# THE DENSITY CONJECTURE FOR ACTIVATED RANDOM WALK

CHRISTOPHER HOFFMAN, TOBIAS JOHNSON, AND MATTHEW JUNGE

ABSTRACT. Bak, Tang, and Wiesenfeld developed their theory of *self-organized criticality* in the late 1980s to explain why many real-life processes exhibit signs of critical behavior despite the absence of a tuning parameter. A decade later, Dickman, Muñoz, Vespignani, and Zapperi explained self-organized criticality as an external force pushing a hidden parameter toward the critical value of a traditional absorbing-state phase transition. As evidence, they observed empirically that for various sandpile models, the particle density in a finite box under driven-dissipative dynamics converges to the critical density of an infinite-volume version of the model. We give the first proof of this well-known *density conjecture* in any setting by establishing it for activated random walk in one dimension. We prove that two other natural versions of the model have the same critical value, further establishing activated random walk as a universal model of self-organized criticality.

## 1. INTRODUCTION

Many complex systems, such as tectonic plates, snow slopes, and financial markets, seem to be driven to a critical state where minor disturbances can lead to major events earthquakes, avalanches, and financial crashes. In 1987, Bak, Tang and Wiesenfeld proposed a general explanation for this phenomenon which they called *self-organized criticality* [BTW87]. They theorized that the critical state arises without any external tuning, but rather from the steady accumulation and occasional dissipation of energy. Their work was paradigm-shifting and ranked among the most cited papers in physics over the ensuing decade [Bak96].

The canonical physical example of self-organized criticality is a pile formed by sprinkling sand over a flat table [BTW88]. The sandpile grows until it reaches a critical slope and can grow no steeper. The in- and outflow of sand roughly balances in the long run, but sometimes small local additions cause large avalanches. Shortly after [BTW87] was published, several experiments and observational studies in nature were conducted and generally found to support the theory of self-organized criticality [HSS<sup>+</sup>90, CSV93, JLN89, KFL<sup>+</sup>95].

Systems exhibiting self-organized criticality are ubiquitous and share many common characteristics. Thus the key features of these systems should not depend on any specific detail of the model, but should be more universal in nature. In his book *How Nature Works*, Bak wrote on this principle, "The critical state must be robust with respect to modifications. This is of crucial importance for the concept of self-organized criticality to have any chance of describing the real world. In fact, this is the whole idea." Bak goes on to describe the search for the simplest model of self-organized criticality [Bak96]. Though several processes have been proposed as universal models of self-organized criticality based on simulations, rigorous proofs of their properties remain elusive.

The proposed models of self-organized criticality typically feature particles on a graph that disperse when their density in a region becomes too large. Bak, Tang and Wiesenfeld proposed the *abelian sandpile model* which has a deterministic dispersion mechanism [BTW87]. Mathematicians from analysts to combinatorialists to algebraists have explored the model's rich mathematical structure; one highlight is the work of Levine, Pegden, and Smart analyzing the model's scaling limit as the viscosity solution of a PDE [PS13, LPS16,

LPS17]. Unfortunately this rich structure prevents the model from exhibiting the universality that a model of self-organized criticality should have, rendering it highly sensitive to the initial configuration and other details of the model [FLW10, Dha99, JJ10].

Manna proposed a probabilistic variant of the abelian sandpile model that was later named the *stochastic sandpile model* [Man91, Dic02]. This model has seen some rigorous analysis, but focus has mostly shifted to a close variant called *activated random walk* (ARW). This is widely believed to be the most promising tractable mathematical model exhibiting self-organized criticality. Physicists believe that all such sandpile models with stochastic dynamics belong to the *Manna universality class* and have the same core behaviors as ARW [Lüb04].

ARW can be formulated as an interacting particle system on a graph with active and sleeping particles. Sleeping particles remain in place, but become active if an active particle moves to their site. Active particles perform simple random walk at exponential rate 1. When an active particle is alone, it falls asleep at exponential rate  $\lambda \in (0, \infty)$ . A precise description is given in Section 2. The cases  $\lambda = 0$  and  $\lambda = \infty$  are known as the frog model and IDLA, respectively [HJJ17, JLS12].

The surveys [DRS10, Rol20, LS23] outlined many fundamental questions about the model, most of which remain unsolved. As described in all three surveys, one of the most central open problems in ARW is known as the *density conjecture*. It claims that finite-volume versions of ARW that resemble the canonical sandpile on a table described earlier have a limiting critical density; furthermore, this critical density is universal and coincides with the critical density of models of ARW with conservative dynamics that do not exhibit selforganized criticality but rather have a traditional phase transition. This conjecture is a crucial step along the path to showing that ARW exhibits the universality that Bak called "the whole idea" of self-organized criticality. In this paper, we prove the density conjecture in full for ARW in one dimension, the first rigorous confirmation that ARW actually organizes itself into a critical state. Our proof develops new tools that have the potential to solve other major problems about ARW and related models.

