ABSTRACT: Motivated by the ion-collision program at the Large Hadron Collider, plans for its high-luminosity upgrade, and on-going discussions for multi-TeV future hadron colliders, we systematically investigate hardscattering, Standard Model processes in many-TeV ion-ion collisions. We focus on the symmetric beam configurations ²⁰⁸Pb-²⁰⁸Pb, ¹³¹Xe-¹³¹Xe, ¹²C-¹²C, and *pp*, and we catalog total and fiducial cross sections for dozens of processes, ranging from associated-Higgs and multiboson production to associated-top pair production, at nextto-leading order in QCD for nucleon-nucleon collision energies from $\sqrt{s_{NN}} = 1$ to 100 TeV. We report the residual scale uncertainties at this order as well as the uncertainties originating from fits of nuclear parton densities. We also discuss the propagation of nuclear dynamics (as encoded in nuclear parton densities) into parton luminosities, and ultimately into predictions for cross sections. Finally, we report on the emergence of trends and the reliability of extrapolating cross sections across different nuclei.

1 Introduction

High-intensity collisions between nuclei at center-of-mass energies of many TeVs is an immensely powerful probe of the partonic structure of nuclei and the interplay of different dynamics [1–7]. The latter includes nucleuslevel dynamics, non-perturbative dynamics at the level of individual nucleons/hadrons, as well as perturbative contributions at the partonic level. Such typical QCD interactions at the three levels are illustrated in Fig. 1. Modern fits of nuclear parton density functions (nPDFs) to data from lepton-nucleus deep-inelastic scattering (DIS) experiments and nucleus-nucleus (or nucleus-proton) collision experiments show clearly that the structure of heavy, medium, and light nuclei differ both qualitatively and quantitatively from that of the proton [8–18]. We refer to Refs. [19–22] for recent reviews on nPDFs and the associated phenomenology.

At the level of scattering cross sections, differences between nucleus-nucleus collisions and proton-proton collisions are further accentuated by several additional effects. For example: the number of nucleons (A) in a nucleus; the impact of Dokshitzer-Gribov-Lipatov-Altarelli-Parisi (DGLAP) scale evolution; kinematic/phase space requirements (like strong cuts imposed on the transverse momentum $[p_T]$ and the rapidity [y] of particles produced in the hard-scattering process); and the opening of possibly important partonic sub-channels at next-toleading order (NLO) in perturbation theory and beyond. The consequence is that we cannot naively extrapolate scattering rates and kinematic distributions of high-energy processes in many-TeV nuclear collisions from protonproton collisions in a trivial but justified way.

Figure 1. Typical QCD dynamics at (a) the parton level, *e.g.*, QCD emission by one of the constituting partons of a specific nucleon, (b) the nucleon level, *e.g.*, parton exchange between several of the constitute partons of a given nucleon), and (c) the nucleus level, *e.g.*, pion exchange between two nucleons.

Motivated by the ion collision programs at the Relativistic Heavy Ion Collider (RHIC) and the Large Hadron Collider (LHC), operation plans at the LHC's high-luminosity upgrade (HL-LHC) [6, 7], and long-term community discussions regarding ion activities at a hypothetical future circular collider at even higher energies [4, 5], we explore the aforementioned interplay by systematically cataloging the scattering rates of dozens¹ of hard-scattering / high-momentum-transfer processes in many-TeV nucleus-nucleus collisions for various nuclei. As a first step in this program, we focus on the symmetric beam configurations 208 Pb- 208 Pb, 131 Xe- 131 Xe, 12 C- 12 C, and (for reference) *pp*. While Pb-Pb and Xe-Xe collisions have been demonstrated at the LHC, the choice of C-C collisions is motivated by plans for 16 O collisions at the LHC [4, 5]. Presently, the knowledge of nPDFs for 12 C is far superior to that of 16 O due to the availability of neutrino DIS data on hydrocarbons (mineral oil) [19–22]. Therefore, due to their proximity on the period table and island of stability, 12 C is taken as a proxy for 16 O.

We consider Standard Model processes ranging from single and multiboson boson production to Higgs- and top-associated production channels. Throughout this work, we assume that the Collinear Factorization Theorem for hard, inclusive proton collisions can also describe the inclusive production of heavy states in nuclear collisions. (The observation of $t\bar{t}$ pairs in nucleus-nucleus and proton-nucleus collisions supports this assumption [23–25].) However, due to the subtleties of defining jets in a medium, we do not consider processes with high- p_T jets at Born level. Furthermore, we carry out this work up to NLO in quantum chromodynamics (QCD) for nucleon-nucleon collision energies spanning the range $\sqrt{s_{NN}} = 1 - 100$ TeV.

The remainder of this study continues in the following manner: In Sec. 2 we describe the computational setup and tool chain on which our calculations are based. We then review the differences between nPDFs at different scales by comparing and contrasting PDFs of individual parton species in Sec. 3 and parton luminosities in Sec. 4. Our main results are reported in Sec. 5, where we present various cross sections and ratios of cross sections for the processes of interest. We take special care to report theoretical uncertainties wherever available. In Sec. 6 we discuss qualitatively and quantitatively the reliability of extrapolating cross sections for one pair of nuclei from predictions for a second pair of nuclei. Finally, we summarize our findings and conclude in Sec. 7.

2 Computational Setup

Calculations of total cross sections for nucleon-nucleon collisions (as driven by nucleus-nucleus collisions) relies on the MADGRAPH5AMC@NLO (MG5AMC) framework [26, 27], version 3.4.2, and its built-in implementation of the Standard Model. For each of the processes that we consider, rates are calculated at leading order (LO) and NLO in QCD. Hard-scattering matrix elements are convolved with the CT18NLO (lhaid=14400) parton densities [28] for *pp* collisions, while different NLO sets of the nCTEQ15HQ parton densities [9, 16] are used for Pb-Pb (nCTEQ15HQ_FullNuc_208_82), Xe-Xe (nCTEQ15HQ_FullNuc_131_54), and C-C (nCTEQ15HQ_FullNuc_12_6)

¹For a full list of all 42 processes, see Tables 1, 2, 3, and 4 in Sec. 5.9.

collisions. Like other fitting groups, the nCTEQ collaboration does not provide LO nPDFs, meaning that we compute LO cross sections with NLO nPDFs. Access to the PDF and nPDF libraries is provided in an automated manner through the LHAPDF6 package [29]. These libraries also handle the running of the strong coupling constant $\alpha_s(\mu_r)$ and DGLAP evolution.

We choose our central ($\zeta = 1$) collinear factorization (μ_f) and renormalization (μ_r) scales to be half the sum of the transverse energy of final-state particles (k) (dynamical_scale_choice=-1):

$$\mu_f, \ \mu_r = \zeta \times \mu_0, \quad \text{where} \quad \mu_0 \equiv \frac{1}{2} \sum_k \sqrt{m_k^2 + p_{Tk}^2} \ .$$
(2.1)

We include theoretical uncertainties originating from two distinct sources. Scale uncertainties are estimated through the so-called nine-point method, which consists of varying ζ discretely and independently over the range $\zeta \in \{0.5, 1.0, 2.0\}$. PDF uncertainties are evaluated with the Hessian method, as required when using the CT18 and nCTEQ15HQ parton densities [9, 30]. In these cases, the PDF libraries are shipped with an orthogonal set of n pairs of PDF eigenvectors, which allows for a determination of the PDF error $\Delta \sigma_{PDF}$ through the formula

$$\Delta \sigma_{\rm PDF} = \sqrt{\sum_{i=1}^{n} \left[\max\left(|\sigma_{+i} - \sigma_0|, |\sigma_{-i} - \sigma_0| \right) \right]^2}, \tag{2.2}$$

where σ_0 stands for the cross section value obtained when using the best PDF fit. For concreteness, we present PDF uncertainties at the 68% confidence level (CL).

Accessibility: In accordance with Findable, Accessible, Interoperable, Reusable (FAIR) principles, our simulation scripts, cross sections, and plotting routines are available from the public repository:

https://gitlab.cern.ch/riruiz/public-projects/-/tree/master/IonsNLO.

3 Parton Densities

Before presenting our survey of cross sections in Sec. 5, we start with a review of parton densities for our representative nuclei. We focus on the four nuclei:

²⁰⁸Pb, ¹³¹Xe, ¹²C, and ¹H (proton),
$$(3.1)$$

which span over two orders of magnitude in atomic mass number (A) and nearly two in atomic number / proton charge (Z). We do so for the following reasons: First, the LHC and its detector experiments were designed for high-energy ²⁰⁸Pb collisions [31, 32]. The experimental collaborations will continue to collect lead collision data well into the high-luminosity era. It is therefore pragmatic and beneficial to focus on predictions for such collisions. Second, during Run II, a ¹³¹Xe program was initiated at the LHC [33]. Like lead, the xenon program is slated to continue, so providing predictions is in order. Next, there are plans to initiate an ¹⁶O program at the LHC [6, 7]. However, at the moment, the oxygen data available for nPDF fits are limited. This is a qualitatively different situation for oxygen's nearby neighbor, ¹²C, for which there is a plethora of data from neutrino deep-inelastic scattering on hydrocarbons [8, 34–37]. Consequently, we use carbon as a proxy for oxygen. Finally, the proton allows us to define a normalization in ratios that isolate nuclear dynamics from hadronic dynamics; predictions for (unbounded) protons will be used as a reference throughout our study.

The precise nPDFs we use are listed in Sec. 2 and consists of nCTEQ15HQ densities, which we analyze in detail in Sec. 3.1. Importantly, the nCTEQ15HQ distributions are fit to heavy quark and quarkonium data that place strong constraints on the gluon nPDF down to $x \sim 10^{-5}$ [16]. In order to further quantify uncertainties associated with nPDF modeling, we compare our nPDFs choices to those from contemporary families in Sec. 3.2.

3.1 Nuclear parton densities

In this section, we delve into the characteristics of the collinear parton densities (f) that go into our study. In the two figures shown in Fig. 2, the top panel serves as our starting point, depicting the quantity xf(x) per nucleon

Figure 2. Top panel: For a collinear factorization scale of $Q = \sqrt{10}$ GeV ≈ 3.2 GeV [2(a)] and 10 GeV [2(b)], the quantity xf(x) per nucleon as function of (averaged) nucleon momentum fraction x for the gluon (g), up quark (u), down quark (d), and sea quark (q_{sea}) contributions to ²⁰⁸Pb. Band thickness corresponds to the nPDF uncertainty at 68% CL. Lower three panels: the ratio of xf(x) per nucleon relative to the corresponding quantity in the proton for ²⁰⁸Pb (second panel), ¹³¹Xe (third panel) and ¹²C (fourth panel).

as a function of the averaged momentum fraction x of a parton within a nucleon.² The utility of quantifying nPDFs in terms of the weighted densities "xf(x)" stems from its robustness / invariance against rescaling:

$$x_N f^N(x_N) = (x_A A) \left(\frac{1}{A} f^A(x_A)\right) = x_A f^A(x_A) ,$$
 (3.2)

where we have affixed A and N labels to denote nucleus- and nucleon-level quantities. This means that the weighted density per nucleon is the same weighted density at the nucleus level. Throughout the remainder of this study, we focus on nucleon-level quantities, which we denote as x and f(x) for brevity, unless needed for clarity.

The contributions of the gluon (g), up quark (u), down quark (d), and sea quark (q_{sea}) densities for ²⁰⁸Pb are displayed at a collinear factorization scale of $Q = \sqrt{10}$ GeV ≈ 3.2 GeV [Fig. 2(a)] and 10 GeV [Fig. 2(b)]. Here, the sea quark distribution is defined as the sum of all quark and antiquark species in the $n_f = 5$ flavor number scheme, minus the u and d valence distributions u_v and d_v . Explicitly, these distributions are given by

$$q_{\text{sea}} = (u - u_v) + \overline{u} + (d - d_v) + \overline{d} + s + \overline{s} + c + \overline{c} + b + \overline{b}, \qquad (3.3a)$$

where
$$u_v = u - \overline{u}, \quad d_v = d - \overline{d}$$
. (3.3b)

²It is important to note that the averaged momentum fraction of a parton within a nucleon covers the domain $x \in [0, A]$, with a strong suppression for x > 1. This quantity is related to the momentum fraction of a parton in the whole nucleus $x_A \in [0, 1]$ by $x = A \cdot x_A$. For further discussion on momentum rescaling in nuclei, see Ref. [38].

We neglect contributions from the top quark and the photon as partons of nuclei due to their absence in nPDFs fits. Finally, the band thickness corresponds to the nPDF uncertainty at 68% CL. In the second panel from the top, we show the ratio of xf(x) per nucleon for ²⁰⁸Pb and ¹H, *i.e.*, xf(x) of the proton. Similarly, the third and bottom panels display the same ratio with respect to the proton's densities but for ¹³¹Xe and ¹²C respectively.

We focus first on the $Q = \sqrt{10}$ GeV ≈ 3.2 GeV case [2(a)], which corresponds roughly to the low-energy boundary at which PDFs and perturbative QCD are meaningfully defined. For lead, we report that the weighted density $xf_g(x)$ for the gluon reaches $xf(x) \sim 5$ (2) for $x \sim 10^{-2}$ (10⁻¹) and with uncertainties at the 10% – 15% level for $x \leq 10^{-2}$. The sea quark distribution is about a third as large but carries comparable uncertainty for $x \leq 10^{-3}$. The u and d distributions both maintain a value of $xf(x) \sim 0.5$ for $x \sim 10^{-4} - 10^{-1}$, with corresponding uncertainties at the 20% – 5% level, and become strongly suppressed for $x \geq 0.2$. For $x \leq 10^{-2}$, the u and d distributions are nearly identical in shape, normalization, and uncertainty; this suggests that they originate from $g \to q\bar{q}$ splittings, which are flavor blind for massless quarks. For $x \geq 10^{-2}$, the d density is larger than the u density, with local maxima at around $x \sim 0.15$, and reflects that lead is a neutron-rich nucleus. For ²⁰⁸Pb, the average nucleon is about (126/208) $\approx 60\%$ neutron-like and (82/208) $\approx 40\%$ proton-like, implying more valence-like d quarks than valence-like u quarks. The uncertainties for g and q_{sea} parton densities are much larger at this value of Q than for u and d densities, which largely reflects the available types of measurements used to constrain nPDFs.

In comparison to the proton [second panel of Fig. 2(b)], we observe a variety of behaviors. For the average nucleon, all four parton species displayed have densities that are smaller than those of the proton for $x \leq 10^{-3}$. However, this observation is subject to the sizable g and q_{sea} uncertainties in this regime. For larger momentum fractions of $x \sim 10^{-3} - 10^{-1}$, the g and d distributions exceed those of the proton, while the q_{sea} one is comparable to that of the proton and the u density remains well below unity. For $x \geq 0.1$, this trend continues for d, u, and q_{sea} and again reflects the neutron-rich nature of ²⁰⁸Pb. Moving from ²⁰⁸Pb to ¹³¹Xe (third panel) and ¹²C (bottom panel), we observe that the distributions of individual parton species each begin to converge and mirror that of the proton, particularly for the gluon and sea distributions and $x \leq 0.1$. The d and u quark distributions maintain smaller normalizations but similar shapes to the proton's distributions for $x \leq 10^{-2}$ as atomic number decreases. Likewise, they maintain differences in normalization and shape for larger x as atomic number decreases. In the ¹²C panel, predictions exhibit PDF uncertainties that are sufficiently small to observe that the d and g ratios continue to grow in the $x \to 1$ limit. While such a trend is evident for d in other nuclei, the gluon uncertainties are too large to identify this clearly. Furthermore, the relative increases in d and g for ¹²C with respect to the proton are larger than the relative decreases in u and q_{sea} .

