (R,D) for (S,X) and $\{(d_\lambda,\mathcal{S}_\lambda)\}_{\lambda\in\Lambda}$ given c(X).
