Abstract

We present the first three-parameter fit to a 3+1 sterile neutrino model using 7.634 years of data from the IceCube Neutrino Observatory on $\nu_\mu + \bar{\nu}_\mu$ charged-current interactions in the energy range 500–9976 GeV. Our analysis is sensitive to the mass-squared splitting between the heaviest and lightest mass state (Δm_{41}^2), the mixing matrix element connecting muon flavor to the fourth mass state ($|U_{\mu 4}|^2$), and the element connecting tau flavor to the fourth mass state ($|U_{\tau 4}|^2$). Predicted propagation effects in matter enhance the signature through a resonance as atmospheric neutrinos from the Northern Hemisphere traverse the Earth to the IceCube detector at the South Pole. The result is consistent with the no-sterile neutrino hypothesis with a probability of 4.3%. Profiling the likelihood of each parameter yields the 90% confidence levels: $2.4 \text{ eV}^2 < \Delta m_{41}^2 < 9.6 \text{ eV}^2$, $0.0081 < |U_{\mu 4}|^2 < 0.10$, and $|U_{\tau 4}|^2 < 0.035$, which narrows the allowed parameter-space for $|U_{\tau 4}|^2$. However, the primary result of this analysis is the first map of the 3+1 parameter space exploring the interdependence of Δm_{41}^2 , $|U_{\mu 4}|^2$, and $|U_{\tau 4}|^2$.

Keywords: atmospheric neutrino IceCube TeV oscillation sterile

1. Introduction

Over the past quarter century, anomalies observed in short-baseline neutrino experiments have been studied within the context of vacuum neutrino oscillations involving the three known flavors (ν_e , ν_μ and ν_τ) and an additional hypothetical ‘sterile neutrino’ (ν_s) that has no left-handed weak interactions. This “3+1” model predicts ν_μ disappearance which has not been observed in short-baseline experiments [1–3].

Neutrino telescopes offer an alternative method to probe for the ν_μ disappearance signal using atmospheric muon-flavor neutrino interactions at TeV-scale energies. For these events, theoretical studies of 3+1 models predict, along with vacuum oscillations, a resonance signature induced by matter propagation effects on the $\bar{\nu}_\mu$ flux traversing the Earth which cause a deficit of “up-going” events [4–10]. While the resonance signature will appear in the $\bar{\nu}_\mu$ flux, current neutrino telescopes cannot efficiently differentiate between a ν_μ and $\bar{\nu}_\mu$ interaction, so measure the combined ($\nu_\mu + \bar{\nu}_\mu$) rate. Further, due to sparse instrumentation, the oscillation signature is highly smeared in reconstructed energy. However, the matter resonance effect may be sufficiently strong that neutrino telescopes still have the sensitivity to explore a wide range of 3+1 model parameter space. Among existing neutrino telescopes, the IceCube Neutrino Observatory, a cubic-kilometer neutrino detector buried 1.5–2.5 km beneath the South Pole in the Antarctic glacier [11], is both the largest and longest running experiment. Therefore, it is the most promising in this search for new physics.

2. Muon flavor disappearance in IceCube and the 3+1 model

The 3+1 model parameterization introduces a new singlet state ν_s and a new mass state ν_4 . The flavor mixing is described by expanding the PMNS 3-flavor mixing matrix to a 4×4 mixing matrix U_{3+1} that connects the flavor states (ν_e , ν_μ , ν_τ , and ν_s) to the mass states (ν_1 , ν_2 , ν_3 , and ν_4):

$$U_{3+1} = \begin{pmatrix} U_{e1} & U_{e2} & U_{e3} & U_{e4} \\ U_{\mu 1} & U_{\mu 2} & U_{\mu 3} & U_{\mu 4} \\ U_{\tau 1} & U_{\tau 2} & U_{\tau 3} & U_{\tau 4} \\ U_{s1} & U_{s2} & U_{s3} & U_{s4} \end{pmatrix}. \quad (1)$$

The matrix elements can be parameterized in terms of three new mixing angles (θ_{14} , θ_{24} and θ_{34}) and two new CP -violating parameters (δ_{14} and δ_{24}). Within this multi-parameter model, three parameters, $|U_{\mu 4}|^2$, $|U_{\tau 4}|^2$, and Δm_{41}^2 , will most affect IceCube’s TeV-scale muon-neutrino disappearance search. This paper focuses on those parameters and sets the other parameters to $|U_{e4}|^2 = 0$, $\delta_{14} = 0$, and $\delta_{24} = \pi$.

Setting $|U_{e4}|^2$ (or, equivalently, the mixing angle θ_{14}) to zero is well-justified since the atmospheric neutrino flux in the TeV energy range has an electron-flavor content of less than 10% [12, 13]. As a result, contributions to muon flavor events involving $|U_{e4}|^2$, which would come mainly from $\nu_e \rightarrow \nu_\mu$ oscillations, can be safely neglected. With $|U_{e4}|^2 = 0$, the CP violation term δ_{14} no longer contributes and is arbitrarily set to zero.