The behavior in the ratios as $x \to 1$ illustrates the well-known Fermi motion model for large-x partons in heavy nuclei. In essence, intra-nuclear exchanges of, *e.g.*, pions as illustrated in Fig. 1(c), between nucleons in a large nucleus will cause some nucleons to carry an energy that is larger than the average nucleon energy (and others to carry a below-average energy). A larger A number corresponds to a larger variation of momenta carried by individual nucleons. In more energetic nucleons, the most energetic partons will subsequently carry an above-average energy, and hence populate the large-x region. However, in single-nucleon systems like the proton, momentum conservation strongly suppresses the large-x region. This leads to a ratio of PDFs (per nucleon) that is larger than unity. It then follows from momentum sum rules that the distributions should be smaller at small momentum fractions. That is to say, momentum and probability conservation dictate that *increases* in parton densities at large momentum fractions should be compensated by *decreases* at small momentum fractions.

Turning to Fig. 2(b), we show the same parton densities (in terms of the quantity xf(x) per nucleon) and the same ratios to densities in the proton, but for an evolution scale of Q = 10 GeV. At this higher scale, several qualitative and quantitative changes can be observed. Foremost is a reduction in PDF uncertainties, particularly in the range of $x \leq 10^{-3} - 10^{-2}$ for the q_{sea} and g distributions. Over the extended range of momentum fractions $x \sim 10^{-4} - 10^{-1}$, the q_{sea} uncertainty and g uncertainties reduce to 10% (5%) at low (high) values of x. For the u and d distributions, the reduction in uncertainties is more modest, reaching similar values of 10% (5%) at low (high) x for the same range of momentum fractions. In increasing $Q \approx 3$ GeV to Q = 10 GeV, the weighted densities xf(x) themselves also increase. For example: at $x \sim 10^{-4}$ the u and d densities increase by

Figure 3. Same as Fig. 2 but for Q = 100 GeV [3(a)] and Q = 1 TeV [3(b)].

a factor of 2 while they remain largely the same at $x \sim 0.1$. Overall, the reduction in uncertainty is due to the growing importance of perturbative $g \to q\bar{q}$ and $q \to qg$ splitting, which is under good theoretical control, and the shrinking importance of the primordial distribution of partons in a nucleus.

Focusing on the lower panels of Fig. 2, we observe the same qualitative behavior at Q = 10 GeV as at $Q \approx 3$ GeV. Notably, however, the smaller PDF uncertainties reveal that for $x \leq 10^{-2}$ the shapes of ratios are largely flat and convergent, indicating that average parton densities in a light and heavy nuclei differ from a free proton in only the normalization. A reduced dependence on A and Z factors is consistent with parton densities at low x being driven more by perturbative QCD than nuclear dynamics. For $x \geq 10^{-2}$, the shapes and normalizations of densities remain qualitatively and quantitatively different from the proton. Finally, in the $x \to 1$ limit, the emergence of an enhanced q_{sea} distribution that mirrors the g distribution at $x \to 1$ can be observed. This is clearest in the ¹²C ratio due to its smaller uncertainties but is also present for ¹³¹Xe and ²⁰⁸Pb. We again attribute the similarity of g and q_{sea} to perturbative $g \to q\bar{q}$ splitting in QCD.

In Fig. 3 we show the same information as in Fig. 2 but for Q = 100 GeV [3(a)] and Q = 1 TeV [3(b)]. Quantitatively, the PDFs show considerable growth and a reduction of uncertainties at these larger scales. Qualitatively, the behavior of densities and ratios of densities are the same as observed at lower Q, and therefore do not need further discussion. One distinction is that the q_{sea} density is, to a good approximation, 10 times larger than the u and d distributions for $x \leq 10^{-3}$; in this range, the u and d distributions and their uncertainties are also approximately equal. This can be interpreted as u and d being sea-like for $x \leq 10^{-3}$ and generated entirely from perturbative $g \to q\bar{q}$ splittings. Under this assumption, all five quarks and all five antiquarks have the same densities for such x and Q, which by the definition of q_{sea} in Eq. (3.3a), predicts the observed tenfold difference.

In summary, for momentum transfers typical of LHC collisions, the densities of partons g, u, d, and q_{sea} for

Figure 4. As a function of (average) momentum fraction x, the ratio of nPDFs (per nucleon) of several families relative to the central set of the nCTEQ15HQ densities, with their 68% CL uncertainty envelope at Q = 100 GeV, of the g (top panel), q_{sea} (second panel), u (third panel), and d (bottom panel) parton species, and for ²⁰⁸Pb [4(a)], ¹³¹Xe [4(b)], and ¹²C [4(c)].

 $x \leq 10^{-3}$ in an average nucleon from heavy, medium, and light nuclei are highly comparable to those found in the proton. In this region, the contribution from perturbative QCD dominates over nuclear dynamics. For the range $x \sim 10^{-3} - 10^{-1}$, there is an enhancement of d quarks and a suppression of u quarks, while the g and q_{sea} distributions are very proton-like. In this region, the relative abundance of protons and neutrons in a nucleus, and hence valence-like u and d quarks drive the parton densities. As $x \to 1$, the d, g, and q_{sea} distributions are enhanced relative to the proton while the u distribution is suppressed. This follows from the interplay of relative proton-neutron abundance, intra-nucleon exchanges, and gluon splittings perturbative QCD.

3.2 Alternative nPDF sets

Presently, several collaborations have published up-to-date nPDF fits with complementary methodologies and decisions on which data sets to incorporate. These include the families KSASG20 [12], TuJu21 [11, 13], EPPS21 [14, 39], nCTEQ15HQ [9, 16], and nNNPDF3.0 [17, 40]. Differences across the sets represent a type of systematic uncertainty associated with modeling and fitting nPDFs.

In order to quantify the impact of this uncertainty on the parton luminosities that we report in Sec. 4 and the cross sections that we report in Sec. 5, we show in Fig. 4 the ratio of nPDFs (per nucleon) relative to our baseline, which we take to be the central set of the nCTEQ15HQ nPDF family,

$$\frac{x f_i(x) \text{ per nucleon}}{x f_i^{\text{nCTEQ}}(x) \text{ per nucleon}} = \frac{f_i(x) \text{ per nucleon}}{f_i^{\text{nCTEQ}}(x) \text{ per nucleon}}.$$
(3.4)

In the figures, we present results, together with the associated 68% CL uncertainty envelope and at Q = 100 GeV, as a function of (average) momentum fraction x for the g (top panel), q_{sea} (second panel), u (third panel), and d (bottom panel) parton species. As before, we consider ²⁰⁸Pb [Fig. 4(a)], ¹³¹Xe [Fig. 4(b)], and ¹²C [Fig. 4(c)]. For concreteness, we compare the nNNPDF3.0, EPPS21, and TuJu21 nPDF sets, which are accessible with the LHAPDF framework. We do not give a full treatise on the origin of any potential discrepancies (or likeness) between various nPDFs due to the nuanced nature of PDF fitting. Such discussions can be found in Refs. [9, 12–14, 16, 17].

Starting with the top panel of Fig. 4(a), we report that the nCTEQ15HQ reference nPDF for the gluon at Q = 100 GeV in ²⁰⁸Pb reaches a baseline uncertainty of $\delta f_g/f_g^{\text{nCTEQ}} \sim 10\%$ (5%) for $x \sim 10^{-4}$ (3 × 10⁻²). At larger x, the uncertainty quickly exceeds $\delta f_g/f_g^{\text{nCTEQ}} \sim 10\%$ (20%) when $x \gtrsim 0.1$ (0.4). For $x \lesssim 10^{-2}$, the three

Figure 5. Same as Fig. 4 but for Q = 1 TeV.

alternative sets exhibit comparable central values and uncertainties for the gluon. Specifically for this range of x, TuJu21 sits just above unity but within the baseline's uncertainty band, while nNNPDF3.0 and EPPS21 have central values that reach as low as $f_g/f_g^{nCTEQ} \sim 0.9$, which is just outside the lower edge of the nCTEQ15HQ uncertainty band. For $x \gtrsim 0.1$, the four nPDF families exhibit large qualitative differences, tending to values above and below unity, with uncertainties that exceed 30% for $x \gtrsim 0.3$.

In the second panel of the same figure, we study the ratio of q_{sea} distributions as predicted by different families of nPDF sets with respect to the reference set, still for ²⁰⁸Pb and Q = 100 GeV. We find that for $x \leq 3 \times 10^{-2}$ the ratio of q_{sea} distributions and the associated uncertainty bands mirror those of the gluon case for the four nPDF families under consideration. This behavior is expected as low-x sea partons at this Q are largely generated perturbatively via $g \to q\bar{q}$ splitting, and should therefore reflect the behavior of the initial gluons (top panel). On the other hand, for $x \geq 0.1$, the shapes and normalizations of q_{sea} partons are qualitatively more comparable to the baseline than in the gluon case but still exhibit uncertainties that exceed 30% for $x \geq 0.3$. In the third and bottom panels of the figure, we report ratios of the u and d distributions as well as their uncertainties. They are all comparable over the range $x \sim 10^{-4} - 0.3$. While some qualitative features emerge at around $x \sim 3 - 4 \times 10^{-2}$, the ratios remain within $\mathcal{O}(10\%)$ of unity over this larger range. On the other hand, for larger x values, the ratios differ qualitatively and quantitatively as do their uncertainties. EPPS21, for example, exhibits distributions that are significantly larger than the baseline while TuJu21's distributions are significantly smaller.

Turning to Fig. 4(b), we present the same information as in the left panel but for the case of 131 Xe, and without EPPS21 as this family of nPDF sets does not contain an nPDF for 131 Xe. Overall, we find qualitatively similar ratios for 131 Xe as found for 208 Pb. More specifically, our baseline ratios exhibits uncertainties that stay within $\delta f/f^{nCTEQ} \sim 10\%$ for $x \sim 10^{-4} - 0.1$. For this same x range, both nNNPDF3.0 and TuJu21 exhibit largely flat ratios but different normalizations. The TuJu21 ratios systematically sit at around $f_i/f_i^{nCTEQ} \sim 1.05$, or about 5% higher for all parton species. The nNNPDF3.0 ratios sit both slightly above (u and d) and slightly below (g and q_{sea}) unity but have uncertainties that are 2 - 3 times larger than the baseline uncertainties. For larger x values, the trends for nNNPDF3.0 and the baseline continue, albeit with larger uncertainties, while TuJu21's distributions for g, u, and d are significantly smaller than the baseline. In Fig. 4(c), we find that the uncertainties and spread of distribution ratios for partons in 12 C are qualitatively similar to those already reported for 208 Pb and 131 Xe, and therefore do not need to be discussed further. Quantitatively, the uncertainties are slightly smaller than for 208 Pb. And even with this reduced uncertainty, the various nPDF families remain in good agreement for $x \lesssim 0.1$. With the exception of TuJu21's gluon distribution, this agreement also holds for $x \gtrsim 0.1$.

For completeness, we show in Fig. 5 the same information as presented in Fig. 4 but for a hard scale of Q = 1 TeV. Qualitatively and quantitatively, we find that the uncertainties and spread of distribution ratios at this higher scale largely remain the same as for Q = 100 GeV. A small reduction in uncertainties can be observed in most panels and is due to the increased importance of perturbative quark and gluon splittings in populating parton densities, which are under good theoretical control. Overall, parton uncertainties span approximately $\delta f_i/f_i^{\rm nCTEQ} \sim 5\% - 20\%$ over the range $x \sim 10^{-4} - 5 \times 10^{-2}$.

4 Parton Luminosities

Parton luminosities (Φ_{ij}) quantify the number incoming parton pairs (ij) in hadron-hadron collisions that go on to scatter at a partonic center-of-mass energy $\sqrt{\hat{s}}$. Since $\sqrt{\hat{s}} = \sqrt{x_1 x_2 s}$ is sourced from a continuum of momentum fractions x_i , luminosities also provide a means of quantifying the net impact of PDFs and their uncertainties, which have strong x dependencies. Furthermore, cross sections scale with parton luminosities. Therefore, when multiplied by coupling constants and other naïve scaling factors, luminosities provide order-of-magnitude estimates for cross section of complicated processes. Such estimates are particularly reliable for $2 \rightarrow 1$ and $2 \rightarrow 2$ processes.

Much like the relationship between parton densities at the *nucleus* and *nucleon* levels, we assume there is a connection between parton luminosities at the nuclear level (Φ_{ij}) and their nucleon counterpart $(\Phi_{ij,NN})$ derived through averaging. In the context of symmetric collisions of two nuclei with atomic number A, the relationship between these two classes of parton luminosities can be expressed as

$$\Phi_{ij}(\tau_{AA}) = \Phi_{ij,NN}(\tau) \times A \times A .$$

$$\tag{4.1}$$

Here, the dimensionless threshold variables τ and τ_{AA} are defined³, respectively, as (a) the ratio between the squared partonic center-of-mass energy \hat{s} and the squared nucleon-nucleon center-of-mass energy s_{NN} , and (b) the ratio between \hat{s} and the squared nucleus-nucleus center-of-mass energy s. Symbolically, these are given by

$$\tau = \frac{\hat{s}}{s_{NN}} = \frac{x_{A1}x_{A2}s}{(s/AA)} = \frac{(x_1A)(x_2A)s}{(s/AA)} = x_1x_2 , \qquad (4.2)$$

$$\tau_{AA} = \frac{\hat{s}}{s} = x_{A1}x_{A2} = \tau AA , \qquad (4.3)$$

where $x_{Ai} \in [0, 1]$ is the nucleus-level momentum fraction carried by parton *i*, and $x_i = (Ax_{Ai}) \in [0, A]$ is the nucleon-level analogue (and is obtained via a rescaling by *A*). Formally, τ can take on values up to $\max(\tau) = A^2$. However, for average momentum fractions in the range $x_i \in [1, A]$ nuclear parton densities are exponentially suppressed [38, 41–45]. We therefore follow convention by neglecting the $x_i \in [1, A]$ and $\tau \in [1, A^2]$ regions of nPDFs and phase space. For concreteness, we evaluate parton luminosities at a collinear factorization scale equal to the partonic center-of-mass energy: $\mu_f = \sqrt{\hat{s}} = \sqrt{\tau s_{NN}}$.