1.1. The density conjecture. Dickman, Muñoz, Vespignani, and Zapperi gave an explanation for self-organized criticality, expounded in [DMnVZ00]. According to their theory, when a model exhibits self-organized criticality, it will have a variant with a conventional phase transition in some explicit parameter. The original model has a hidden version of the parameter, and self-organized criticality occurs because it is driven by some external force to the critical value for the conventional phase transition. This theory is now widely accepted by physicists.

In the context of ARW, the conventional phase transition occurs in the *fixed-energy* version of the system, which takes place on a torus or infinite lattice with no boundary. Its particle dynamics are conservative, meaning that particles are not created or destroyed. The particle density is an explicit parameter of the initial distribution and remains constant in time. The model undergoing self-organized criticality is the *driven-dissipative* version of ARW. Here, the process runs on a finite graph with particles killed at the boundary. Eventually, it reaches an absorbing state  $\xi_1$ , a configuration in which all particles are sleeping. Then a new particle is added and the system runs again until it reaches its next absorbing state  $\xi_2$ , and so on. The sequence of absorbing states  $\xi_1, \xi_2, \ldots$  is called the driven-dissipative Markov chair; its state space consists of stable configurations. This chain is mixing on any given finite graph, and so it has a unique stationary distribution that is the distributional limit of  $\xi_n$ .

Dickman et al. made several claims in support of their theory, originally for the stochastic sandpile model but in subsequent publications for ARW as well. First, they claimed that the fixed-energy model has a traditional absorbing-state phase transition parametrized by the density of the system: for small density, all particles eventually sleep forever, while for large density activity continues at all sites forever. Both phases are nontrivial, i.e., the critical density  $\rho_{\rm FE}$  is strictly between 0 and 1 on a *d*-dimensional lattice. Next, Dickman et al. claimed that the dynamics of the driven-dissipative model push its density to  $\rho_{\rm FE}$ , in the following sense:

**Density Conjecture** ([DMnVZ00]). The mean density of the invariant distribution for the driven-dissipative system on a d-dimensional box of width n converges as  $n \to \infty$  to some value  $\rho_{\text{DD}}$ , which coincides with  $\rho_{\text{FE}}$ .

Dickman et al. supported these claims with numerical evidence from simulations. Mathematicians were inspired to study activated random walk, and starting in the 2010s significant progress was made on the model, primarily on the conjecture that  $0 < \rho_{\rm FE} < 1$  for the fixedenergy model on infinite lattices. This line of research has been a great success, as we will discuss in Section 1.3, with both upper and lower bounds recently established in all dimensions. But this work has not translated into progress toward the density conjecture. One obstacle is that few results have applied to the driven-dissipative model; another is that most of the fixed-energy results prove fixation or nonfixation far from the critical density. The density conjecture has remained a distant goal, despite being the main basis for the belief in ARW as a universal model of self-organized criticality.

1.2. **Main result.** We prove the density conjecture in one dimension, showing that the driven-dissipative model naturally drives itself to the critical density of the fixed-energy model on the line. We further show that the fixed-energy model on the cycle has a phase transition at this same critical density, and that a large number of particles originating at a single site naturally spread out until they reach this critical density. Our proof that these critical densities coincide for all four models provides strong evidence for activated random walk as a universal model for self-organized criticality, and it begins the investigation into its critical state.

The four models of ARW we consider are defined as follows. All the models and all the critical densities depend on the sleep rate parameter  $\lambda > 0$ .

**Driven-dissipative model:** The ARW dynamics take place on  $[\![0, n]\!] := \{0, \ldots, n\}$  with sinks at -1 and n + 1. At each step of the chain one active particle is added and then the system evolves until only sleeping particles remain in  $[\![0, n]\!]$ . This produces a Markov chain whose state space consists of configurations of sleeping particles on  $[\![0, n]\!]$ . The active particle may be added uniformly at random or at a fixed site, with no effect on the stationary distribution of the chain [LL21]. We let  $S_n$  be the number of sleeping particles left in  $[\![0, n]\!]$  in a sample from the stationary distribution. Define the limiting expected density of sleeping particles

$$\rho_{\rm DD} := \lim_{n \to \infty} \frac{\mathbf{E}[S_n]}{n+1},$$

should it exist.