In a matter-enhanced disappearance search, δ_{24} is expected to produce a minimal effect in the analysis for two reasons. First, at energies above 500 GeV, the lower bound of this analysis, δ_{24} is sub-leading to the other parameters [14]. Second, non-zero δ_{24} weakens the disappearance of the ν_μ flux while simultaneously strengthening the disappearance of the $\bar{\nu}_\mu$ flux, partially canceling out the effect to the overall $\nu_\mu + \bar{\nu}_\mu$ flux. However, since the ν_μ cross-section is larger than the $\bar{\nu}_\mu$ cross-section, the overall $\nu_\mu + \bar{\nu}_\mu$ event rate will slightly increase (i.e., the disappearance will weaken) with increasing δ_{24} . Therefore, the most conservative choice is to fix δ_{24} to the value that produces the weakest oscillation effect, $\delta_{24} = \pi$.

With the above assumptions, IceCube TeV-scale muon-flavor disappearance analyses depend upon two mixing matrix elements related to two mixing angles:

$$|U_{\mu 4}|^2 = \sin^2 \theta_{24} \quad (2)$$

$$|U_{\tau 4}|^2 = \sin^2 \theta_{34} \cos^2 \theta_{24}. \quad (3)$$

Terms depending on $|U_{\tau 4}|^2$ have a smaller effect than those that depend on $|U_{\mu 4}|^2$. Therefore, previous matter-enhanced IceCube analyses have assumed $\theta_{34} = |U_{\tau 4}|^2 = 0$ [15–17], reducing the model to only two parameters and improving the speed of fits to data. However, as the precision of the IceCube data set has been enhanced through increased statistics (a factor of 15 between Ref. [15] and Refs. [16, 17]) and better estimation

Experiment [Ref.]	$ U_{\tau 4} ^2$ at 90% (99%) CL	Δm_{41}^2
IceCube-DeepCore [18]	< 0.15	> 1 eV ²
Super-Kamiokande [19]	< 0.18 (0.23)	> 0.1 eV ²
T2K [20]	< 0.50	> 0.1 eV ²
ANTARES [21]	< 0.40 (0.68)	> 0.5 eV ²

Table 1: Summary of previous limits on $|U_{\tau 4}|^2$ at 90% (99%, if available) CL and the applicable Δm_{41}^2 range where the predicted oscillation is sufficiently fast to be effectively averaged over. In these analyses there is a dependence between $|U_{\tau 4}|^2$ and $|U_{\mu 4}|^2$ values, thus the applicable $|U_{\mu 4}|^2$ parameter space for these constraints is also limited.

of systematic uncertainties, the effect of a non-zero $|U_{\tau 4}|^2$ must now be studied.

Figure 1 presents ‘oscillograms’ illustrating how the atmospheric neutrino flux changes for some representative sterile neutrino mixing parameters. The left plot shows $\bar{\nu}_\mu$ disappearance as a function of true neutrino energy and direction, assuming a particular value of Δm_{41}^2 and $|U_{\mu 4}|^2$, while keeping $|U_{\tau 4}|^2 = 0$. The neutrino’s direction serves as a proxy for the distance and amount of matter it traversed between creation and arrival at the IceCube detector. The direction is given by $\cos(\theta_z)$, where θ_z is the zenith angle. In these coordinates, $\cos(\theta_z) = -1$ corresponds to “up-going” events that traverse the Earth’s diameter, while $\cos(\theta_z) = 0$ are events coming from the horizon. For the chosen values of Δm_{41}^2 and $|U_{\mu 4}|^2$, the sterile-induced signature is the resonant deficit localized in direction and energy at $\cos(\theta_z) \approx -1$ and $E_\nu \sim 10^4$ GeV. These disappearing neutrinos primarily oscillate into the sterile ν_s state. The middle plot shows how the oscillogram changes further when introducing a non-zero $|U_{\tau 4}|^2$. The $\bar{\nu}_\mu$ resonant disappearance is smeared lower in energy and becomes more up-going. In this scenario, there is also significant $\bar{\nu}_\mu \rightarrow \bar{\nu}_\tau$ appearance that further modifies the observed signal, as seen in the right plot.

As seen in Table 1, the present limits on $|U_{\tau 4}|^2$ apply in restricted Δm_{41}^2 ranges where rapid oscillations cause the experiments to be insensitive to this parameter, reducing the analyses to two-parameter fits in $|U_{\mu 4}|^2$ and $|U_{\tau 4}|^2$, which are correlated. This motivates the present study to *simultaneously* improve our knowledge of all three parameters, Δm_{41}^2 , $|U_{\mu 4}|^2$, and $|U_{\tau 4}|^2$. This letter will present frequentist and Bayesian results that characterize these parameters.