In the following, we focus on four sets of parton luminosities at the nucleon level. The first one, $\Phi_{gg,NN}$, is relevant for processes induced by gluon fusion, e.g., $gg \to t\bar{t}$, and is defined by

$$\Phi_{gg,NN}(\tau) = \int_{\tau/A}^{A} \frac{dx}{x} g(x,\mu_f) g\left(\frac{\tau}{x},\mu_f\right) \approx \int_{\tau}^{1} \frac{dx}{x} g(x,\mu_f) g\left(\frac{\tau}{x},\mu_f\right).$$
(4.4)

Next, we consider the qg luminosity, which is relevant for prompt photon production $(qg \rightarrow \gamma q)$ and $\mathcal{O}(\alpha_s)$ corrections to W/Z production $(qg \rightarrow Vq)$. Summing over all five active quark flavors $(q_i = u, d, s, c, b)$, we have:

³It is worth stressing the distinction between τ , which is defined at the nucleon level, and τ_{AA} , which is defined at the nucleus level and is bound by unity, *i.e.*, max(τ_{AA}) = 1. See footnote 2 and Eq. (3.2) for further details.

$$\Phi_{qg,NN}(\tau) = \sum_{i=u,d,\dots} \int_{\tau/A}^{A} \frac{dx}{x} \left[g(x,\mu_f) \ q_i \left(\frac{\tau}{x},\mu_f\right) + \ g(x,\mu_f) \ \bar{q}_i \left(\frac{\tau}{x},\mu_f\right) + \ q_i(x,\mu_f) \ g\left(\frac{\tau}{x},\mu_f\right) + \ \bar{q}_i(x,\mu_f) \ g\left(\frac{\tau}{x},\mu_f\right) \right],$$
(4.5a)

$$\approx \sum_{i=u,d,\dots} \int_{\tau}^{1} \frac{dx}{x} \left[g(x,\mu_f) \ q_i\left(\frac{\tau}{x},\mu_f\right) \ + \ g(x,\mu_f) \ \bar{q}_i\left(\frac{\tau}{x},\mu_f\right) \ + \ \left(x\leftrightarrow\frac{\tau}{x}\right) \right],\tag{4.5b}$$

followed the neutral-current $q\bar{q}$ luminosity, again for five active quark flavors,

$$\Phi_{q\bar{q},NN}(\tau) = \sum_{i=u,d,\dots} \int_{\tau/A}^{A} \frac{dx}{x} \left[q_i(x,\mu_f) \ \bar{q}_i\left(\frac{\tau}{x},\mu_f\right) + \bar{q}_i(x,\mu_f) \ q_i\left(\frac{\tau}{x},\mu_f\right) \right]$$
(4.6a)

$$\approx \sum_{i=u,d,\dots} \int_{\tau}^{1} \frac{dx}{x} \left[q_i(x,\mu_f) \ \bar{q}_i\left(\frac{\tau}{x},\mu_f\right) + \bar{q}_i(x,\mu_f) \ q_i\left(\frac{\tau}{x},\mu_f\right) \right], \tag{4.6b}$$

and the charged-current $q\bar{q}'$ luminosity

$$\Phi_{q\bar{q}',NN}(\tau) = \sum_{i=u,\dots} \int_{\tau/A}^{A} \frac{dx}{x} \left[q_i(x,\mu_f) \ \bar{q}'_i\left(\frac{\tau}{x},\mu_f\right) + \bar{q}_i(x,\mu_f) \ q'_i\left(\frac{\tau}{x},\mu_f\right) \right]$$
(4.7a)

$$\approx \sum_{i=u,\dots} \int_{\tau}^{1} \frac{dx}{x} \left[q_i(x,\mu_f) \ \bar{q}'_i\left(\frac{\tau}{x},\mu_f\right) + \bar{q}_i(x,\mu_f) \ q'_i\left(\frac{\tau}{x},\mu_f\right) \right].$$
(4.7b)

In the charged-current luminosity, the sum runs over $SU(2)_L$ doublet pairs, *i.e.*, $q_i \overline{q}'_i = u \overline{d}, c\overline{s}, \ldots$, but excludes third-generation quarks due to the absence $t(\overline{t})$ (anti)quarks in modern nPDF sets.

In Fig. 6(a), we provide predictions for the (average) gg, qg, $q\bar{q}$ and $q\bar{q}'$ parton luminosities per nucleon as a function of the partonic center-of-mass energy $\sqrt{\hat{s}}$. In the upper panel of the figure, these predictions are presented specifically for symmetric collisions of ²⁰⁸Pb nuclei at a nucleon-nucleon collision energy of $\sqrt{s_{NN}} = 5$ TeV.

Reflecting the behavior of the g density in lead for different factorization scales in Sec. 3.1, the gg luminosity per nucleon is large at small partonic collision energies and rapidly falls with increasing values of $\sqrt{\hat{s}}$ in a way that is steeper than for the other luminosities considered. Quantitatively, at $\sqrt{s_{NN}} = 5$ GeV, $\Phi_{gg,NN}$ reaches up to 10^9 at small $\sqrt{\hat{s}}$ with an uncertainty of about 20%, which follows from the large uncertainty of the gluon density for $x \leq 10^{-3}$ and scales $\mu_f \leq 10$ GeV. The uncertainties, however, decrease with increasing values of $\sqrt{\hat{s}}$ as the bulk of the integral in Eq. (4.4) increasingly involves the gluon density in the regime where it is known best (see the upper panels of Figs. 2 and 3). In particular, for partonic center-of-mass energies around $\sqrt{\hat{s}} \simeq 100$ GeV ($\tau \simeq 10^{-4}$), which typically correspond to the production of a single weak or Higgs boson, the uncertainties reach a minimum of 2% - 3% for a luminosity per nucleon of $\Phi_{NN} \sim 2 \times 10^5$. With further increasing $\sqrt{\hat{s}}$, the luminosity continues to drop due to the suppression of the gluon nPDF at larger momentum fractions of $x \gtrsim 0.1$; ultimately, this is a consequence of momentum conservation and the decreasing likelihood of a single partonic collision occurring at a scale of $\sqrt{\hat{s}} \rightarrow \sqrt{s_{NN}}$ ($\tau \rightarrow 1$). Likewise, the increasing uncertainty at large $\sqrt{\hat{s}}$ corresponds to the poorer constraints on the gluon nPDF, particularly for $x \gtrsim 0.2$ regardless of the scale.

The neutral-current $q\bar{q}$ and charged-current $q\bar{q}'$ luminosities exhibit qualitatively similar behavior as the gg luminosity for small partonic center-of-mass energies, although with a smaller normalization by a factor of about 50 - 100 for $\sqrt{\hat{s}} \leq 100$ GeV. Such behavior originates from multiple sources. For example: the definitions of $\Phi_{ij,NN}$ in Eqs. (4.5)-(4.7) sum over all quark species and therefore is largely insensitive to the difference between protons and neutrons, *i.e.*, it is approximately isospin symmetric. Another example: for the regime under consideration, the dynamics of the quark densities are mostly driven by $g \to q\bar{q}$ perturbative splittings. At some point, however, contributions from valence quarks impact the up and down quark densities, and therefore the $q\bar{q}$ and $q\bar{q}'$ luminosities. This reduce the steepness by which the two luminosities decrease with increasing partonic energy. In other words: the gg luminosity decrease quicker with increasing $\sqrt{\hat{s}}$ than the $q\bar{q}$ and $q\bar{q}'$ luminosities because of the presence of valence quarks at large x (or τ). At collision energies of about $\sqrt{\hat{s}} \sim 750$ GeV ($\tau \sim 0.02$),

Figure 6. Upper panel: For a nucleon-nucleon center-of-mass energy $\sqrt{s_{NN}} = 5$ TeV (a) and 10 TeV (b), average parton luminosities (per nucleon) in symmetric ²⁰⁸Pb collisions for the gg (red), neutral-current $q\bar{q}$ (green), charged-current $q\bar{q}'$ (black) and qg (blue) initial states. Band thickness corresponds to the 68% CL PDF uncertainty. Lower panels: Ratios of luminosities relative to those in proton-proton collisions for symmetric ²⁰⁸Pb (second panel), ¹³¹Xe (third panel), and ¹²C (bottom panel) collisions.

the gg, $q\bar{q}$ and $q\bar{q}'$ luminosity curves cross, and for larger energies $\Phi_{q\bar{q},NN}$, $\Phi_{q\bar{q}',NN} > \Phi_{gg,NN}$. We report uncertainties of about $\delta\Phi_{NN}/\Phi_{NN} \sim 15\%$ for partonic scattering scales of 5-10 GeV, which reduce to 2-3% in the central $\sqrt{\hat{s}}$ regime that we consider, before increasing to 5% for scales in the range $\sqrt{\hat{s}} \sim 500$ GeV - 2 TeV.

Finally, our results show that the qg luminosity at $\sqrt{s_{NN}} = 5$ TeV is the largest over the entire kinematic regime considered. It converges to the gg density for $\sqrt{\hat{s}} \leq 30$ GeV and then surpasses it up to a factor of 10 for $\sqrt{\hat{s}} \gtrsim 300$ GeV. The related uncertainties correspond to a geometric average of the uncertainties associated with the $q\bar{q}$ and gg luminosities. Hence, they vary from 5% - 15%. The largest uncertainties of 10% - 15% are found for partonic center-of-mass energies below 20 GeV and above 800 GeV, whereas for more central energies the uncertainties are stable and reach a few percent. These properties stem from the fact that the qg partonic configuration combines the large gluon density at small x with the valence-quark domination of the u and ddensities at large x.

In the second panel of Fig. 6(a) we present the ratios of the four luminosities for ²⁰⁸Pb collisions relative to same luminosities for proton collisions. We observe that in the center of the kinematic regime under consideration, $\sqrt{\hat{s}} \sim 100 - 200 \text{ GeV} \ (\tau \sim 10^{-3})$, the ratio of lead-lead and proton-proton gg luminosities is compatible with unity (up to uncertainties), reflecting an accidental cancellation between the suppression of gluon densities at small momentum fractions ($x \leq 10^{-3}$) and the enhancement of gluon densities at large ($x \gtrsim 0.3$). The belowunity value of the gg parton luminosity ratio for smaller center-of-mass energies then reflects the suppression

Figure 7. Same as Fig. 6 but for (a) $\sqrt{s_{NN}} = 50$ TeV and (b) $\sqrt{s_{NN}} = 100$ TeV.

of the gluon nPDF at smaller x values, although this conclusion is subject to the large uncertainties in this kinematic limit. For larger energies the ratio of lead-lead to proton-proton luminosities is smaller than unity, and even suggests a stronger suppression than for lower collision energies. Once again, the uncertainties in this regime prevent too conclusive statements, although this behavior is consistent with a shallow suppression (up to uncertainties) of the gluon density for $x \gtrsim 0.1 - 0.3$.

In the case of the ratio of qg luminosities, and particularly for $\sqrt{\hat{s}} \gtrsim 200 \text{ GeV}$ ($\tau \gtrsim 10^{-3}$), the aforementioned suppression of the gluon density at moderate-to-high x is compensated by the enlarged valence down quark content in ²⁰⁸Pb. (We reiterate that ²⁰⁸Pb is neutron rich and therefore the average nucleon is neutron-like.) These competing effects lead to a qg luminosity that is comparable to the proton for $\sqrt{\hat{s}} \gtrsim 100 \text{ GeV}$ ($\tau \gtrsim 4 \times 10^{-4}$). However, for partonic center-of-mass energies below this threshold, the qg luminosity of lead falls, reaching about three-quarters the size of the proton's at about $\sqrt{\hat{s}} \sim 5 \text{ GeV}$ ($\tau \sim 10^{-6}$). Qualitatively, similar conclusions holds for the two ratios of quark-antiquark luminosities, although in some respects the effects are exacerbated. For example: the $q\bar{q}$ and $q\bar{q'}$ luminosity ratios are smaller than for gg and qg at the smallest partonic center-of-mass energies uncer consideration but are larger and closer to unity at the largest $\sqrt{\hat{s}}$.

In the third and fourth panels of Fig. 6(a), we present the same ratios in the case of symmetric xenon collisions and carbon collisions, respectively. As expected, the ratios approach unity as A becomes smaller, *i.e.*, more proton like. Uncertainties are additionally reduced, mirroring the reduced uncertainties originating from the nPDF fits. It is interesting to note that the dynamic behavior in nPDF at $x \gtrsim 10^{-2}$, which leads to individual parton species having a much larger or much smaller density than the proton, is softened at the level of luminosities. While nucleon-level luminosities in nuclei can exceed those of the proton, the excess is modest. This is because parton luminosities at a fixed $\sqrt{\hat{s}}$ typically sample a large range of possible momentum fractions, which leads to a compensation between enhancements and suppressions from opposing extremes. The notable exception is the extreme case of very small $\sqrt{\hat{s}}$; in this case, parton luminosities at the nucleon level tend to be 10% - 50% (up to uncertainties) smaller than in the proton.

In Figs. 6(b), 7(a), and 7(b), we present the same results as for Figs. 6(a) but for nucleon-nucleon collision energies of $\sqrt{s_{NN}} = 10$, 50 and 100 TeV, respectively. The qualitative behavior of the results is similar to that featured at 5 TeV, although the uncertainties are found to decrease with increasing evolution scale since the bulk of the relevant dynamics becomes dictated by $g \rightarrow q\bar{q}$ splitting, and hence perturbative QCD, which is under good theoretical control. The exception is the large partonic center-of-mass energy regime, which exhibits predictions with larger uncertainties; this follows from nPDF uncertainties of in the large-*x* regime (see, *e.g.*, Fig. 4).

5 Total and Fiducial Cross Sections

In this section we present the main results of our work: a survey of production cross sections (σ), at NLO in QCD, and their uncertainties for high-energy processes in symmetric ion collisions with nucleon-nucleon collision energies spanning $\sqrt{s_{NN}} = 1 - 100$ TeV. We focus on processes that at lowest order (LO), *i.e.*, the Born level, are described by tree-level partonic processes of the form

$$i + j \rightarrow \mathcal{F}$$
 (5.1)

Here, i, j are any massless QCD partons $(n_f = 5)$ and \mathcal{F} is an $n_{\mathcal{F}}$ -body final state with up to three SM particles from the collection $\{W^{\pm}, Z, \gamma, H, t, \bar{t}\}$.

For incoming ions \mathcal{A}_1 and \mathcal{A}_2 , the inclusive, *nucleus*-level cross section (σ) is given by

$$\sigma(\mathcal{A}_1 \mathcal{A}_2 \to \mathcal{F} + X) = A_1 \times A_2 \times \sigma_{NN}(N_1 N_2 \to \mathcal{F} + X) , \qquad (5.2)$$

where X represents any and all outgoing hadronic activity associated with the beam remnants. In addition, A_k is the atomic number of incoming nucleus $k \in \{1, 2\}$, and σ_{NN} is the inclusive *nucleon*-level cross section for $N_1N_2 \to \mathcal{F}$, with N_k being an "average" nucleon of \mathcal{A}_k . In general, but especially in the large-A limit, N_k can be modeled⁴ as a linear combination / admixture of a proton \mathcal{P} and neutron \mathcal{N} , *i.e.*,

$$|N\rangle = \alpha |\mathcal{P}\rangle + \beta |\mathcal{N}\rangle , \qquad (5.3)$$

where $|\alpha|^2 = (Z/A)$, $|\beta|^2 = (A - Z)/A$, and $|\alpha|^2 + |\beta|^2 = 1$. The kinematics of N_k and \mathcal{A}_k are then related by a rescaling of one or the other by A_k or $1/A_k$ [38, 46]. We focus on symmetric ion beams, meaning that $\mathcal{A}_1 = \mathcal{A}_2$ and $N_1 = N_2$. Furthermore, for $(A_k, Z_k) = (1, 1)$, \mathcal{A}_k and N_k reduce to being each a proton, $\mathcal{A}_1 = \mathcal{P}$ and $N_1 = \mathcal{P}$.

To calculate nucleon-level cross sections, we apply the Collinear Factorization Theorem [47–49],

$$\sigma_{NN} = \int dP S_{n_{\mathcal{F}}} \frac{d\sigma_{NN}}{dP S_{n_{\mathcal{F}}}}, \quad \text{where}$$
(5.4a)

$$\frac{d\sigma_{NN}}{dPS_{n_{\mathcal{F}}}} = \frac{1}{(1+\delta_{ij})} \sum_{i,j=u,g,\dots} \Delta_{ij} \otimes f_{i/\mathcal{A}_1} \otimes f_{j/\mathcal{A}_2} \otimes \frac{d\hat{\sigma}_{ij\to\mathcal{F}}}{dPS_{n_{\mathcal{F}}}}, \qquad (5.4b)$$

which has been derived for (select processes in) proton scattering and is assumed to hold for hard, inclusive nuclear collisions. In the above, Δ_{ij} is the Sudakov factor that accounts for renormalization-group (RG) evolution, *e.g.*, parton showering; at the level of inclusive cross sections, it can be approximated as a Dirac- δ function and its convolution⁵ $\Delta_{ij} \otimes$ can be set to unity. The quantities $f_{i/A_k}(x_k, \mu_f)$ are the nPDFs of parton species *i* for averaged nucleons in nucleus \mathcal{A}_k . Their two arguments are: (i) the momentum fraction $x_k = E_i/E_k$, which defines the momentum p_i of parton *i* relative to the momentum P_k^N of its parent nucleon N_k as

$$p_i = x_k P_k^N = (x_k/A_k) P_k^A$$
, with $P_k^N = \frac{\sqrt{s_{NN}}}{2} (1, 0, 0, \pm 1)$, (5.4c)

 $^{^{4}}$ While the notion of modeling nuclei as a collection of bound nucleons is historical and justifiable, this formulation is not strictly necessary. It is possible to model nuclei directly in terms of partonic degrees of freedom [38].