**Point-source model:** The process starts with N active particles at the origin of  $\mathbb{Z}$  and no particles elsewhere. It continues until all N particles are sleeping. Let  $L_N$  be length of the shortest interval containing all the sleeping particles after stabilization.

Define the limiting expected density of sleeping particles

$$\rho_{\mathsf{PS}} := \lim_{N \to \infty} \mathbf{E} \left[ \frac{N}{L_N} \right],$$

should it exist.

- **Fixed-energy model on**  $\mathbb{Z}$ : This version takes place on  $\mathbb{Z}$  with the initial number of active particles at each site chosen according to some stationary distribution with mean  $\rho$ . The system *fixates* if, under the ARW dynamics, each particle eventually sleeps forever. Rolla, Sidoravicius, and Zindy proved that there exists a critical value  $\rho_{\text{FE}}$  such that if  $\rho > \rho_{\text{FE}}$  then the system a.s. does not fixate, and if  $\rho < \rho_{\text{FE}}$  then the system fixates a.s. [RSZ19].
- **Fixed-energy model on the cycle:** The underlying graph in this model is the cycle of length *n*. Start with  $\lfloor \rho n \rfloor$  particles placed uniformly at random and run the process until all particles are sleeping. Let  $\tau_n$  be the total number of jump and sleep instructions followed by all of the particles. Should it exist,  $\rho_{CY}$  is the density such that that for some b, c > 0, we have  $\mathbf{P}(\tau_n > e^{cn}) \to 1$  if  $\rho > \rho_{CY}$  and  $\mathbf{P}(\tau_n < n^b) \to 1$  if  $\rho < \rho_{CY}$ .

Prior to this work only  $\rho_{\text{FE}}$  was even known to exist. The density conjecture is the statement that  $\rho_{\text{DD}}$  exists and is equal to  $\rho_{\text{FE}}$ . Physicists sometimes view  $\mathbb{Z}$  as the limiting case of the cycle and instead state the density conjecture as the existence and equality of  $\rho_{\text{DD}}$  and  $\rho_{\text{CY}}$ , as in [DVZ98]. In any event, we settle the conjecture in dimension one.

**Theorem 1.1.** For each  $\lambda > 0$ , the critical densities  $\rho_{DD}$ ,  $\rho_{PS}$ ,  $\rho_{FE}$ , and  $\rho_{CY}$  exist and are equal.

We in fact prove stronger versions of this result, including exponential concentration bounds around the critical value for the finite-volume models and statements about the driven-dissipative model from arbitrary starting configurations; see Sections 8.2 and 8.3. We further note that the celebrated bounds  $\rho_{\rm FE} > 0$  and  $\rho_{\rm FE} < 1$  (for small  $\lambda$ ), first proven in [RS12] and [BGH18], are nearly trivial consequences of our approach, as we describe in Section 8.4.

Key to our analysis is a new stochastic process we develop called *layer percolation*. ARW and other abelian models are typically studied via their odometer functions, which count the number of times a particle moves or falls asleep at each site. The odometer function describing the behavior of the system is the minimal element of a wider class of feasible odometer functions. Our innovation is to represent these odometer functions as paths of infections in a (2+1)-dimensional oriented infection process. The growth rate of the infection path along one of the dimensions corresponds to the density of particles left sleeping by the odometer function. The set of infected sites in layer percolation has a limiting growth rate  $\rho_*$  along this dimension, and we prove Theorem 1.1 by showing that each of the four critical densities is equal to  $\rho_*$ . We believe that our approach has the potential to solve many of the remaining problems about ARW described in [DRS10, Rol20, LS23].

1.3. **Prior results.** The bulk of mathematical research on ARW has been on the fixedenergy model on infinite lattices, and more specifically on showing  $0 < \rho_{FE} < 1$  in all dimensions. The first major result on ARW was Rolla and Sidoravicius's proof of the lower bound for d = 1 [RS12]. The upper bound for d = 1 proved more difficult and was established first only for sufficiently small values of the sleep parameter  $\lambda$  [BGH18] and then later for all choices of  $\lambda$  [HRR23]. Both sides of the bound are now known for  $d \ge 2$  by the collective efforts of [ST17, ST18, Hu22, FG22, AFG22]. Additionally, [RSZ19] proved that  $\rho_{FE}$  is the same for fixed-energy ARW on  $\mathbb{Z}^d$  with any ergodic initial configuration of active particles, bolstering ARW's candidacy as a model of self-organized criticality.