3. Event selection and analysis

The analysis considers a muon deficit within the combined atmospheric and astrophysical muon-flavor neutrino and antineutrino fluxes. The selection is dominated by the atmospheric flux that is initiated through cosmic ray interactions with the Earth’s atmosphere. To generate the atmospheric flux, IceCube uses the MCEq software [12], which takes a specific cosmic ray model as input and produces the resulting flux, calculated according to a particular hadronic interaction model. We use the Hillas-Gaisser 2012 H3a cosmic ray model [22] with the SIBYLL 2.3c hadronic interaction model [23]. The flux further depends on the Earth’s atmospheric density profile,

obtained from data from the AIRS instrument on NASA’s Aqua satellite [24].

The prompt atmospheric component originates from the decays of charmed mesons produced by cosmic ray interactions. These heavier hadrons decay before substantial energy loss, resulting in a harder spectrum than the ‘conventional’ flux discussed above. We use the expected flux derived in Ref. [25] as input. A prompt atmospheric component has yet to be identified in IceCube, with a 1σ upper limit found at a factor of ~ 5 greater than the baseline model used [26]. Within the energy range of interest for this analysis, the prompt component is expected to contribute less than 1% to the overall event rate.

The astrophysical neutrino flux was first measured by IceCube [27, 28, 26], and is fit by an isotropic, falling power-law spectrum:

$$\frac{dN_\nu}{dE} = \Phi_{\text{astro}} \times \left(\frac{E_\nu}{100 \text{ TeV}} \right)^{-\gamma_{\text{astro}}}, \quad (4)$$

where Φ_{astro} is the normalization for a single neutrino flavor and charge (i.e., either ν or $\bar{\nu}$) and γ_{astro} is the spectral index. This analysis is not sensitive to the details of the spectral shape of the astrophysical neutrino flux. However, Φ_{astro} and γ_{astro} are included as nuisance parameters with central values and correlated priors chosen according to a combined fit of the results of Refs. [26, 29, 30]. The central values used are $\Phi_{\text{astro}} = 0.787 \times 10^{-18} \text{ GeV}^{-1} \text{ sr}^{-1} \text{ s}^{-1} \text{ cm}^{-2}$ and $\gamma_{\text{astro}} = 2.5$. The analysis assumes equal flavor content ($\nu_e:\nu_\mu:\nu_\tau::1:1:1$) and equal $\nu/\bar{\nu}$ flux.

In a 3+1 model, the resonance occurs as the neutrinos propagate through the Earth’s matter. The effects of the parameters, $|U_{\mu 4}|^2$, $|U_{\tau 4}|^2$, and Δm_{41}^2 , are simulated using the neutrino propagation software nuSQuIDS [31], which adopts the neutrino mixing matrix [32] and the interaction cross-section [33] relevant at these energies to model coherent and incoherent interactions, including tau neutrino regeneration [34].

An example of the effect that the existence of a sterile neutrino would have on the oscillations was discussed earlier and shown in Figure 1 as a function of true neutrino energy E_ν and true neutrino direction $\cos(\theta_z)$. The Earth’s density as a function of radius is taken to follow the PREM model [35].

Neutrino interactions are detected using the IceCube Neutrino detector located at the geographic South Pole. For a detailed description of the apparatus, see Ref. [11]. Upgoing charged-current (CC) muon (anti)neutrino interactions that occur below and within the IceCube detector are identified via muon tracks observed in the detector. Tracks are reconstructed [36, 37] based on emitted Cherenkov light collected by ‘Digital Optical Modules’ (DOMs) [38] arranged in two hexagonal arrays. The main array comprises 78 strings, each carrying 60 DOMs with 17 m spacing, separated by 125 m. The DeepCore [39] subdetector, an 8-string array with variable string-spacing between 42 m and 72 m and vertical DOM separation of 7 m, is also used in this analysis.

This analysis follows recent TeV-scale IceCube 3+1 analyses [16, 17, 40] in the event selection and reconstruction procedure. A total of 305,735 track-like events, selected to have reconstructed energy between 500 GeV and 9976 GeV, were collected over a live time of 7.634 years between May 2011 and

Figure 1: **Left:** This oscillogram shows $\bar{\nu}_\mu$ disappearance while propagating through the Earth, as a function of true neutrino energy and direction, assuming $\Delta m_{41}^2 = 4.5 \text{ eV}^2$, $|U_{\mu 4}|^2 = 0.03$ and $|U_{\tau 4}|^2 = 0.0$. **Center:** This oscillogram demonstrates how the $\bar{\nu}_\mu$ disappearance changes with the non-zero value of $|U_{\tau 4}|^2 = 0.1$. **Right:** This oscillogram shows the $\bar{\nu}_\mu \rightarrow \bar{\nu}_\tau$ appearance once $|U_{\tau 4}|^2$ has been set to the non-zero value.