⁵The symbols \otimes denote a convolution over a dimensionless variable z, x_1 , or x_2 , over the range [0, 1].

where $P_k^{\mathcal{A}} = \sqrt{s}(1, 0, 0, \pm 1)/2$ is the incoming ion's momentum, and (ii) the collinear factorization scale, below which initial-state QCD radiation is resummed and nPDFs are RG-evolved via the DGLAP evolution equations.

Finally, $d\hat{\sigma}_{ij\to\mathcal{F}}$ is the totally differentiated *parton*-level $ij\to\mathcal{F}$ cross section given by

$$\frac{d\hat{\sigma}_{ij\to\mathcal{F}}}{dPS_{n_{\mathcal{F}}}} = \frac{1}{2\hat{s}} \frac{1}{\mathcal{S}_i \mathcal{S}_j N_c^i N_c^j} \sum_{\text{dof}} |\mathcal{M}|^2 .$$
(5.4d)

Here, $\hat{s} = (p_i + p_j)^2$ is the (squared) hard scattering scale, S_k and N_c^k are respectively the spin- and color-averaging factors, \mathcal{M} is the $ij \to \mathcal{F}$ matrix element, and the summation is over all discrete degrees of freedom (dof), *e.g.*, helicity and color. The $n_{\mathcal{F}}$ -body phase space volume element is

$$dPS_{n_{\mathcal{F}}} = \frac{1}{\Omega} (2\pi)^4 \, \delta^4 \left(p_i + p_j - \sum_{l=1}^{n_{\mathcal{F}}} p_l \right) \times \prod_{l=1}^{n_{\mathcal{F}}} \frac{d^3 p_l}{(2\pi)^3 2E_l} \,, \tag{5.4e}$$

where our definition includes a symmetry factor Ω relevant for the production of identical particles. Formally, Ω is the product of $(n_l!)$ factors, where n_l is the number indistinguishable final-state particles of species l.

For processes without infrared divergences in their Born-level matrix element, *e.g.*, inclusive W or Z production via the Drell-Yan process ($q\bar{q}$ annihilation), we compute the total cross section, *i.e.*, we integrate over all available phase space. For those processes containing infrared singularities in their matrix elements at the Born level, *e.g.*, $W\gamma$ production, we compute fiducial cross sections by imposing the following phase space restrictions on the relevant elements of \mathcal{F} :

$$p_T^l > 150 \text{ GeV} \text{ and } |\eta^l| < 2.4$$
 (5.5)

For a final state particle l, p_T^l is the magnitude of its transverse momentum and η^l is its pseudorapidity. All cross sections are computed numerically according to the methodology described in Sec. 2.

In Sec. 5.1 we focus on single boson production, while in Sec. 5.2 we consider diboson production without the Higgs or a photon. Associated photon $(V\gamma)$ production is discussed in Sec. 5.3. Associated Higgs (VH)production is covered in Sec. 5.4. Triboson (VV'V'') processes are covered in Secs. 5.5 and 5.6. We address photon $(\gamma + X)$ processes in Sec. 5.7 before finishing with top quark pair $(t\bar{t}X)$ processes in Sec. 5.8. We give a summary of our results in Sec. 5.9.

5.1 Inclusive single boson production

We begin our survey with the inclusive production of a single weak boson, and specifically with processes facilitated at LO by quark-antiquark annihilations, illustrated in Fig. 8(a), and given by

$$q\overline{q}, q\overline{q'} \rightarrow W^{\pm}, W^{-}, W^{+}, Z$$
 (5.6)

NLO QCD predictions for weak boson production were computed first in Refs. [50, 51], and at higher orders in Refs. [52–55]. We show in the top panel of Fig. 9(a) the nucleus-level total cross section at NLO in QCD for W^{\pm} (blue), W^{-} (red), W^{+} (black), and Z (green) production, shown in descending order, in ²⁰⁸Pb-²⁰⁸Pb collisions as a function of nucleon-nucleon collision energy $\sqrt{s_{NN}}$. The band thickness corresponds to the residual scale uncertainty at this order. In the second panel we show the ratio of NLO cross sections and their scale uncertainties relative to the central LO cross section for ²⁰⁸Pb collisions. This is the QCD K-factor at NLO and is conventionally defined by the relationship

$$K^{\rm NLO} \pm \delta K = \sigma^{\rm NLO} / \sigma^{\rm LO} \pm \delta \sigma / \sigma^{\rm LO} , \qquad (5.7)$$

where δK represents the uncertainty in K^{NLO} that stems from the uncertainty in the NLO cross section prediction, which we denote by $\delta \sigma$. In the third panel we have the ratio of the nucleon-level NLO cross sections (σ_{NN}) and their PDF uncertainties for ²⁰⁸Pb collisions relative to the central NLO rate for protons. In the fourth and bottom panels we show the same ion-over-proton ratios but for ¹³¹Xe and ¹²C, respectively.

Figure 8. Representative Feynman diagrams at the Born level depicting partonic production of (a) a weak boson $V \in \{W^{\pm}, Z\}$, (b) pair production of two weak bosons, and (c) associated V-Higgs (H) production.

Focusing first on the top panel, we report that over the range $\sqrt{s_{NN}} = 1$ TeV -100 TeV, the nucleus-level scattering rates and their residual scale uncertainty at NLO for lead collisions span approximately

$$\sigma_{AA \to V}^{\rm NLO} \sim 10^2 \ \mu \rm{b} - 5 \times 10^4 \ \mu \rm{b},$$
 (5.8a)

$$\delta \sigma^{\rm NLO} / \sigma^{\rm NLO} \sim \pm 10\% - \pm 30\%$$
 (5.8b)

For all collider energies, the W^{\pm} production rate is the largest, followed by W^- , W^+ , and finally Z production. This hierarchy reflects an interplay between (a) the different gauge charges of quarks and (b) the size of parton densities. For instance: the difference between the W^{\pm} and Z rates at a fixed collider energy is largely due to the differences in gauge couplings. The ratio of the $W - u - \overline{d}$ and $Z - d - \overline{d}$ couplings (squared) scales as $(\Gamma_{Wu\overline{d}}/\Gamma_{Zd\overline{d}})^2 \sim (\sqrt{2}\cos\theta_W)^2 \sim 1.5$. This is approximately the difference observed between the W^+ (or W^-) production rate and the Z production rate.

In addition, since $M_W, M_Z \leq \mathcal{O}(100 \text{ GeV})$, inclusive W/Z production at low (high) collider energies is driven by valence-sea (sea-sea) quark scattering. Since the hard scattering scale $\sqrt{\hat{s}} = M_V$ is fixed by the matrix element and phase space, the kinematic threshold $\tau = x_1 x_2 = \hat{s}/s_{NN}$ necessarily decreases with increasing collision energies; this corresponds to probing smaller x_k and an increased importance of low-x partons. As shown in Secs. 3 and 4, ²⁰⁸Pb has a larger d_v content than u_v content due to its surplus of neutrons. This means ²⁰⁸Pb exhibits a larger $d_v \overline{u}_{\text{sea}}$ luminosity than $u_v \overline{d}_{\text{sea}}$ luminosity. In other words, at lower $\sqrt{s_{NN}}$ we expect a $W^$ production rate that is larger than the W^+ rate. At larger collider energies, the $u_{\text{sea}}\overline{d}_{\text{sea}}$ and $d_{\text{sea}}\overline{u}_{\text{sea}}$ luminosities are similar since their production is driven by $g \to q\overline{q}$ splitting in QCD, which is flavor symmetric. This leads to the comparable W^+ and W^- production rates observed in the figure. We additionally refer to Tables 1-4 (rows 1-4) for a quantitative comparison of the predictions at $\sqrt{s_{NN}} = 5$ TeV and 100 TeV, illustrating this behavior.

For the NLO K-factor, we observe that all four channels exhibit comparable NLO QCD corrections, with

$$K_{AA \to V}^{\rm NLO} \sim 1.2 - 1.4$$
, (5.9)

ranging from low-to-high $\sqrt{s_{NN}}$. These are consistent with perturbative QCD (pQCD) corrections for protonproton collisions. There is similarity because the $\mathcal{O}(\alpha_s)$ corrections to quark-antiquark annihilation (Drell-Yan) are driven by the finite parts of virtual and soft-real corrections, which are positive, universal, and scale as $d\sigma^{\text{virt+soft}}|_{\text{finite}} \sim \mathcal{O}(\alpha_s C_F \pi/3) \sim \mathcal{O}(0.14)$ [50, 51]. However, at larger collider energies, the increased importance of pQCD corrections, which reach $\mathcal{O}(+40\%)$, is due the largeness of the gluon density and thus the importance of the $qg \rightarrow Vq$ and $\bar{q}g \rightarrow V\bar{q}$ channels that open at this order. This demonstrates that even for "simple" processes LO predictions can severely underestimate total cross sections at large collision energies.

Focusing on the lower three panels, we observe a number of differences and similarities between the proton and an average nucleon from our representative isotopes. Qualitatively, we observe that for $\sqrt{s_{NN}} \gtrsim 20$ TeV (per nucleon), or when $(\sqrt{\hat{s}}/\sqrt{s_{NN}}) \sim (M_V/\sqrt{s_{NN}}) \lesssim 4 \times 10^{-4}$, all cross section ratios are largely flat and differ only by process-dependent normalizations. For instance: the per nucleon production rates of Z bosons at large collider energies are about $\mathcal{O}(80\%)$ compared to proton-proton collisions, while the W^- production rates are about $\mathcal{O}(90\% - 95\%)$. For the charge-symmetric channels, that is W^{\pm} and Z production, this "convergence"-like behavior occurs even earlier at $\sqrt{s_{NN}} \gtrsim 5$ TeV. This indicates that the *rate* at which cross sections grow with collider energy is the same for the proton and the three ions, suggesting that the growth is dominated by partonic dynamics, *i.e.*, by DGLAP evolution, and not by hadronic or nuclear dynamics.

Figure 9. (a) Top panel: the nucleus-level total cross section at NLO in QCD for W^{\pm} (blue), W^{-} (red), W^{+} (black), and Z (green) production, shown in descending order, in symmetric ²⁰⁸Pb-²⁰⁸Pb collisions as a function of nucleon-nucleon collision energy $\sqrt{s_{NN}}$. Band thickness corresponds to the residual scale uncertainty at this perturbative order. Second panel: The ratio of NLO cross sections and their scale uncertainties relative to the central LO cross section for ²⁰⁸Pb collisions. Third panel: The ratio of the nucleon-level NLO cross sections (σ_{NN}) and their PDF uncertainties for ²⁰⁸Pb collisions relative to the central NLO rate for protons. Fourth and bottom panel: same as third panel but for ¹³¹Xe and ¹²C, respectively. (b) Same as Fig. 9(a) but for W^+W^- (red), $W^{\pm}Z$ (green), WW^+Z (blue), W^-Z (black), and ZZ (orange) production, again shown in descending order.

Extracting the precise dependence of these global normalizations on the (A, Z) numbers is obfuscated by two features: (i) the sizable uncertainties of nPDFs, which can exceed $\mathcal{O}(\pm 20\%)$, and (ii) the relative nucleon content of our isotopes, which are comparable and are approximately $Z : (A - Z) \sim 40 : 60 (40 : 60) [50 : 50]$ for ²⁰⁸Pb (¹³¹Xe) [¹²C]. However, we note ongoing efforts to determine such scaling relationships across nPDFs [56].

5.2 Diboson processes

We continue our survey with the inclusive production of two weak bosons. We specifically focus on processes facilitated at LO by quark-antiquark annihilation, illustrated in Fig. 8(b), and given by

$$q\overline{q}, q\overline{q'} \rightarrow W^+W^-, W^{\pm}Z, W^-Z, W^+Z, ZZ$$
 (5.10)

NLO in QCD predictions were first computed in Refs. [57-62] and at higher orders in Refs. [63-65].

We show in the top panel of Fig. 9(b) the nucleus-level total cross section at NLO in QCD for W^+W^- (red), $W^{\pm}Z$ (green), W^-Z (black), W^+Z (blue), and ZZ (orange) production in symmetric ²⁰⁸Pb-²⁰⁸Pb collisions as a function of nucleon-nucleon collision energy $\sqrt{s_{NN}}$. The band thickness corresponds to the residual scale uncertainty at this order. In the lower panels we show the same ratios as in Fig. 9(a) for single-boson production. In the top panel, we observe that over the range $\sqrt{s_{NN}} = 1 \text{ TeV} - 100 \text{ TeV}$, the nucleus-level scattering rates and their residual scale uncertainty at NLO for lead-lead collisions span approximately

$$\sigma_{AA \to VV}^{\text{NLO}} \sim 0.1 \ \mu\text{b} - 40 \ \mu\text{b}, \tag{5.11a}$$

$$\delta \sigma^{\rm NLO} / \sigma^{\rm NLO} \sim \pm 10\% - \pm 50\%$$
 . (5.11b)

For all collider energies, the W^+W^- production rate is the largest, followed by those for $W^{\pm}Z$, W^-Z , W^+Z , and finally ZZ production. This hierarchy again reflects the interplay between the gauge charges of quarks and the density of quarks and gluons. The systematic $\mathcal{O}(10^3)$ drop in cross sections for diboson production relative to the single-boson case in Sec. 5.1 is also consistent with naïve power counting and phase-space suppression associated with adding one final-state leg. That is, for $V, V' \in \{W^{\pm}, Z\}$ and a hard scale of $Q = 2M_V$ one has⁶

$$\frac{\sigma(AA \to VV' + X)}{\sigma(AA \to V + X)} \sim \mathcal{O}\left[\frac{\alpha_W}{4\pi}\log^2\left(\frac{Q^2}{M_V^2}\right)\right] \sim 5 \times 10^{-3} .$$
(5.12)

Furthermore, as in the single-boson case, the W^-Z rate is larger than the W^+Z due to the d content of ²⁰⁸Pb.

In the second panel of the figure, we show the NLO K-factors for diboson production. These are large ($\gtrsim 1.5$), grow monotonically with energy, and span from low-to-high $\sqrt{s_{NN}}$:

$$K_{AA \to WZ}^{\rm NLO} \sim 1.4 - 2.2$$
, (5.13a)

$$K_{AA \to WW}^{\text{NLO}} \sim 1.3 - 1.7$$
, (5.13b)

$$K_{AA \to ZZ}^{\rm NLO} \sim 1.3 - 1.5$$
 (5.13c)

The largeness of the perturbative corrections is real and is the result of so-called "radiation amplitude zeros" in the Born amplitudes [66–71]. In essence, the tree-level $q\overline{q'} \to WZ$ process has a large, destructive interference that suppresses the LO cross section. This interference is disrupted in the qg and $\bar{q}g$ channels and leads to a net $\mathcal{O}(\alpha_s)$ correction that is comparable to or larger than the Born result. Moreover, as the collider energy increases, the gluon density becomes enhanced (see Sec. 3), leading to much larger qg and $\bar{q}g$ luminosities (see Sec. 4), and ultimately to $\mathcal{O}(\alpha_s)$ corrections to diboson production that increase with $\sqrt{s_{NN}}$. For proton collisions, pQCD corrections are more modest at next-to-next-to-leading order (NNLO), modulo the opening of gg fusion channels, suggesting that the perturbative expansion stabilizes [63–65].