The other models of ARW considered in this paper have been studied as well, though the literature on them is smaller. The fixed-energy model on a cycle of length n or a torus of width n has been shown to have two phases, with fixation occurring either in polynomial or exponential time [BGHR19, FG22, AFG22], but with no proof that the transition is sharp or that it coincides with  $\rho_{\rm FE}$ . The point-source model is studied only in [LS21], which relates the density of the model after stabilization to  $\rho_{\rm FE}$  and  $\rho_{\rm DD}$ , without proving existence of  $\rho_{\rm DD}$  or  $\rho_{\rm PS}$ .

For the driven-dissipative model, there are also few results. The model shows up implicitly in criteria for proving fixation or activity of the fixed-energy model like [RT18, Proposition 3]. The mixing time of the driven-dissipative model is studied in [LS21, BS22]. This work is relevant to universality of ARW—fast mixing suggests universality because the chain forgets its initial configuration quickly—but its main technique is to approximate ARW with internal diffusion-limited aggregation (the  $\lambda = \infty$  case of ARW), which gives away too much to be of use in proving the density conjecture. The strongest result on the driven-dissipative process comes in the recent paper [For24] by Forien: starting with initial density  $\rho > \rho_{FE}$  of active particles on an interval of length n, with probability bounded from 0 the final density on the interval after stabilization is strictly less than  $\rho$  with positive probability. This result is the first to connect  $\rho_{FE}$  to the driven-dissipative model in a significant way, and it holds arbitrarily close to the critical density. Our paper proves the stronger result that for any  $\epsilon > 0$ , the final density after stabilization is less than  $\rho_{FE} + \epsilon$  with probability converging exponentially to 1.

1.4. **Proof sketch.** To prove the density conjecture, we show that the critical densities for all four models are equal to a constant  $\rho_* = \rho_*(\lambda)$  to be defined in terms of our layer percolation process. Let us start with the driven-dissipative model. Levine and Liang proved that if we stabilize ARW on the interval [0, n] starting with one active particle on each site, we obtain an exact sample from the invariant distribution of the driven-dissipative Markov chain [LL21, Theorem 1]. Thus, to prove that  $\rho_{\text{DD}} = \rho_*$ , we seek to show that the number of sleeping particles on [0, n] after stabilization is within  $(\rho_* - \epsilon)n$  and  $(\rho_* + \epsilon)n$  with high probability.

Stable odometers. As is typical, we use the sitewise construction of ARW. Each site contains a stack of instructions telling particles to move or sleep when present on the site. The final state of the system after stabilization can be determined solely from the odometer, the function counting the number of instructions executed at each site. According to the leastaction principle, the true odometer is the minimal element of a larger collection we call the stable odometers, which if executed would produce feasible flows of particles leading to a stable configuration. Hence, the number of sleeping particles left on [0, n] by the true odometer is the most of any stable odometer. This background material is covered in Section 2.1.

Thus, if we can construct any stable odometer leaving  $(\rho_* - \epsilon)n$  particles on [0, n], then we obtain our lower bound on particle density for the driven-dissipative model. Conversely, we can obtain the upper bound by showing the nonexistence of any stable odometer leaving more than  $(\rho_* + \epsilon)n$  particles. Broadly speaking, constructing an odometer and applying the least-action principle is the idea used in fixation results like [RS12, Theorem 2]. Similarly, some existing nonfixation results proceed by showing the nonexistence of stable odometers that leave many sleeping particles (see [BGH18, Section 6], for example). Embedding stable odometers in layer percolation. The main innovation of our paper is a stochastic process called layer percolation that helps us understand the set of stable odometers. The process can be thought of as a sequence  $(\zeta_k)_{k\geq 0}$  of subsets of  $\mathbb{N}^2$ . We think of a point  $(r, s) \in \zeta_k$  as a *cell* in column r and row s at step k of layer percolation that has been *infected*. At each step, every cell infects cells in the next step at random; the set  $\zeta_{k+1}$  consists of all cells infected by a cell in  $\zeta_k$ . The infections are defined in terms of the random instructions from the sitewise representation of layer percolation. Each stable odometer on [0, n] is embedded in layer percolation as an *infection path*, a chain of infections ending at some cell  $(r, s) \in \zeta_n$ . Under this correspondence, the ending row s of the infection path is equal to the number of particles that the odometer leaves sleeping on the interval. We define layer percolation and give this correspondence in Section **3**.