May 2019. Tracks are selected so their reconstructed direction is within $-1 \leq \cos(\theta_z) \leq 0$, where $\cos(\theta_z) = -1$ corresponds to upgoing tracks and $\cos(\theta_z) = 0$ to events at the horizon. Even at the horizon, the matter traversed corresponds to 124 km of water-equivalent overburden at the top of the detector. Hence, upgoing tracks are likely to originate from muon-neutrino interactions near the detector rather than from atmospheric muons penetrating through the Earth. The selected sample is therefore expected to be composed of $>99.9\%$ $\nu_\mu + \bar{\nu}_\mu$ CC events [17]. Since the event selection includes events that originate outside of the detector as well as tracks that exit the detector, the muon energy resolution is $\sigma(\log_{10}(E_\mu)) \sim 0.5$. However, the combination of long track lengths of $\mathcal{O}(1 \text{ km})$ and large detector size allows direction reconstruction to better than 1° [36, 41].

Simulated neutrino interaction points are chosen and weighted using the LeptonInjector and LeptonWeighter software [42]. After selecting a neutrino interaction point, the secondary products are propagated through the rock and ice using the PROPOSAL software [43].

The $\nu_\tau/\bar{\nu}_\tau$ CC interactions will create τ^-/τ^+ that can decay leptonically to μ^-/μ^+ , producing tracks in the sample. While the direct production of tau-neutrinos in the dominant atmospheric flux is very low, nonzero $|U_{\tau 4}|^2$, i.e. nonzero θ_{34} (Eq. 3), allows for non-negligible $\bar{\nu}_\mu \rightarrow \bar{\nu}_\tau$ appearance above 500 GeV. Tau neutrinos also contribute to the astrophysical flux. Past matter-induced IceCube sterile neutrino analyses [16, 17] did not simulate tau-flavor contributions. For this analysis, $\nu_\tau/\bar{\nu}_\tau$ simulations were produced and PROPOSAL was modified to account for the τ polarization when decaying into a μ . For the sterile hypothesis parameters used in Figure 1, $\bar{\nu}_\mu \rightarrow \bar{\nu}_\tau$ appearance contributes an additional 2% of tracks in the upward direction, while contributing negligible events from the horizon.

The systematic uncertainties adopted in this analysis have been detailed in previous IceCube analyses [16, 17, 40]. The list appears in Table 2. The eighteen parameters fall into four categories: conventional atmospheric flux parameters, detector

Systematic Parameter	Prior	Pull(σ)
Conventional Flux Parameters		
Normalization (N)	1.00 ± 0.40	0.51
Spectral shift ($\Delta\gamma_{\text{conv.}}$)	0.00 ± 0.25	0.44
Atm. Density	0.00 ± 1.00	-0.03
WP	0.00 ± 0.40	-0.13
WM	0.00 ± 0.40	-0.06
YP	0.00 ± 0.30	-0.35
YM	0.00 ± 0.30	-0.04
ZP	0.00 ± 0.12	-0.02
ZM	0.00 ± 0.12	0.01
Detector Parameters		
DOM Efficiency	0.97 ± 0.10	-0.02
Hole Ice (p_2)	-1.00 ± 10.00	-0.23
Ice Gradient 0	$0.00 \pm 1.00^*$	0.10
Ice Gradient 1	$0.00 \pm 1.00^*$	0.09
Astrophysics Parameters		
Normalization ($\Phi_{\text{astro.}}$)	$0.787 \pm 0.36^*$	0.99
Spectral shape ($\Delta\gamma_{\text{astro.}}$)	$2.50 \pm 0.36^*$	0.92
Cross Section Parameters		
Cross Section σ_{ν_μ}	1.00 ± 0.03	-0.00
Cross Section $\sigma_{\bar{\nu}_\mu}$	1.000 ± 0.075	0.02
Kaon Energy Loss σ_{KA}	0.00 ± 1.00	-0.13

Table 2: The list of systematic uncertainties used in this analysis. The second column provides their central values and prior widths, while the third column gives the best fit value pulls from the central value. Asterisks indicate correlated priors. Atmospheric flux parameterizations involving WP through ZM are defined in Ref. [17].

parameters, astrophysical neutrino flux parameters, and cross-section parameters.

The majority of these nuisance parameters concern the con-

ventional atmospheric flux. Two parameters quantify the uncertainty in the cosmic ray flux. The first is an overall normalization factor N , while the second is a spectral shape correction term $\Delta\gamma_{\text{conv}}$, applied as

$$\Phi(E_\nu; \Delta\gamma_{\text{conv}}) = N \Phi_{\text{conv.}}(E_\nu) \left(\frac{E_\nu}{2.2 \text{ TeV}} \right)^{-\Delta\gamma_{\text{conv}}}, \quad (5)$$

where $\Phi_{\text{conv.}}$ is the nominal conventional neutrino flux and $\Delta\gamma_{\text{conv}}$ is centered at zero. The only significant change from previous analyses [16, 17, 40] was to extend the prior on the cosmic ray spectral slope width $\Delta\gamma_{\text{conv}}$ from 0.03 to 0.25, to accommodate deviations from the Hillas-Gaisser 2012 H3a cosmic ray model spectrum recently observed in the rigidity region of interest $E = 10^3 \text{ GeV} - 10^4 \text{ GeV}$ [44]. Another six conventional flux nuisance parameters vary the meson production rate in the hadronic interactions between cosmic rays and the Earth's atmosphere. The six parameters correspond to the uncertainties for meson productions in different sectors of the interaction kinematic phase space, as described in Ref. [45]. We only account for the uncertainties from Ref. [45] that have a dominant effect on this analysis. A final parameter quantifies uncertainties in the Earth's atmospheric density profile.