The three lower panels show the (per nucleon) cross section ratios with respect to the cross section for ppcollisions. For the W^+W^- , $W^{\pm}Z$, and ZZ channels we report that the ratios sit at or just below unity for $\sqrt{s_{NN}} \gtrsim 2-4$ TeV. This follows from the three channels being charge- and flavor-symmetric.⁷ More specifically, the enhanced d-quark density (or $d\overline{u}$ luminosity) that drives the W^-Z ratio well above unity for $\sqrt{s_{NN}} \lesssim 30$ TeV is mostly, but not exactly, compensated by the suppressed u-quark density (or $u\bar{d}$ luminosity) that drives the W^+Z ratio well below unity for $\sqrt{s_{NN}} \lesssim 20$ TeV. So while the relative importance of the u and d densities in $q\bar{q} \to VV'$ (or $qg \to VV'q$) scattering shifts as the (A, Z) composition of an average nucleon becomes more proton-like or more neutron-like, we still sum over all charge and flavor configurations of initial-state parton pairs. As a consequence, differences in scattering rates between a "neutron-like" nucleon and the proton (approximately) vanish due to (approximate) isospin symmetry. Remaining differences between the isotopes and the proton in W^+W^- , $W^{\pm}Z$, and ZZ are then due to (i) violations of isospin symmetry between protons and neutrons at the hadronic level and (ii) intra-nuclear exchanges at the nuclear level. For instance: the ratios for these three channels reflect the fact that the $q\bar{q}$, $q\bar{q'}$, and qg luminosities at $\sqrt{\hat{s}} = 100 \text{ GeV}$ (see Sec. 4) sit just below those for the proton. Finally, we find that the ratios stabilize and become flat-like when collision energies exceed $\sqrt{s_{NN}} \sim 40 - 50$ TeV. This corresponds to the ratio $(\sqrt{\hat{s}}/\sqrt{s_{NN}}) \sim (2M_V/\sqrt{s_{NN}}) \lesssim 4 \times 10^{-4}$. We refer to Tables 1-4 (rows 5-9) for a quantitative comparison of diboson predictions at $\sqrt{s_{NN}} = 5$ TeV and 100 TeV.

⁶The double logarithm originates from phase space integration over the additional propagator in VV' production. At high energies, these capture the leading contributions of the emission of "soft" and "collinear" weak bosons.

⁷We briefly note that charge- and flavor-symmetric channels, which run over all quark species, do not imply flavor universality, which means being the same for all quark species. ZZ production, for example, is flavor symmetric since all $q\bar{q}$ and qg configurations are included but it is not flavor universal since the $Z - q - \bar{q}$ coupling depends on flavor. This implies that flavor-summed channels can still be sensitive to the relative abundance of partons, and hence the proton-to-neutron ratio of a nucleus.

Figure 10. (a) Same as Fig. 9(a) but for $W^{\pm}\gamma$ (green), $W^{-}\gamma$ (red), $W^{+}\gamma$ (black), and $Z\gamma$ (blue) production with the phase space cuts of Eq. (5.5), shown in descending order. (b) Same as Fig. 9(a) but for $W^{\pm}H$ (blue), ZH (green), $W^{-}H$ (red), and $W^{+}Z$ (black) production, also shown in descending order.

5.3 Photon associated processes

We now focus on the production of a high-energy photon (γ) in association with one weak boson, as illustrated diagrammatically in Fig. 8(b), and given at LO by

$$q\overline{q}, q\overline{q'} \to W^{\pm}\gamma, W^{-}\gamma, W^{+}\gamma, Z\gamma$$
 (5.14)

To regulate infrared divergences in matrix elements, we impose the phase space cuts of Eq. (5.5). Full NLO in QCD predictions for $V\gamma$ were first reported in Refs. [72, 73] and are now available at higher orders [73].

We show in the top panel of Fig. 10(a) the nucleus-level total cross section at NLO in QCD for $W^{\pm}\gamma$ (green), $W^{-}\gamma$ (red), $W^{+}\gamma$ (black), and $Z\gamma$ (blue) production, shown in descending order, in ²⁰⁸Pb-²⁰⁸Pb collisions and as a function of $\sqrt{s_{NN}}$. The band thickness corresponds to the residual scale uncertainty at this order. In the lower panels we show the same ratios as in Fig. 9(a) for single-boson production. Focusing on the top panel, nucleus-level cross sections and uncertainties at NLO roughly span

$$\sigma_{AA \to V\gamma}^{\rm NLO} \sim 10^{-3} \ \mu b - 1 \ \mu b,$$
 (5.15a)

$$\delta \sigma^{\rm NLO} / \sigma^{\rm NLO} \sim \pm 10\% - \pm 20\%$$
 . (5.15b)

For all collision energies, the $W^{\pm}\gamma$ rate is the largest, followed by the $W^{-}\gamma$, $W^{+}\gamma$, and finally $Z\gamma$ rates. As in the single boson case (Sec. 5.1), this hierarchy reflects gauge charges and parton densities.

We immediately focus on the K-factors, which are large and span with increasing energy:

$$K_{AA \to W\gamma}^{\rm NLO} \sim 2 - 10 , \qquad (5.16a)$$

$$K_{AA \to Z\gamma}^{\rm NLO} \sim 1.5 - 3$$
 (5.16b)

As in the diboson case (Sec. 5.2), the largeness of these corrections can be attributed to the presence of radiation amplitude zeros at the Born level. The amplitude zero is more severe in $V\gamma$ production than in VV' production due to (i) the Abelian nature of QED and (ii) the masslessness of the photon [66–71]. However, potential enhancements from soft-photon emission is moderated by the phase space cuts of Eq. (5.5). The absence of a $\gamma - Z - Z$ and $\gamma - \gamma - Z$ vertices also implies that $Z\gamma$ production experiences a smaller destructive interference at the Born level than $W\gamma$ production, which implies a smaller amplitude zero and subsequently to a smaller QCD K-factor at NLO. And as in the VV' case, corrections at NNLO suggest that the perturbative series stabilizes [74].

The three lower panels show the (per nucleon) cross section ratio with respect to the pp cross section. We report that the cross section ratios for charge- and flavor-symmetric channels $(W^{\pm}\gamma \text{ and } Z\gamma)$ have mostly flat ratios at or just below unity for $\sqrt{s_{NN}} \gtrsim 5$ TeV, whereas the charge- and flavor-asymmetric channels $(W^{-}\gamma \text{ and } W^{+}\gamma)$ deviate significantly from unity, particularly for $\sqrt{s_{NN}} \lesssim 30$ TeV. For example: at $\sqrt{s_{NN}} \sim 2$ TeV, the per nucleon rates for $W^{-}\gamma$ in lead, xenon, and carbon are nearly twice as large as the rate of for proton-proton collisions. Despite being a charge- and flavor-symmetric channel, $Z\gamma$ production can only occur through the emission of a photon off an initial-state quark. Hence, $Z\gamma$ is sensitive to the net weak and electric charges carried by *all* partons in an average nucleon, and consequentially the nucleon's net nuclear isospin. For all three ion configurations, we find that the ratios stabilize, *i.e.*, become flat, for collision energies that exceed $\sqrt{s_{NN}} \gtrsim 60-70$ TeV, or when $(\sqrt{\hat{s}}/\sqrt{s_{NN}}) \sim (M_V + p_T^{\gamma})/\sqrt{s_{NN}} \sim 4 \times 10^{-3}$. We refer to Tables 1-4 (rows 10-13) for a quantitative comparison of $V\gamma$ predictions at $\sqrt{s_{NN}} = 5$ TeV and 100 TeV.

5.4 Higgs associated processes

We now focus on the production of the Higgs boson (H) in association with one weak boson, as illustrated diagrammatically in Fig. 8(c), and specifically on processes given at LO by

$$q\overline{q}, q\overline{q'} \to W^{\pm}H, ZH, W^{-}H, W^{+}H$$
 (5.17)

NLO in QCD predictions for VH production were first reported in Ref. [75] and are now available at higher orders [76, 77].

We show in the top panel of Fig. 10(b) the nucleus-level total cross section at NLO in QCD for $W^{\pm}H$ (blue), ZH (green), $W^{-}H$ (red), and $W^{+}H$ (black) production, shown in descending order, in ²⁰⁸Pb-²⁰⁸Pb collisions versus $\sqrt{s_{NN}}$. As above, band thickness denotes residual scale uncertainty at this order. The lower panels show the same ratios as shown in Fig. 9(a) for single-boson production. Nucleus-level cross sections and scale uncertainties at NLO for lead-lead collisions span approximately

$$\sigma_{AA \to VH}^{\text{NLO}} \sim 10^{-3} \ \mu \text{b} - 0.6 \ \mu \text{b},$$
 (5.18a)

$$\delta \sigma^{\rm NLO} / \sigma^{\rm NLO} \sim \pm 10\% - \pm 20\%$$
 . (5.18b)

For all collision energies, the $W^{\pm}H$ rate is the largest, followed by the ZH, $W^{-}H$, and then $W^{+}H$ rates.

The most remarkable feature is the similarity of the individual ZH, W^-H , and W^+H rates, which is qualitatively different than what was observed for single-boson production (Sec. 5.1) and diboson production (Sec. 5.2). This behavior is accidental: the smaller $Z - q - \bar{q}$ couplings that lead to a suppressed single-Z production rate [see Fig. 9(a)] is balanced by the larger H - Z - Z coupling. For example: at $\sqrt{s_{NN}} = 100$ TeV the (ZH)-over- (W^-H) cross section ratio is approximately

$$\frac{\sigma_{AA \to ZH}^{\text{NLO}}}{\sigma_{AA \to W^{-}H}^{\text{NLO}}} \bigg|_{\sqrt{s_{NN}} = 100 \text{ TeV}}^{^{208}\text{Pb} - ^{208}\text{Pb}} \approx 1.071 , \qquad (5.19)$$

Figure 11. Representative Born-level Feynman graphs depicting the production of three weak bosons.

whereas the Z-over- W^- cross section ratio weighted by the (ZH)-over- (W^-H) coupling ratio is

$$\left(\frac{M_Z}{M_W \cos \theta_W}\right)^2 \times \left. \frac{\sigma_{AA \to Z}^{\rm NLO}}{\sigma_{AA \to W^-}^{\rm NLO}} \right|_{\sqrt{s_{NN}} = 100 \text{ TeV}}^{^{208}\rm{Pb} - ^{208}\rm{Pb}} \approx (1.286)^2 \times (0.617) \approx 1.020 .$$
(5.20)

We attribute the small, $\mathcal{O}(5\%)$ difference between these sets of ratios to the small kinematical differences in matrix elements, e.g., $\sqrt{\hat{s}} \sim M_V$ versus $\sqrt{\hat{s}} \sim (M_V + m_H)$, as well as to the small variations in PDFs, e.g., $x \sim M_V/\sqrt{s_{NN}}$ versus $x \sim (M_V + m_H)/\sqrt{s_{NN}}$.

The second panel shows the QCD K-factor at NLO, which grows monotonically and spans

$$K_{AA \to VH}^{\rm NLO} \sim 1.2 - 1.3$$
 (5.21)

for all channels. The color structure of VH production is identical to single weak boson production (Sec. 5.1) and therefore each receives the same QCD corrections at NLO. However, in the present case, NLO corrections are more modest than in single boson production. This follows from the increase in hard scale for the present case, *i.e.*, $\sqrt{\hat{s}} \sim (M_V + m_H)$ for associated VH production versus $\sqrt{\hat{s}} \sim M_V$ for single V production. A larger hard scale implies that the strong coupling constant $\alpha_s(\mu_r = \sqrt{\hat{s}})$ runs to smaller values in VH production, and hence leads to smaller shifts in normalization.

The three lower panels show the (per nucleon) cross section ratio with respect to the cross section for pp collisions. As in the diboson case (Sec. 5.2), we find that the cross section ratios for charge- and flavor-symmetric channels ($W^{\pm}H$ and ZH) have a ratio just below unity for collision scales above $\sqrt{s_{NN}} \gtrsim 5$ TeV. Contrary to this, the charge- and flavor-asymmetric channels ($W^{-}H$ and $W^{+}H$) deviate from unity for all $\sqrt{s_{NN}}$, with the most significant deviations below $\sqrt{s_{NN}} \lesssim 30$ TeV. For all three configurations of symmetric ion collisions, we find that the ratios stabilize, *i.e.*, become flat, for collision energies that exceed $\sqrt{s_{NN}} \gtrsim 40 - 50$ TeV. This corresponds to the ratio ($\sqrt{\hat{s}}/\sqrt{s_{NN}}$) ~ ($M_V + m_H$)/ $\sqrt{s_{NN}} \sim 4 - 5 \times 10^{-3}$. We refer to Tables 1-4 (rows 14-17) for a quantitative comparison of VH predictions at $\sqrt{s_{NN}} = 5$ TeV and 100 TeV.

5.5 Triboson Processes I: WWX and ZZX

Turning to the first set of triboson processes, we consider in Fig. 12(a) those processes with at least two W bosons and in Fig. 12(b) those processes with at least two Z bosons, as schematically illustrated by the Feynman diagrams in Fig. 11. Specifically, we consider the channels given at LO by the following partonic processes:

$$q\overline{q}, q\overline{q'} \rightarrow W^+W^-W^{\pm}, W^+W^-Z, W^+W^-\gamma, W^+W^-H, \text{ and}$$
 (5.22a)

$$q\bar{q}, q\bar{q'} \rightarrow ZZW^{\pm}, ZZZ, ZZH, ZZ\gamma$$
. (5.22b)

NLO predictions for W^+W^-X and ZZX were first reported in Refs. [27, 78–82]. We remind the reader that for processes with a final-state photon, we impose the phase space cuts given in Eq. (5.5).

In the top panel of Fig. 12(a) we show the nucleus-level cross section at NLO in QCD for $W^+W^-W^{\pm}$ (blue), W^+W^-Z (green), $W^+W^-\gamma$ (red), and W^+W^-H (black) production in descending order for ²⁰⁸Pb-²⁰⁸Pb collisions as a function of nucleon-nucleon collision energy. In the top panel of Fig. 12(b) we additionally show, also in descending order, predictions for ZZW^{\pm} (green), ZZZ (blue), ZZH (black) and $ZZ\gamma$ (red) production. In all cases, band thickness represents the residual scale uncertainty. In the lower panels we show the same nucleon-level ratios as in Fig. 9(a) for single-boson production.

Figure 12. Same as Fig. 9(a) but for (a) $W^+W^-W^{\pm}$ (blue), W^+W^-Z (green), $W^+W^-\gamma$ (red), and W^+W^-H (black), as well as for (b) ZZW^{\pm} (green), ZZZ (blue), ZZH (black) and $ZZ\gamma$ (red), all in descending order.

For $\sqrt{s_{NN}} = 1 - 100$ TeV, nucleus-level cross sections and uncertainties at NLO roughly span

$$\sigma_{AA \to WWV}^{\text{NLO}} \sim 10^{-5} \ \mu \text{b} - 0.2 \ \mu \text{b},$$
 (5.23a)

$$\sigma_{AA \to ZZV}^{\rm NLO} \sim 10^{-5} \ \mu b - 6 \times 10^{-2} \ \mu b,$$
 (5.23b)

$$\delta \sigma^{\rm NLO} / \sigma^{\rm NLO} \sim \pm 10\% - \pm 20\%$$
 . (5.23c)

Across all collision energies, the $W^+W^-W^{\pm}$ and W^+W^-Z channels shown in Fig. 12(a) have the largest rates and are highly comparable, particularly for $\sqrt{s_{NN}} \gtrsim 30 - 40$ TeV; below this energy range, the $W^+W^-W^{\pm}$ rate is slightly larger. Below these curves by roughly a factor of 4 lies the ZZW^{\pm} channel in Fig. 12(b). The $W^+W^-\gamma$, ZZZ, and W^+W^-H channels are the next largest in descending order, reaching $\sigma^{\text{NLO}} \sim \mathcal{O}(10^{-4} \ \mu\text{b}) [\mathcal{O}(10^{-2} \ \mu\text{b})]$ at $\sqrt{s_{NN}} \sim 5$ TeV [100 TeV]. The ZZH and $ZZ\gamma$ rates in Fig. 12(b) have the smallest rates, with $ZZ\gamma$ being smallest. This comparison is illustrated quantitatively in Tables 1-4 (rows 18-25) for $\sqrt{s_{NN}} = 5$ TeV and 100 TeV.