Detector uncertainties account for another four nuisance parameters. These include uncertainties in the DOM efficiency, in the property of the ice immediately surrounding the DOMs and two parameters for the uncertainties and non-uniformities of the bulk ice of the Antarctic glacier. These bulk ice model uncertainties have been described in Ref. [46].

Two nuisance parameters are included to vary the normalization and spectral shape of the astrophysical neutrino flux given in Equation (4).

Finally, three cross-section nuisance parameters are included. Two are for uncertainties in neutrino and antineutrino interactions, and one last parameter is for kaon interaction cross-section uncertainties as they propagate through the Earth's atmosphere.

Two analyses were conducted: a frequentist parameter estimation and a point-wise Bayesian model comparison. In both cases, the physics parameters are sampled in a three-dimensional grid in $(\Delta m_{41}^2, |U_{\mu 4}|^2, |U_{\tau 4}|^2)$ -space. The parameter bounds and step sizes are:

$$\begin{aligned} \Delta m_{41}^2 &\in [0.1, 50] \text{ eV}^2 \text{ in steps of } 0.1 \text{ in } \log_{10}(\Delta m_{41}^2), \\ |U_{\mu 4}|^2 &\in [0.001, 0.5] \text{ in steps of } 0.1 \text{ in } \log_{10}(|U_{\mu 4}|^2), \\ |U_{\tau 4}|^2 &\in [0.001, 0.5] \text{ in steps of } 0.2 \text{ in } \log_{10}(|U_{\tau 4}|^2). \end{aligned}$$

The abstract and conclusion state the frequentist result.

The data are binned in two dimensions: reconstructed cosine of the zenith angle, $\cos(\theta_z)$, and \log_{10} of reconstructed muon energy, E . The reconstructed zenith is bounded between $\cos(\theta_z) = -1$ and $\cos(\theta_z) = 0$, with 20 bins of width $\Delta \cos(\theta_z) = 0.05$. The reconstructed muon energy is bounded between 500 GeV and 9976 GeV, in 13 bins of width $\Delta \log_{10}(E/\text{GeV}) = 0.1$. A likelihood \mathcal{L} is constructed using a modified Poisson distribution to account for limited Monte Carlo statistics in estimating an expected event rate [47]. Systematic parameters are incorporated

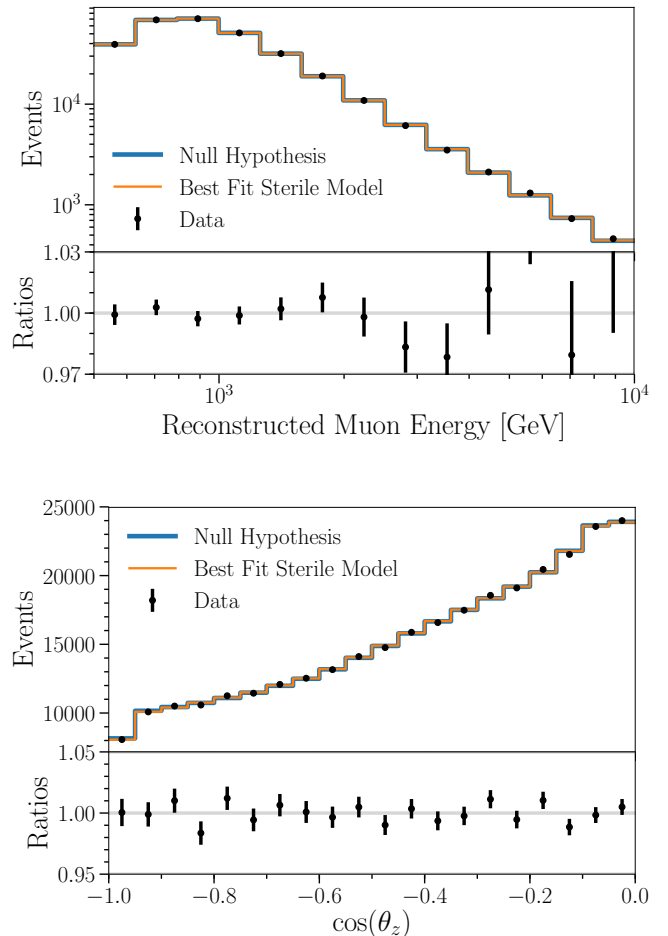

Figure 2: The 1D distribution of events selected as a function of reconstructed energy (top) and direction (bottom). Overlaid with the data are the expected distributions from the no-sterile null model (blue) and the best fit sterile neutrino model (orange). The data points include error bars, which are too small to be observed. The ratio of the data to the best fit model expectation is also presented.

by factoring in a prior likelihood for each parameter, assuming a normal distribution with a given central value and width.