As with single boson production (Sec. 5.1), diboson production (Sec. 5.2), and $VH/V\gamma$ associated production (Secs. 5.3 and 5.4), the relative sizes of the triboson channels can be understood by power counting of coupling constants and phase space suppression. The latter manifests through the appearance of a $(1/4\pi)$ factor for each new final-state particle. For example: the $W^+W^-W^{\pm}$ rate at NLO in QCD is roughly $\mathcal{O}(5 \times 10^{-6})$ smaller than the inclusive W^{\pm} rate [see Fig. 9(a)]. To some degree, the WWW channel can be modeled as a real radiative correction to inclusive W^{\pm} production via a $\gamma^* \to W^+W^-$ leg. By power counting and phase-space suppression alone, one can estimate a cross-section ratio of

$$\frac{\sigma_{AA \to WWW}^{\text{NLO}}}{\sigma_{AA \to W}^{\text{NLO}}} \sim \mathcal{O}\left(\frac{\alpha}{4\pi}\frac{\alpha_W}{4\pi}\right) \sim 1.5 \times 10^{-6} .$$
(5.24)

Interfering channels, such as those with $Z^*/H^* \to W^+W^-$ legs, and differences in QCD corrections (discussed next) can account for the difference between Eq. (5.24) and $\mathcal{O}(5 \times 10^{-6})$. For completeness, we note that a comparable ratio can also be obtained by instead treating WWW production as a single-emission radiative correction to various diboson production channels.

In the second panels, we observe a variety of QCD K-factors at NLO. These span roughly

$$K_{AA \to WW\gamma}^{\rm NLO} \sim 1.5 - 4 , \qquad (5.25a)$$

$$K_{AA \to ZZW}^{\rm NLO} \sim 1.5 - 3$$
, (5.25b)

$$K_{AA \to WWW,WWZ}^{\text{NLO}} \sim 1.5 - 2.5$$
, (5.25c)

$$K_{AA \to ZZ\gamma}^{\rm NLO} \sim 1.4 - 2 , \qquad (5.25d)$$

$$K_{AA \to WWH, ZZH, ZZZ}^{\text{NLO}} \sim 1.4 - 1.5$$
 (5.25e)

While more modest than for VV' processes (see Secs. 5.2 and 5.3), several of the K-factors here are large (≥ 2) , particularly for channels with final-state photons. Overall, the sizable importance of these K-factors can be attributed to the combination of three ingredients [80]: (i) the disruption of radiation zeros, which can be expected since the gauge and color structures of many VVV sub-channels are similar to diboson production; (ii) the opening of new partonic channels, *i.e.*, (gq)-scattering; and (iii) sizable finite virtual+soft corrections, which are positive and can be larger than those in single-boson production.

In the three lower panels we again show the (per nucleon) cross section ratio with respect to pp collisions. For $\sqrt{s_{NN}} \gtrsim 10$ TeV, we observe that for all channels the ratios are approximately flat and are consistent with being at or just below unity. Again, we attribute this similarity to pp collisions to summing over all charge and flavor configurations for each process under consideration. This sum renders the nucleon-level cross section (approximately) isospin-invariant, that is to say, it does not depend on the colliding nucleon being a pure proton state, pure neutron state, or some admixture of the two.

5.6 Triboson II: WZX, $\gamma\gamma V$, HHV, and other processes

We now continue in Fig. 13 with various other triboson processes that are given at LO by:

$$q\overline{q}, q\overline{q'} \to W^{\pm}Z\gamma, W^{\pm}ZH, W^{\pm}\gamma H, Z\gamma H$$
 and (5.26a)

$$q\bar{q}, q\bar{q'} \rightarrow W^{\pm}\gamma\gamma, W^{\pm}HH, Z\gamma\gamma, ZHH$$
. (5.26b)

The phase space cuts in Eq. (5.5) are imposed on channels with final-state photons. Predictions at NLO in QCD for these processes were first reported in Refs. [27, 83–88]

In the top panel of Fig. 13(a) we show the nucleus-level cross section at NLO in QCD for $W^{\pm}Z\gamma$ (black), $W^{\pm}ZH$ (blue), $W^{\pm}\gamma H$ (red), and $Z\gamma H$ (green) production in descending order for symmetric ²⁰⁸Pb-²⁰⁸Pb collisions as a function of the nucleon-nucleon collision energy $\sqrt{s_{NN}}$. Additionally, in the top panel of Fig. 13(b) we show, also in descending order, predictions for $W^{\pm}\gamma\gamma$ (red), $W^{\pm}HH$ (black), $Z\gamma\gamma$ (blue) and ZHH (green) production. In all cases, band thickness corresponds to the residual scale uncertainty at NLO in pQCD. In the lower panels we display the same nucleon-level ratios as in Fig. 9(a).

For $\sqrt{s_{NN}} = 1 - 100$ TeV, nucleus-level cross sections and uncertainties at NLO are roughly

$$\sigma_{AA \to WZX}^{\text{NLO}} \sim 10^{-6} \ \mu \text{b} - 10^{-2} \ \mu \text{b},$$
 (5.27a)

$$\sigma_{AA \to W\gamma\gamma}^{\rm NLO} \sim 10^{-7} \ \mu b - 10^{-3} \ \mu b,$$
 (5.27b)

$$\sigma_{AA \to VHH, Z\gamma\gamma, V\gamma H}^{\text{NLO}} \sim 10^{-6} \ \mu \text{b} - 10^{-4} \ \mu \text{b}, \qquad (5.27c)$$

$$\delta \sigma^{\rm NLO} / \sigma^{\rm NLO} \sim \pm 10\% - \pm 30\%$$
 (5.27d)

For all $\sqrt{s_{NN}}$ values, the $W^{\pm}Z\gamma$ channel has the largest rate, followed by the $W^{\pm}ZH$ and $W\gamma\gamma$ channels by factors of a few to several. About a factor of 10 below stand the remaining channels, which all have comparable rates. As with previous channels involving final-state photons, the hierarchy is influenced by the $p_T^{\gamma} > 150 \text{ GeV} \sim 2M_V \text{ cut}$. Also playing a role at large $\sqrt{s_{NN}}$ is the emergence of collinear/soft $V^* \to V'V''$ splittings, for $V \in \{\gamma, W^{\pm}, Z\}$, which are logarithmically enhanced [89–94].

Figure 13. Same as Fig. 9(a) but for (a) $W^{\pm}Z\gamma$ (black), $W^{\pm}ZH$ (blue), $W^{\pm}\gamma H$ (red), and $Z\gamma H$ (green), as well as (b) $W^{\pm}\gamma\gamma$ (red), $W^{\pm}HH$ (black), $Z\gamma\gamma$ (blue) and ZHH (green), all in descending order.

In comparison to the triboson processes in Sec. 5.5, we observe that the WZX and $W\gamma\gamma$ channels have comparable rates to those reported in Fig. 12. This is follows from the presence of similar gauge couplings and large QCD corrections. All remaining channels have categorically smaller cross sections than those reported in Fig. 12 and follows from a mixture of relative coupling suppression, *e.g.*, $(\alpha/\alpha_W) \sim 0.2$, more modest QCD corrections, and, most importantly, strong destructive interference. For example: the ratio of the WZH and $W\gamma H$ cross sections at $\sqrt{s_{NN}} = 100$ TeV greatly exceeds the aforementioned coupling ratio and is approximately

$$\frac{\sigma_{AA \to W^{\pm} \gamma H}^{\text{NLO}}}{\sigma_{AA \to W^{\pm} ZH}^{\text{NLO}}} \bigg|_{\sqrt{s_{NN}} = 100 \text{ TeV}}^{208 \text{Pb} - 208 \text{Pb}} \sim \mathcal{O}(4 \times 10^{-2}) .$$
(5.28)

In the second panels, we observe much larger and much smaller QCD K-factors at NLO than reported for the WWV and ZZV channels in Sec. 5.5. Here, they roughly span

$$K_{AA \to WZ\gamma, W\gamma\gamma}^{\rm NLO} \sim 2 - 6 , \qquad (5.29a)$$

$$K_{AA \to Z\gamma\gamma, V\gamma H, WZH}^{\text{NLO}} \sim 1.5 - 2 , \qquad (5.29b)$$

$$K_{AA \to VHH}^{\rm NLO} \sim 1.3 - 1.4$$
 . (5.29c)

The largest corrections occur for $W\gamma\gamma$ and $WZ\gamma$ production, which feature large amplitude zeros⁸ [95, 96]. The rise in K^{NLO} in these two channels with increasing collision energy, and hence an increasing g density, can be interpreted as the emerging dominance of (qg)-scattering, which opens at $\mathcal{O}(\alpha_s)$. NNLO predictions for these

⁸Strong "zeros" are anticipated in all processes of the form $AA \rightarrow W + n\gamma + mZ$ [69–71].

channels are not yet available; however, it is suspected that, as in NNLO predictions for diboson production, a modest rate increase will still occur due to the opening of the (gg)-scattering channels and NLO corrections to (qg)-scattering. This suggests that the scale uncertainties at NLO for triboson processes are not reliable estimates of missing higher-order terms.

We present in the three lower panels (per nucleon) cross section ratios with respect to pp collisions. We observe that most all channels converge to flat values at or just below unity for $\sqrt{s_{NN}} \gtrsim 5 - 10$ TeV. This further supports our argument that charge- and flavor-summed channels are approximately isopsin symmetric. The only exception consists of the $Z\gamma\gamma$ channel, which as argued for $Z\gamma$ production (Sec. 5.2), is indirectly sensitive to the net nuclear isospin of the average nucleon because the $Z-q-\bar{q}$ and $\gamma-q-\bar{q}$ couplings are flavor-dependent. The cross section ratios for these two processes converge to flat values below unity for $\sqrt{s_{NN}} \gtrsim 60 - 70$ TeV. This corresponds to the fraction $(\sqrt{\hat{s}}/\sqrt{s_{NN}}) \sim (M_Z + 2p_T^{\gamma})/\sqrt{s_{NN}} \lesssim 6 \times 10^{-3}$. We refer to Tables 1-4 (rows 26-33) for a quantitative comparison of predictions for this set of triboson processes at $\sqrt{s_{NN}} = 5$ TeV and 100 TeV.

5.7 Inclusive photon processes

Moving beyond massive electroweak bosons, we now consider inclusive photon production processes. Specifically, we focus on prompt photon production, *i.e.*, the production of a single, high-energy, central photon in association with anything, as illustrated diagrammatically in Fig. 14, as well as on photon pair production (Fig. 8) and triple photon production(Fig. 11). At LO, these are described by

$$qg, \ \overline{q}g, \ q\overline{q} \to \gamma + X, \text{ where } X \in \{q, \overline{q}, g\}, \text{ and } q\overline{q} \to \gamma\gamma, \ \gamma\gamma\gamma \ .$$
 (5.30)

To regulate infrared divergencies in matrix elements, we impose the phase space cuts of Eq. (5.5). Predictions at NLO in QCD for inclusive photon production processes were first reported in Refs. [97–104, 104].

We show in the top panel of Fig. 15(a) the nucleus-level total cross section at NLO in QCD for $\gamma + X$ (blue), $\gamma\gamma$ (black), and $\gamma\gamma\gamma$ (red), shown in descending order, in ²⁰⁸Pb-²⁰⁸Pb collisions and as a function of $\sqrt{s_{NN}}$. The band thickness corresponds to the residual scale uncertainty at this order. In the lower panels we show the same ratios as shown in Fig. 9(a). Focusing on the top panel, cross sections and uncertainties at NLO roughly span

$$\sigma_{AA \to \gamma + X}^{\text{NLO}} \sim 10^{-3} \ \mu \text{b} - 10^2 \ \mu \text{b},$$
 (5.31a)

$$\sigma_{AA \to \gamma\gamma}^{\text{NLO}} \sim 10^{-5} \ \mu \text{b} - 10^{-1} \ \mu \text{b},$$
 (5.31b)

$$\sigma_{AA \to \gamma\gamma\gamma}^{\rm NLO} \sim 10^{-9} \ \mu b - 4 \times 10^{-5} \ \mu b,$$
 (5.31c)

$$\delta \sigma^{\rm NLO} / \sigma^{\rm NLO} \sim \pm 10\% - \pm 20\%$$
 (5.31d)

For all $\sqrt{s_{NN}}$, single prompt photon production has the largest rate, followed by pair and triple production. The strong hierarchy across all three channels reflects the relative coupling and phase space suppression for producing one, two, or three photons as well as the role of different parton densities. For example: already at LO, $\gamma + X$ is sensitive to the gluon nPDF though the (qg) luminosity, which is the largest of all partonic configurations across all center-of-mass energies (see Sec. 4). At NLO, the $gg \to q\bar{q}\gamma$ channel opens, which contributes to large $\mathcal{O}(\alpha_s)$ corrections; for context, $gg \to q\bar{q}\gamma$ contributes to the dijet+photon process. On the other hand, the $\gamma\gamma$ and $\gamma\gamma\gamma$ processes are strictly initiated by $(q\bar{q})$ annihilation at LO and are only sensitive to the gluon distribution at $\mathcal{O}(\alpha_s)$, *i.e.*, at NLO in QCD. The difference in parton luminosities alone accounts for an $\mathcal{O}(40)$ times difference between the prompt photon and multi-photon production rates. As shown by the following ratios, coupling and naïve phase space suppression can account for most of the differences at high energies:

$$\left(\frac{\alpha}{\alpha_s}\right) \times \left(\frac{\sum_{q=u}^b e_q^4}{\sum_{q=u}^b e_q^2}\right) \times \left(\frac{\mathcal{L}_{q\bar{q}}}{\mathcal{L}_{qg}}\right) \times \left.\frac{\sigma_{AA\to\gamma+X}^{\text{NLO}}}{\sigma_{AA\to\gamma\gamma}^{\text{NLO}}}\right|_{\sqrt{s_{NN}}=100 \text{ TeV}}^{208 \text{ Pb}-208 \text{ Pb}} \approx (0.075) \times (0.40) \times \left(\frac{1}{40}\right) \times (1480) \approx 1.11 , \qquad (5.32)$$

$$\left(\frac{\alpha}{4\pi}\right) \times \left. \frac{\sigma_{AA \to \gamma\gamma}^{\rm NLO}}{\sigma_{AA \to \gamma\gamma\gamma}^{\rm NLO}} \right|_{\sqrt{s_{NN}} = 100 \text{ TeV}}^{2^{08}\rm Pb - 2^{08}\rm Pb} \approx \left(6 \times 10^{-4}\right) \times (1900) \approx 1.14 .$$
 (5.33)

Figure 14. Representative Feynman diagrams, at the Born level, depicting inclusive photon production.

The closeness of these ratios to unity underscores how so few terms, namely gauge coupling, gauge charges, and luminosities, drive the global of size of photon processes. Exact differences in matrix elements, including color factors and sizable subleading channels, account for the remainder.

Focusing on the QCD K-factors, which are all sizable for $\sqrt{s_{NN}} = 1 - 100$ TeV, we report:

$$K_{AA \to \gamma + X}^{\text{NLO}} \sim 1.75 - 2 , \qquad (5.34a)$$

$$K_{AA \to \gamma\gamma}^{\text{NLO}} \sim 1.5 - 2.4 , \qquad (5.34b)$$

$$K_{AA \to \gamma\gamma\gamma}^{\text{NLO}} \sim 1.5 - 2.7$$
 (5.34c)

Unlike many channels previously discussed, the NLO K-factor for prompt photon production remains relatively stable/flat with collider energy. Diphoton and triphoton production, on the other hand, exhibit QCD K-factors at NLO that grows with collider energy. We attribute this difference to the opening of new partonic channels in the $\gamma\gamma$ and $\gamma\gamma\gamma$ processes at $\mathcal{O}(\alpha_s)$, and particularly gluon-initiated channels, which introduce a reliance on the (qg) parton luminosity and hence an increased dependence on $\sqrt{s_{NN}}$. As prompt photon production is already sensitive to (qg)-scattering at LO, such a dependence on $\sqrt{s_{NN}}$ is already present at LO. Instead, at NLO prompt photon production receives sizable real corrections from dijet+photon process $pp \rightarrow jj\gamma$, including the $gg \rightarrow$ $q\bar{q}\gamma$ subchannel, as well as virtual corrections, which introduce logarithmic and color-factor enhancements [99– 101, 103]. We do not separately identify $q^* \rightarrow q\gamma$ fragmentation; this has some role in the largeness of QCD corrections found in Fig. 15(a). Corrections at NNLO in QCD to inclusive single and diphoton production remain large [105–108], again through a mix of new production topologies and virtual corrections. However, agreement with LHC pp data suggest higher order perturbative corrections will not introduce additional large corrections [109–112].

The three lower panels show the (per nucleon) cross section ratios with respect to the pp cross section. We report that all three cross section ratios sit significantly below unity for $\sqrt{s_{NN}} \leq 10 - 20$ TeV, and converge to flat values at or just below unity for $\sqrt{s_{NN}} \gtrsim 50$ TeV. (The ratios for the $\gamma + X$ channel appear to converge at lower collision energies, with $\sqrt{s_{NN}} \gtrsim 20 - 30$ TeV.) Overall, this corresponds to the ratio $(\sqrt{\hat{s}}/\sqrt{s_{NN}}) \sim (2p_T^{\gamma})/\sqrt{s_{NN}} - (3p_T^{\gamma})/\sqrt{s_{NN}} \lesssim 0.01$. We refer to Tables 1-4 (rows 34-36) for a quantitative comparison of predictions for single and multi-photon production at $\sqrt{s_{NN}} = 5$ TeV and 100 TeV.

Despite appearing charge and flavor symmetric, the three photon channels listed in Eq. (5.30) are inherently sensitive to the net electric charge, and hence net nuclear isospin, of nucleons. More specifically, ²⁰⁸Pb, ¹³¹Xe, and ¹²C are neutron-rich, meaning that the *average* nucleon is more neutron-like than proton-like. This implies that the average electric charge of an average nucleon is smaller than a proton. Hence, by electric charge conservation the average nucleons for our three isotopes have a larger number density of partons with negative electric charge than found in a proton. For instance: nucleon-level sum rules for valence *u*- and *d*-quarks can be written as [38]:

$$\int_{0}^{A} dx \ \left[u_{v}(x) - d_{v}(x) \right] = \left[2Z + (A - Z) \right] - \left[Z + 2(A - Z) \right] = 2Z - A , \qquad (5.35)$$

which is negative for our three isotopes but positive for the proton. Assuming $\overline{u}(x) = \overline{d}(x)$, the relationship implies larger $(d_v g)$ and $(d_v \overline{d})$ luminosities and smaller $(u_v g)$ and $(u_v \overline{u})$ luminosities than found in a proton. Since inclusive photon production is proportional to the electric charges of quarks, when $\gamma + X$, $\gamma\gamma$, and $\gamma\gamma\gamma$ production is driven by valence quarks, *i.e.*, when $(p_T^{\gamma}/\sqrt{s_{NN}}) \sim \mathcal{O}(1)$, then one expects nucleon-level cross section ratios well below unity. Conversely, when production is driven by sea quarks, *i.e.*, when $(p_T^{\gamma}/\sqrt{s_{NN}}) \ll \mathcal{O}(1)$,

Figure 15. Same as Fig. 9(a) but for (a) $\gamma + X$ (blue), $\gamma \gamma$ (black), and $\gamma \gamma \gamma$ (red) production, as well as for (b) $t\bar{t}$ (black), $t\bar{t}Z$ (purple), $t\bar{t}H$ (blue), $t\bar{t}\gamma$ (pink) $t\bar{t}W^-$ (green), and $t\bar{t}W^+$ (yellow) production, all in descending order.

then one expects nucleon-level cross section ratios close unity. (Since the contribution from u_v and d_v can never be removed, the ratio will always remain below unity.)

5.8 Top quark processes

Finally, we consider the pair production of top quarks, together with the associated production of top quark pairs with an additional electroweak boson. Specifically, we focus on those processes described schematically by Fig. 16 at LO, and by the partonic configurations

$$q\bar{q}, q\bar{q'}, gg \rightarrow t\bar{t}, t\bar{t}Z, t\bar{t}H t\bar{t}\gamma, t\bar{t}W^-, t\bar{t}W^+$$
 (5.36)

For processes with a final-state photon, we impose the phase space cuts given in Eq. (5.5). Predictions for $t\bar{t}$ and $t\bar{t}X$ at NLO in QCD were first reported in Refs. [113–120] and are available for some channels at higher precision [121, 122].

In the top panel of Fig. 15(b) we show the nucleus-level cross section at NLO in QCD for $t\bar{t}$ (black), $t\bar{t}Z$ (purple), $t\bar{t}H$ (blue), $t\bar{t}\gamma$ (pink) $t\bar{t}W^-$ (green), and $t\bar{t}W^+$ (yellow) production in descending order for symmetric ²⁰⁸Pb-²⁰⁸Pb collisions as a function of $\sqrt{s_{NN}}$. As before, band thickness corresponds to the residual scale uncertainty at NLO in pQCD. In the lower panels we show the same nucleon-level ratios as in Fig. 9(a). For $\sqrt{s_{NN}} = 1 - 100$ TeV, nuclear cross sections and uncertainties at NLO are approximately

$$\sigma_{AA \to t\bar{t}}^{\text{NLO}} \sim 10^{-2} \ \mu \text{b} - 10^3 \ \mu \text{b},$$
 (5.37a)

$$\sigma_{AA \to t\bar{t}V}^{\rm NLO} \sim 10^{-4} \ \mu \rm{b} - 1 \ \mu \rm{b},$$
 (5.37b)

$$\delta \sigma^{\rm NLO} / \sigma^{\rm NLO} \sim \pm 10\% - \pm 20\%$$
 . (5.37c)

Figure 16. Representative Feynman graphs, at the Born level, depicting production of (a) $t\bar{t}$ and (b) $t\bar{t}V$ and $t\bar{t}H$.

For all collision energies, $t\bar{t}$ production is the dominant channel; this is to be expected as $t\bar{t}$ is only a two-body final state, meaning it is less suppressed by (electroweak) coupling constants and phase-space constraints. Roughly two orders of magnitude below lie the rates for the associated production channels. This difference is consistent with naïve power counting and phase space suppression, *e.g.*, $(\alpha_W/4\pi) \sim 3 \times 10^{-3}$. Furthermore, at lower collision energies, there is an increased importance of phase space suppression associated with kinematic thresholds.

For all $\sqrt{s_{NN}}$ under consideration, the $t\bar{t}Z$ and $t\bar{t}H$ channels are respectively the leading and sub-leading associate production channels. The former is roughly 1.5 - 2 times larger than the latter, with the difference slowly increasing with collision energy. In this case, the difference in scattering rates is a subtle interplay between kinematic factors and the electroweak couplings of the Z and H boson to the top quark. More specifically, in the large $\sqrt{s_{NN}}$ limit, $t\bar{t}Z$ and $t\bar{t}H$ production in AA collisions are driven by (gg)-scattering, implying that the final-state Z and H bosons are both sourced from top quarks. In this same limit, inclusive $t\bar{t}Z$ production is enhanced by the emission of (relatively) soft and collinear Z bosons [89–94]. This kinematical enhancement is offset by the $t - \bar{t} - Z$ coupling itself, which is much smaller than the $t - \bar{t} - H$ coupling. As a consequence, we see that at $\sqrt{s_{NN}} = 100$ TeV the $(t\bar{t}Z)$ -over- $(t\bar{t}H)$ cross section ratio weighted by (a) the $(t\bar{t}H)$ -over- $(t\bar{t}Z)$ coupling ratio and (b) electroweak logarithms for a representative hard scale of $Q = (2m_t + m_Z)$ roughly gives⁹

$$\frac{\left(\frac{gm_t}{2M_W}\right)^2}{\left(\frac{g}{\cos\theta_W}\right)^2 \left[(Q_t \sin^2\theta_W)^2 + (T_{3L}^t - Q_t \sin^2\theta_W)^2 \right] \times \log^2\left(\frac{Q^2}{M_Z^2}\right)} \times \frac{\sigma_{AA \to t\bar{t}Z}^{\text{NLO}}}{\sigma_{AA \to t\bar{t}H}^{\text{NLO}}} \right|_{\sqrt{s_{NN}} = 100 \text{ TeV}}^{2^{08}\text{Pb} - 2^{08}\text{Pb}} \approx (0.627) \times (1.715) \approx 1.075.$$
(5.38)

For lower collision energies with $\sqrt{s_{NN}} \lesssim 30$ TeV, the $t\bar{t}W^-$ and $t\bar{t}W^+$ channels are the next largest scattering channels with $t\bar{t}\gamma$ exhibiting the smallest rate of all channels listed in Eq. (5.36). For larger $\sqrt{s_{NN}}$ values, the situation is reverse: the $t\bar{t}\gamma$ production rate exceeds both $t\bar{t}W^{\pm}$ cross sections. Over the entire range, $t\bar{t}W^-$ has a slightly larger cross section than $t\bar{t}W^+$. This is due to the fact that $t\bar{t}W$ is driven by $(q\bar{q'})$ - and (qg)-scattering coupled with the neutron-rich nature of ²⁰⁸Pb.

Focusing on $t\bar{t}\gamma$ production, note that the (relatively) dynamical dependence of $t\bar{t}\gamma$ on collision energy indicates a dependence on phase space. (At LO in the electroweak theory, electroweak couplings are scale invariant and therefore are constant as $\sqrt{s_{NN}}$ changes.) We attribute the behavior observed in Fig. 15(b) to the transverse momentum requirement on the photon, which scales as $p_T^{\gamma} \sim 2M_V$. As a consequence, the kinematic threshold for $t\bar{t}\gamma$ production is about $\min(\sqrt{\hat{s}}) \sim (2m_t + p_T^{\gamma}) \gtrsim 500$ GeV. Evidently, the process is significantly more phase-space suppressed than $t\bar{t}W^{\pm}$ for $\sqrt{s_{NN}} \ll 10 - 20$ TeV and relatively unsuppressed for $\sqrt{s_{NN}} \gg 20 - 30$ TeV.

⁹This argument is complicated by the presence of relative helicity suppression in the $t\bar{t}H$ process and the Z boson's polarization. For transversely polarized Z bosons (Z_T) , the $t - \bar{t} - Z_T$ coupling is helicity conserving, meaning that squared matrix elements contain relative factors of $|\mathcal{M}_{t\bar{t}Z_T}|^2 \sim [(q_t^{\prime})^2/\hat{s}] \sim \mathcal{O}(1)$, where q_t is the off-shell momentum of an internal top quark and is naturally the scale of the hard process, $\sqrt{\hat{s}}$. The $t - \bar{t} - H$ coupling, on the other hand, is helicity inverting, meaning that squared matrix elements contain relative factors of $|\mathcal{M}_{t\bar{t}H}|^2 \sim (m_t^2/\hat{s}) \sim (m_t^2)/(2m_t + m_H)^2 \sim \mathcal{O}(10^{-1})$. However, in practice, the Q^2 argument in the double log in Eq. (5.38) is also much smaller. For longitudinally polarized Z bosons (Z₀), the $t - \bar{t} - Z_0$ coupling is helicity inverting, meaning that the $t\bar{t}Z_0$ rate should converge to the $t\bar{t}H$ rate according to the Goldstone Equivalence Theorem [123, 124].

In the second panels, we observe a variety of QCD K-factors at NLO. These span roughly

$$K_{AA \to t\bar{t}, t\bar{t}Z/H/\gamma}^{\rm NLO} \sim 1.6 - 1.5$$
, (5.39a)

$$K_{AA \to t\bar{t}W^{\pm}}^{\rm NLO} \sim 1.4 - 2.8$$
 . (5.39b)

While corrections at NLO in QCD for $t\bar{t}$ and $t\bar{t}Z/H/\gamma$ production seem modest, corrections beyond this order are still sizable [121, 122, 125, 126]. This is particularly true for $t\bar{t}W^{\pm}$ production [122, 125, 126], which proceeds at LO by $q\bar{q'}$ annihilation and only at NLO in QCD does the (qg)-scattering channel open. The large and comparable K-factors for $t\bar{t}W^-$ and $t\bar{t}W^+$ essentially reflect the opening of this partonic channel and a gluon distribution that grows with increasing $\sqrt{s_{NN}}$ (for a fixed scale). In summary, QCD corrections at NLO and beyond for inclusive and associated $t\bar{t}$ production in AA collisions are necessary for reliable theoretical predictions. However, further exploration in this direction requires two-loop computations and is beyond the scope the present work.

In the three lower panels we show (per nucleon) cross section ratios with respect to pp collisions. For $\sqrt{s_{NN}} \gtrsim 5-15$ TeV, we observe that all charge-symmetric and flavor-symmetric channels, *i.e.*, the $t\bar{t}, t\bar{t}Z, t\bar{t}H$, and $t\bar{t}\gamma$ channels, converge to a flat value close to unity. This similarity reflects the fact that these channels are driven by (gg)-scattering, which exhibits a parton luminosity (see Sec. 4) that is largely insensitive to the precise (A, Z) configuration, *i.e.*, is approximately isospin symmetric. On the other hand, for $t\bar{t}W^-$ and $t\bar{t}W^+$ production, we find large pulls above and below unity respectively. As in inclusive W^- and W^+ production in Sec. 5.1, these pulls are due to the processes $q\bar{q'} \rightarrow t\bar{t}W^-$ and $q\bar{q'} \rightarrow t\bar{t}W^+$ being charge-/flavor-asymmetric partonic scattering processes, that are thus sensitive to the (A, Z) configuration of a nucleus. As for other processes, the cross section ratios for these two processes converge to flat values. Interestingly though, since the PDF uncertainties for $t\bar{t}W^-$ and $t\bar{t}W^+$ production are sufficiently small and sufficiently away from unity, it is possible to estimate the limits of the ratios. For asymptotically large collision energies, we find at the nucleon level

$$\mathcal{R}_{NN}(t\bar{t}W^{-}) = \lim_{\sqrt{s_{NN}} \to \infty} \left(\frac{\sigma_{NN \to t\bar{t}W^{-}}^{\mathrm{NLO}}}{\sigma_{pp \to t\bar{t}W^{-}}^{\mathrm{NLO}}} \right) \approx 1.2 - 1.3 , \qquad (5.40a)$$

$$\mathcal{R}_{NN}(t\bar{t}W^+) = \lim_{\sqrt{s_{NN}} \to \infty} \left(\frac{\sigma_{NN \to t\bar{t}W^+}}{\sigma_{pp \to t\bar{t}W^+}^{\text{NLO}}} \right) \approx 0.8 - 0.9 , \qquad (5.40b)$$

for our representative ion configurations. The processes reach these plateaus when $\sqrt{s_{NN}} \gtrsim 70 - 80$ TeV. This corresponds to the fraction $(\sqrt{\hat{s}}/\sqrt{s_{NN}}) \sim (2m_t + M_W)/\sqrt{s_{NN}} \lesssim 5 - 6 \times 10^{-3}$. We refer to Tables 1-4 (rows 37-42) for a quantitative comparison of predictions for top quark production at $\sqrt{s_{NN}} = 5$ TeV and 100 TeV.