To test our event selection and reconstruction, we compare our selected events with model expectations. Figure 2 shows the observed events in reconstructed energy (top) and reconstructed direction (bottom) versus the no-sterile model, shown in blue. When the data are collapsed to a single dimension, the analysis loses sensitivity to the expected sterile signal. This figure shows, in orange, the expected distribution from the best-fit sterile model discussed in the next section. As a goodness-of-fit test, when we run 2000 pseudo-experiments for this best-fit sterile model, we find that the 1D data distributions fall within expectation for the energy distribution with a p-value of 31%, and for the zenith distribution with a p-value of 39%.

4. Results and discussion

For the frequentist analysis, the best-fit point is found at $\Delta m_{41}^2 = 5.0 \text{ eV}^2$, $|U_{\mu 4}|^2 = 0.032$, and $|U_{\tau 4}|^2 = 0.010$. The 99%, 95%, and 90% confidence levels (CL) of the fit are shown in Figure 3, assuming Wilks' theorem and three degrees of freedom for a subset of the $|U_{\tau 4}|^2$ range sampled. In addition, the 99% CL median sensitivity is shown, calculated using 300 pseudo-experiments assuming the no-sterile hypothesis. The colored bands show where the middle 68.27% and 95.45% of the simulated 99% CLs lie.

When 2000 pseudo-experiments are run with the best-fit parameters injected as the true hypothesis, this goodness-of-fit test finds that the observed data are within the expectation, with a p-value of 87%. The best-fit nuisance parameters are all within 1σ of their associated nominal values.

Figure 4 is helpful in understanding the best fit 3+1 model. The left plot shows the bin-by-bin ratios between the predicted event rates at the best-fit point and at the null hypothesis. One can think of this prediction as the oscillogram smeared by uncertainties but without statistical variations expected in data. The characteristic deficit at low $\cos\theta_z$ that one associates with the resonance in a non-zero $|U_{\tau 4}|^2$ model is evident. An arc that results from the L/E dependence of vacuum oscillations, which appears in all 3+1 models, can be observed at higher values of $\cos\theta_z$.

In the proceeding plots in Figure 4, we show pulls, where we define the pull of model N relative to model M as

$$\text{Pull}(N; M) = \frac{E(N) - E(M)}{\sqrt{E(M)}}, \quad (6)$$

where $E(N)$ is the expected event rate for model N . We can also measure the pull of the data D relative to a model so that $E(D)$ in the above equation is the measured event rate.

The middle plot in Figure 4 presents the predicted pull, bin-by-bin, between the null hypothesis and the best-fit hypothesis, emphasizing the bins that have the most statistical power in distinguishing the two. The right plot shows the difference between the absolute values of the pull of the data from either hypothesis, i.e., $|\text{Pull}(\text{data}; \text{best fit})| - |\text{Pull}(\text{data}; \text{null})|$. If we think of $|\text{Pull}(\text{data}; N)|$ as a measure of the disagreement of the data from model N , then $|\text{Pull}(\text{data}; \text{best fit})| - |\text{Pull}(\text{data}; \text{null})|$ highlights (in red) which bins have better agreement with the best-fit model compared to the null model. These bins are most strongly contributing to the test statistic $-2\Delta\mathcal{L}$.

The test statistic found at the best fit versus the no-sterile hypotheses point gives a $-2\Delta\mathcal{L} = 6.9$. According to Wilks' theorem, with three degrees of freedom, the sterile hypothesis is favored over the null hypothesis with a probability of 7.5%. However, pseudo-experiments can be conducted in order to calculate a more accurate probability without relying on Wilks' theorem. With 1000 simulations, we obtain a preference for the sterile hypothesis over the null hypothesis of 4.3%, corresponding to a 2σ significance, as reported in the abstract and conclusion.

We can compare this to the result of a traditional 3+1 fit that assumes $|U_{\tau 4}|^2 = 0$. If we restrict $|U_{\tau 4}|^2 = 0$, we find the best

fit to be $\Delta m_{41}^2 = 5.0 \text{ eV}^2$ and $|U_{\mu 4}|^2 = 0.025$, with $-2\Delta\mathcal{L} = 4.7$. Assuming Wilks' theorem, this gives a consistency with the null hypothesis of 10%, in agreement with pseudo-experiment simulations, and corresponding to 1.7σ significance.

Accurately determining preferred regions without relying on Wilks' Theorem by using pseudo-experiments, as in Figure 3, would require hundreds of simulations to be run at each sampled physics parameter point; this is computationally unfeasible. Instead, we ran simulations at a selection of parameter points, described in Appendix A. This study found that assuming Wilks' theorem with three degrees of freedom provides similar or more conservative exclusions at the 99%, 95% and 90% CL. To reduce the computational overheads, we draw these confidence regions assuming Wilks' theorem.

To compare to other experiments, we minimize over Δm_{41}^2 and compare contours in the $(|U_{\mu 4}|^2, |U_{\tau 4}|^2)$ parameter space. We show these comparisons in Figure 5. The 90% CL contours are shown in the lower left panel. We see that, in this 2D space, the present analysis gives complementary coverage to other experiments. The upper left and far right panels in Figure 5 show the $-2\Delta \log \mathcal{L}$ distribution when $(\Delta m_{41}^2, |U_{\tau 4}|^2)$ and $(\Delta m_{41}^2, |U_{\mu 4}|^2)$, respectively, have been minimized over. The grey lines show the $-2\Delta \log \mathcal{L}$ critical values for the 90% and 99% CL at one degree of freedom. For $|U_{\mu 4}|^2$ and $|U_{\tau 4}|^2$, the 90% (99%) CL ranges for our analysis are

$$0.0081 < |U_{\mu 4}|^2 < 0.10 \quad (|U_{\mu 4}|^2 < 0.16) \\ |U_{\tau 4}|^2 < 0.035 \quad (|U_{\tau 4}|^2 < 0.48).$$

One sees that the $-2\Delta \log \mathcal{L}$ distribution is relatively shallow. Thus, the best fit is not strongly preferred over a wide range of values in matrix element space. Therefore, while some matrix element combinations are disfavored by other experiments, other parameter combinations remain viable.

One can perform a Bayesian analysis using the Bayes factor

$$\mathcal{K} = \frac{\mathcal{E}_i}{\mathcal{E}_j}, \quad (7)$$

where \mathcal{E} is the 'evidence' for the model, given by

$$\mathcal{E} = \int d\theta_\eta \mathcal{L}(\theta, \theta_\eta) \Pi(\theta_\eta), \quad (8)$$

where $\mathcal{L}(\theta, \theta_\eta)$ is the likelihood as a function of the fitted physics parameters θ and systematic parameters θ_η , and $\Pi(\theta_\eta)$ is the prior. The best fit Bayes factor, relative to the null, is $\log_{10}(\mathcal{K}) = -1.4$ at $\Delta m_{41}^2 = 5.0 \text{ eV}^2$, $|U_{\mu 4}|^2 = 0.040$, and $|U_{\tau 4}|^2 = 0.0063$. With our sampling, this point is adjacent to the best-fit frequentist point. Following Jeffreys' scale [48], this corresponds to a "strong" preference over the null model. Figure 6 shows the Bayesian fit across a subset of sampled values of $|U_{\tau 4}|^2$. The black star indicates the point with the greatest evidence.

The Bayesian and frequentist fits have different interpretations. Bayesian credible regions indicate our expectation that the model parameters are at a given value. Frequentist confidence regions are constructed to have a specified prior probability (the confidence level) of including the true parameter values.

Figure 3: The 99%, 95%, and 90% CL regions for a selection of $|U_{\tau 4}|^2$ values tested, where the best fit is marked with the black star (★). The contours are drawn assuming Wilks' theorem with 3 degrees of freedom. The colored bands show where the middle 68.27% (green) and 95.45% (yellow) of simulated 99% CLs for no signal lie.

Figure 4: **Left:** Ratio of the expected event rate for the best fit hypothesis over the null hypothesis, bin-by-bin, in the $\log_{10}(E)$ versus $\cos(\theta_z)$ plane. **Middle:** Statistical pulls of the best fit predicted event rate compared to the null expectation, bin-by-bin. **Right:** Difference between the absolute value of the pull of the data from the null hypothesis, and the absolute value of the pull of the data from the best fit hypothesis. Red bins indicate where the data are in better agreement with the best fit hypothesis, than with the null hypothesis; these are the bins driving the fit to the best fit hypothesis point.

IceCube does not expect a substantial increase in statistical strength in the near future because another decade would be required to double the data set; nevertheless, future improvements to the analysis are possible. The IceCube Upgrade [49] that will come online in the next few years is focused on increasing detector efficiency at energies below that used in this analysis. While this upgrade will improve the understanding of the ice properties, the events it can detect will not lie in the

energy range of interest for this specific analysis. Therefore, near-future improvements to this study need to focus on the expansion of the data set, such as the inclusion of cascade event signatures [50] and improved event reconstruction in the relevant energy range by, for example, separating events that begin within the detector from events that start outside of the detector.