5.9 Summary of cross sections

We summarize our catalog of ²⁰⁸Pb-²⁰⁸Pb cross sections in Table 1. For each process that we considered (column 1), we give the per nucleon cross sections at NLO in pQCD [µb] for a representative collision energy of $\sqrt{s_{NN}} = 5$ TeV (column 3), the associated scale [%] and PDF uncertainty [%] (columns 4-5), and the QCD K-factor at NLO (column 6). We also give the analogous information for a representative collision energy of $\sqrt{s_{NN}} = 100$ TeV (column 7-10). For reproducibility, we provide the MG5AMC syntax used generate the matrix elements for each computation (column 2). For ¹³¹Xe, ¹²C, and ¹H, we show the same information respectively in Tables 2, 3, and 4.

Per nucleon NLO in QCD cross sections (in μ b) for various processes, for proton collisions, and the representative collision energies $\sqrt{s_{NN}} = 5$ TeV and 100 TeV, the corresponding MG5AMC simulation syntax (with define ww = w+ w-), the associated scale and PDF uncertainties [%], and QCD *K*-factor.

6 Extrapolating Cross Sections from One Nucleus to Another

In Sec. 5 we surveyed the inclusive and fiducial cross sections for dozens of high-energy processes as a function of collider energy. One observation (of many) was that the ratios of the nucleon-level cross section for symmetric ²⁰⁸Pb, ¹³¹Xe, and ¹²C collisions with respect to symmetric proton collisions tended to converge to some number for sufficiently high collider energies. In many cases, these were near but not equal to unity. Despite different nuclei exhibiting qualitatively different parton densities (Sec. 3) and parton luminosities (Sec. 4), findings suggest that it may be possible to extrapolate reliably a particular cross section for one pair of colliding nuclei from a second pair at sufficiently high collider energies. In this section, we explore quantitatively this possibility.

For the inclusive production of a particular final state \mathcal{F} , possibly with phase space restrictions, we consider the cross section estimate (est.) obtained by multiply a true nuclear-level cross section (true) by the appropriate ratio of atomic numbers. Symbolically, this is given by

$$\sigma^{\text{est.}}(\mathcal{A}_1 \mathcal{A}_2 \to \mathcal{F} + X) = \left(\frac{A_1 A_2}{A_3 A_4}\right) \times \sigma^{\text{true}}(\mathcal{A}_3 \mathcal{A}_4 \to \mathcal{F} + X)$$
(6.1a)

$$= (A_1 A_2) \times \sigma_{NN}^{\text{true}}(N_3 N_4 \to \mathcal{F} + X) .$$
(6.1b)

According to the definition in Eq. (5.2), this reduces to the product of (a) the target atomic numbers (A_1A_2) and (b) the starting nucleon-level cross section $\sigma_{N_3N_4}$. One can then define the following as the relative difference [%] between the estimated and true nucleus-level cross sections:

$$\frac{\delta\sigma_{\mathcal{A}_{3}\mathcal{A}_{4}}^{\mathcal{A}_{1}\mathcal{A}_{2}}}{\sigma_{\mathcal{A}_{1}\mathcal{A}_{2}}^{\text{true}}} = \frac{\sigma^{\text{est.}}(\mathcal{A}_{1}\mathcal{A}_{2} \to \mathcal{F} + X) - \sigma^{\text{true}}(\mathcal{A}_{1}\mathcal{A}_{2} \to \mathcal{F} + X)}{\sigma_{\mathcal{A}_{1}\mathcal{A}_{2}}^{\text{true}}(\mathcal{A}_{1}\mathcal{A}_{2} \to \mathcal{F} + X)}$$
(6.2a)

$$= \frac{(A_1A_2) \times \sigma_{NN}^{\text{true}}(N_3N_4 \to \mathcal{F} + X) - (A_1A_2) \times \sigma_{NN}^{\text{true}}(N_1N_2 \to \mathcal{F} + X)}{(A_1A_2) \times \sigma_{NN}^{\text{true}}(N_1N_2 \to \mathcal{F} + X)}$$
(6.2b)

$$= \frac{\sigma_{NN}^{\text{true}}(N_3N_4 \to \mathcal{F} + X) - \sigma_{NN}^{\text{true}}(N_1N_2 \to \mathcal{F} + X)}{\sigma_{NN}^{\text{true}}(N_1N_2 \to \mathcal{F} + X)} .$$
(6.2c)

For the case of symmetric beams, we have $\mathcal{A}_4 = \mathcal{A}_3$ and $\mathcal{A}_2 = \mathcal{A}_1$ as well as $N_4 = N_3$ and $N_2 = N_1$, but otherwise the expression remains the same. Two observations can be drawn from Eq. (6.2): First and most importantly, the expression quantifies the error in using Eq. (6.1) to extrapolate cross sections across nuclei. Second but more interesting, we find that an uncertainty at the *nuclear level* can be expressed in terms of *nucleon-level* quantities. To guide further discussion, we note that intuitively the closer this error is to zero, the better the extrapolation. However, a nonzero number is also useful as one can extract an "offset" factor Δ_{offset} . One can then, in principle, improve the extrapolation formula of Eq. (6.1) by the following modification

$$\sigma^{\text{est.}}(\mathcal{A}_1 \mathcal{A}_2 \to \mathcal{F} + X) = (A_1 A_2) \times \sigma^{\text{true}}_{NN}(N_3 N_4 \to \mathcal{F} + X) + \Delta_{\text{offset}} .$$
(6.3)

In Figs. 17 and 18, we show as a function of nucleon-nucleon collision energy $\sqrt{s_{NN}}$ the extrapolation error, as defined in Eq. (6.2), in estimating the scattering cross sections at NLO in QCD for our various processes and isotopes from the true predictions for ²⁰⁸Pb. Also shown is the uncertainty band stemming from the PDF uncertainty of ²⁰⁸Pb. In all plots, we consider (top panel) ¹H, (middle panel) ¹²C, and (bottom panel) ¹³¹Xe.

We start our assessment with Fig. 17, where we have: (a) single weak boson production, (b) diboson production, (c) associated photon-weak boson production, and (d) associated Higgs-weak boson production. The first remarkable finding is the extrapolation to ¹³¹Xe. For all processes and collision energies, the extrapolation error sits at or just around zero, with a PDF uncertainty in the range of $\mathcal{O}(\pm 5\%) - \mathcal{O}(\pm 20\%)$. For $\sqrt{s_{NN}} \gtrsim 5-10$ TeV, a similar trend holds for ¹²C. While the error for carbon converges to $\delta\sigma/\sigma|_{\text{est.}} \sim 0\%$ to -10%, this lies within the $\mathcal{O}(\pm 5\%) - \mathcal{O}(\pm 20\%)$ PDF uncertainty. For low collision energies, *i.e.*, $\sqrt{s_{NN}} \lesssim 5 - 10$ TeV, the error can grow to about $\delta\sigma/\sigma|_{\text{est.}} \sim -25\%$. We broadly attribute these similarities and differences to two ingredients: (i) the relative nucleon content of the isotopes, which are comparable and are approximately $Z: (A - Z) \sim 40: 60 (40: 60) [50: 50]$ for ²⁰⁸Pb (¹³¹Xe) [¹²C], and (ii) the growing important of valence quarks (gluons) at the lowest (highest) collision energies that we consider. For example: As discussed in Sec. 5.3, $V\gamma$ production is sensitive to the nucleus' isospin since this is related to the net electric charge of its constituents.

Figure 17. As a function of $\sqrt{s_{NN}}$, the extrapolation error [Eq. (6.2)] in estimating the NLO in QCD cross section, with PDF uncertainty, for (a) single weak boson, (b) diboson, (c) associated photon, and (d) associated Higgs production in ¹H (top panel), ¹²C (middle), and ¹³¹Xe (bottom) collisions from ²⁰⁸Pb collisions.

Figure 18. Same as Fig. 17 but for (a) W^+W^-X , (b) ZZX, (c) $W^{\pm}ZX$ and γHX , (d) $\gamma\gamma X$ and HHX, (e) inclusive photon, and (e) top quark processes.

When extrapolating predictions for proton collisions from lead collisions (in practice, one will more likely do the reverse), we observe much larger extrapolation errors and hence much worse agreement. At the largest collider energies, cross sections can be off by as much as $\delta\sigma/\sigma|_{est.} \sim -25\%$, and over $\delta\sigma/\sigma|_{est.} \sim +100\%$ at the lowest energies. The largest disagreements are driven by the W^-X channels, and ultimately reflects the difference in valance d quark distributions in lead and the proton. However, in charge-symmetric channels such as $W^{\pm} + \gamma/Z/H$, W^+W^- , and ZZ production, we find much better agreement. With the exception of $V\gamma$, extrapolation errors for these channels are small and comparable to those for ¹²C and ¹³¹Xe; differences remain below the $\mathcal{O}(10\%)$ level.

Moving onto Fig. 18, we show the same information as in Fig. 17 but for (a) W^+W^-X , (b) ZZX, (c) $W^{\pm}ZX$ and γHX , (d) $\gamma \gamma X$ and HHX, (e) inclusive photon, and (e) top quark processes. Globally, we observe

qualitatively and quantitatively similar behavior: For channels that are charge- and flavor-symmetric, scattering rates for symmetric ²⁰⁸Pb collisions can be used to reliably estimate scattering rates for symmetric ¹H, ¹²C, and ¹³¹Xe rates to within $\mathcal{O}(10\%)$, particularly for collision energies $\sqrt{s_{NN}} \gtrsim 5$ TeV – 10 TeV. The exception are channels with one or more high-energy photons in the final state; these retain sizable sensitivity to the net isospin of the nucleus. For charge- and flavor-asymmetric channels, *e.g.*, $t\bar{t}W^-$ and $t\bar{t}W^+$, we find that the extrapolation errors can quickly converse to nonzero values that are process and isotope dependent, suggesting that the offset correction in Eq. (6.3) is a viable remedy.

7 Discussion and Conclusions

The density and distribution of partons in nuclei differ both qualitatively and quantitatively from protons. This stems from an interplay of nuclear, hadronic, as well as partonic dynamics, and has a direct impact on parton luminosities. (See Fig. 1 for illustrations of typical dynamics at these levels.) Subsequently, scattering cross sections of high-mass particle physics processes in high-energy ion collisions differ both qualitatively and quantitatively from those in proton collisions. We explore a variety of such high-energy processes, ranging from single W^{\pm} and Z production and associated $W^{\pm}H$ and ZH production to triple W^+W^-H and ZZH production as well as associated $t\bar{t}W^{\pm}$ and $t\bar{t}Z$ production.

In this work, we have attempted to map out the ion and collider energy dependence by systematically cataloging the scattering rates and theoretical uncertainties of 42 high- p_T processes in ²⁰⁸Pb-²⁰⁸Pb, ¹³¹Xe-¹³¹Xe, and ¹²C-¹²C collisions over the energy range $\sqrt{s_{NN}} = 1-100$ TeV. Our work takes advantage of publicly available precision Monte Carlo simulation tools developed initially for proton-proton collisions [26, 27]. Our work also relies on advances in nuclear PDF fits, which have seen significant improvements over the past decade [20]. We carry out this work up to NLO in QCD in order to properly account for additional partonic and kinematic subchannels, which can be numerically important due to the presence of accidental cancellations at lowest order in perturbation theory, large virtual corrections at one loop, the largeness of the strong coupling constant, *etc.*

While our main results are shown in Sec. 5 (cross sections), Secs. 3 and 4 feature, respectively, a study of nPDFs and luminosities (and their ratios) for various partons, nuclei, scales, and kinematic ranges. When taken altogether, we are able to build an interesting narrative on how the interplay between nuclear dynamics (*e.g.*, meson exchange), hadronic dynamics (*e.g.*, long-range gluon exchanges), and partonic dynamics (*e.g.*, DGLAP evolution) propagate into cross sections. In many cases, this interplay leads to sufficiently large differences in cross sections with sufficiently small uncertainties that they can be observed experimentally in ongoing and future high-energy ion collisions. However, at the same time, we find consistently the increasing role of partonic dynamics as the dominant driver of phenomenology at increasing collider energies for many processes. Motivated by this, we explored in Sec. 6 the error one makes when trying to extrapolate cross sections for one nucleus from predictions for a second nucleus.

In the context of the inclusive production of high-energy systems in multi-TeV collisions, more interesting findings include the following:

- While nPDFs are known to exhibit large A dependence for $x \gtrsim 0.1$, much of this variation is softened at the level of parton luminosities. We attribute this to an increased role of the gluon density and $g \to q\bar{q}$ splittings (that are driven by perturbative dynamics), which are flavor symmetric (for massless quarks) and therefore exhibits approximate nuclear isospin symmetry, *i.e.*, is approximately independent of (A, Z) configurations. This is particularly true for kinematic thresholds below $(\hat{s}/s_{NN}) \lesssim 10^{-3}$.
- Categorically, for processes that sum over all charge and flavor configurations, we find that the ratio of nucleon-averaged cross sections σ_{NN} [as defined in Eq. (5.2)] with respect to the proton cross section σ_{pp} converges a flat value at or just below unity once the nucleon-nucleon collision energy surpasses √s_{NN} ≥ 5-10 TeV. Not only does this include simpler single- and diboson processes, e.g., Z and W[±]H production, but more complex triboson and top quark processes, e.g., W⁺W⁻Z and tt
 H production. This follows from the increased importance of sea quarks and sea antiquarks (and hence gluons) in the production of sub-TeV systems in multi-TeV collisions, and the smaller sensitivity of these partons to an averaged nucleon's (A, Z)

configuration. The exception are channels with multiple Z bosons and photons since these are indirectly sensitive to the net isospin of nucleons, but the impact is small.

- Categorically, for processes that are charge or flavor asymmetric, e.g., W^- , W^-H , $W^-\gamma$, and $t\bar{t}W^-$ production, the aforementioned convergence still occurs when collision energies are sufficiently large such that $(\sqrt{\hat{s}}/\sqrt{s_{NN}}) \leq 4 6 \times 10^{-3}$. This universal-like behavior across so many processes and ion configurations suggests the onset of a common phenomenon, such as an increased importance / dominance of sea quarks and hence gluons in many-TeV collisions.
- In many cases, we found large QCD corrections at NLO (with $K^{\text{NLO}} > 1.5 2$). Such large corrections, which are well-documented for proton collisions, have various origins. These include radiation amplitude zeros (accidental cancellations at lowest order), the opening of new partonic channels, DGLAP evolution, and sizable virtual corrections. It is important to stress that any ion collision prediction of high-energy systems, albeit a precision measurement or not, should include QCD corrections if and when available. Importantly, nPDF uncertainties in cross sections are comparable or smaller than scale NLO in QCD uncertainties.
- In practice (see Sec. 6), many nucleus-level cross sections and uncertainties for many processes can be reliably extrapolated, even at NLO in QCD, by scaling proton cross sections by the appropriate A factor(s). For channels that are charge- and flavor-symmetric, scattering rates for symmetric ²⁰⁸Pb collisions can be used to reliably estimate scattering rates for symmetric ¹H, ¹²C, and ¹³¹Xe collisions to within $\mathcal{O}(10\%)$, particularly for collision energies $\sqrt{s_{NN}} \gtrsim 5$ TeV 10 TeV. Exceptions consist of channels with one or more high-energy photons in the final state; these retain sizable sensitivity to the net isospin of the nucleus.

In conclusion, with the start of Run III activities at the LHC and ongoing preparations for its high luminosity era, we look forward to the upcoming transition to a precision particle physics program using high-energy ion-ion and ion-proton collisions. And subsequently, through the combined use of precision matrix elements, precision event generators / simulation tools, precision detector systems, a precise determination of the nuclear structure could be achieved through the extraction of nuclear PDFs from measurements of hard, electroweak-scale processes in multi-TeV ion collisions.