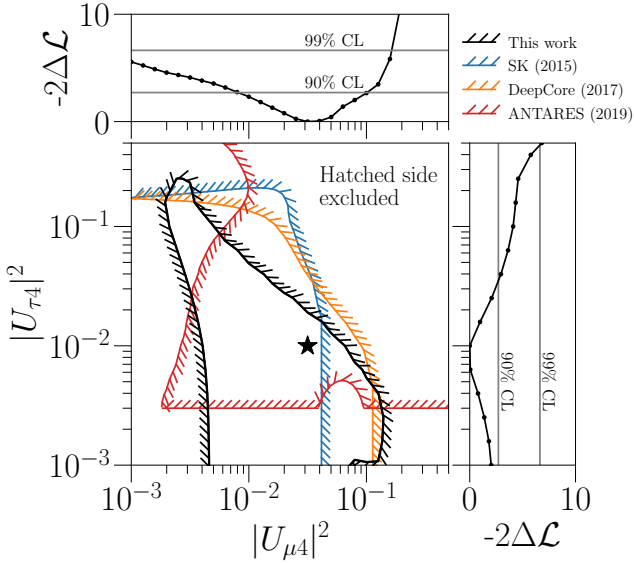

Figure 5: Comparison of the 90% CL contour of this analysis to Super-Kamiokande (SK) [19], IceCube-DeepCore (DeepCore) [18], and ANTARES [21]. Since other experiments do not perform a 3D fit over $(\Delta m_{41}^2, |U_{\mu 4}|^2, |U_{\tau 4}|^2)$, results are profiled over Δm_{41}^2 to allow the comparison (bottom left). The hatched lines indicate the area which is excluded by the respective experiment. For ANTARES, the horizontal line at $|U_{\tau 4}|^2 = 0.003$ indicates the lower bound of that analysis. The top (right) plot shows our test statistic distribution when all parameters but $|U_{\mu 4}|^2$ ($|U_{\tau 4}|^2$) have been profiled over. The relatively shallow $-2\Delta \log \mathcal{L}$ distributions indicate the best fit point (star) is not strongly favored within the wide allowed range. The two gray lines mark the 90% and 99% critical values for Wilks' theorem in one dimension.

5. Conclusion

This paper has presented the first sterile-neutrino analysis that fits simultaneously for Δm_{41}^2 , $|U_{\mu 4}|^2$, and $|U_{\tau 4}|^2$ in a 3+1 sterile model. Our study uses 305,735 IceCube muon-track events, originating from ν_{μ} and ν_{τ} CC interactions, produced below and within the detector with energies between 500 GeV and 9976 GeV. The frequentist best-fit parameter point is at $\Delta m_{41}^2 = 5.0 \text{ eV}^2$, $|U_{\mu 4}|^2 = 0.032$, $|U_{\tau 4}|^2 = 0.01$, and preferred over the null hypothesis (three-neutrino) with a probability of 4.3%. The Bayesian result identifies preferred regions localized on parameter values consistent with the frequentist confidence limits, demonstrating a consistent picture.

As seen in Figure 5, our result is consistent with other experiments when the analysis is reduced to two parameters, $|U_{\mu 4}|^2$ and $|U_{\tau 4}|^2$, through profiling in order to enable comparison. However, information is lost when one reduces to these parameters because the full 3+1 model predicts dependence on Δm_{41}^2 in the range of 1 to 10 eV^2 , as can be seen in the three-parameter fits presented in Figure 3. Hence, experiments that by design average over this range of Δm_{41}^2 lack essential sensitivity. Our result, therefore, illustrates the importance of expanding to three parameters fits for Δm_{41}^2 , $|U_{\mu 4}|^2$, and $|U_{\tau 4}|^2$ to test the 3+1 model, particularly for experiments that do not suffer fast oscillations for Δm_{41}^2 in the 1–10 eV^2 range.

Fit Param.	Frequentist	Bayesian
Δm_{41}^2	5.0 eV^2	5.0 eV^2
$ U_{\mu 4} ^2$	0.032	0.040
$ U_{\tau 4} ^2$	0.010	0.0063
$-2\Delta \mathcal{L} = 6.9$ ($p = 4.3\%$)		$\log_{10} \mathcal{K} = -1.4$

Table 3: Summary of the three-parameter-fit results. The results from the frequentist and Bayesian studies identify consistent parameter regions of interest.

Appendix A. Wilks' vs. frequentist coverage tests

The analysis presents confidence limits based on Wilks' theorem with three degrees of freedom. In order to test the validity of this assumption, frequentist "spot-checks" were performed. In this study, simulations were fit to obtain a sampled $-2\Delta \log \mathcal{L}$ distribution. We report the results in Table A.4, where each column gives the true coverage found through simulations, which should be compared to the coverage at the defined Wilks' theorem confidence levels of 90%, 95% and 99%.

Sampled Point ($\Delta m_{41}^2, U_{\mu 4} ^2, U_{\tau 4} ^2$)	Coverage, assuming Wilks' CL		
	90%	95%	99%
(0, 0, 0)	93.9 ^{+0.8} _{-0.8} %	97.7 ^{+0.5} _{-0.6} %	99.4 ^{+0.2} _{-0.4} %
(5, 0.03, 0.01)	89.0 ^{+1.4} _{-1.6} %	95.2 ^{+1.0} _{-1.2} %	99.6 ^{+0.3} _{-0.5} %
(1.0, 0.0063, 0.10)	93.4 ^{+1.1} _{-1.3} %	97.4 ^{+0.7} _{-0.9} %	99.2 ^{+0.4} _{-0.6} %
(10, 0.16, 0.0016)	92.4 ^{+1.2} _{-1.4} %	96.8 ^{+0.8} _{-1.0} %	99.6 ^{+0.3} _{-0.5} %

Table A.4: Summary of the Wilks' coverage test at a selection of sampled points.