Analysis of layer percolation. Since the number of particles left sleeping by a stable odometer on [0, n] corresponds to the ending row of an infection path in layer percolation, and the true odometer maximizes the number of particles left sleeping out of all stable odometers, the question turns to the maximum row present in the set  $\zeta_n$  of infected cells. Using properties of regularity and superadditivity present in layer percolation but not in ARW, we show that this maximum row grows linearly and that its growth rate converges to a deterministic constant we call  $\rho_*$  (see Proposition 5.18). Thus it is likely that layer percolation contains infection paths ending in row  $(\rho_* - \epsilon)n$  but no infection paths ending in row  $(\rho_* + \epsilon)n$ .

Back to odometers. The existence of infection paths ending in row  $(\rho_* - \epsilon)n$  but not in row  $(\rho_* + \epsilon)n$  should translate back to the existence of stable odometers leaving as many as  $(\rho_* - \epsilon)n$  but no more than  $(\rho_* + \epsilon)n$  particles sleeping on [0, n], which would complete the proof that  $\rho_{\text{DD}} = \rho_*$ . But the correspondence between stable odometers in ARW and infection paths in layer percolation is not as neat as we have made it out to be. A full accounting of these complications is best given later, but the summary is that they force us to prove a stronger version of the statement that layer percolation contains infection paths ending in row  $(\rho_* - \epsilon)n$  but not in row  $(\rho_* + \epsilon)n$ . In Section 6, we prove that there likely exist infection paths ending in row  $(\rho_* - \epsilon)n$  in any column in a wide, deterministic range. This predictable behavior helps us construct stable odometers from infection paths, and it also allows us to prove that the probability of infection paths ending at row  $(\rho_* + \epsilon)n$  not only vanishes but does so at exponential rate, the subject of Section 7.

The other three models of ARW. Similar techniques can be used in all models of ARW we consider. For example, in the point-source model we consider an initial configuration of N particles at the origin rather than one particle everywhere; but the correspondence with layer percolation works in the same way regardless of the initial configuration. Several of the bounds are transferred from one model to another without applying layer percolation again. These final proofs are given in Section 8.

#### 2. Odometers

In Section 2.1, we present background material on the sitewise construction of activated random walk. In this representation of the process, particles move about the graph and fall asleep according to stacks of random instructions at each site, executed at random times. Because the process then obeys an abelian property—executing the same instructions in different orders results in the same stable configuration—this representation works well for determining the final state of the system when run until stabilization, and it is used in nearly

all work on activated random walk. We mostly follow [Rol20], and we have tried to leave as many technicalities aside as possible.

In Section 2.2, we describe what we mean by a *stable odometer* and prove the *least-action principle*, which states that the true odometer resulting from running activated random walk until all particles stabilize is the minimal stable odometer.

2.1. The sitewise construction. An activated random walk *configuration* is a placement of particles on a set of sites V; particles can be sleeping or active, but multiple particles on the same site must all be active. We represent a configuration as an element of  $\{\mathfrak{s}, 0, 1, 2, \ldots\}^V$ , where  $\mathfrak{s}$  represents a single sleeping particle and a natural number represents that quantity of active particles. We define  $|\mathfrak{s}| = 1$  so that we can write  $|\sigma(v)|$  for a configuration  $\sigma$  to refer to the number of particles, sleeping or active, at v. We say that a configuration  $\sigma$  is stable on U for  $U \subseteq V$  if  $\sigma(v) \in \{0, \mathfrak{s}\}$  for all  $v \in U$ , and we call it stable if it is stable on all sites V.

Activated random walk is a continuous-time Markov chain in which active particles jump to neighbors at rate 1 according to some given set of transition probabilities and when alone on a site fall asleep at rate  $\lambda$  for a given parameter  $0 < \lambda < \infty$ . See [Rol20, Sections 2 and 11] for further formalities and existence results for the Markov chain. We specialize now to the case of nearest-neighbor symmetric random walk on  $\mathbb{Z}$  or a subinterval, which is all we consider in this paper, but all of Section 2 generalizes in an obvious way to arbitrary graphs and random walk transition probabilities.

As is typical, we analyze activated random walk via its sitewise representation, for which we follow the approach of [Rol20, Section 2.2]. Assign each site v a list of instructions, which in our one-dimensional setting consist of the symbols left, right, and sleep. We write  $\operatorname{Instr}_{v}(k)$  to denote the kth instruction at site v, and we take ( $\operatorname{Instr}_{v}(k), k \geq 1$ ) to be i.i.d. with

(1) 
$$\operatorname{Instr}_{v}(k) = \begin{cases} \operatorname{left} & \operatorname{with probability} \frac{1/2}{1+\lambda}, \\ \operatorname{right} & \operatorname{with probability} \frac{1/2}{1+\lambda}, \\ \operatorname{sleep} & \operatorname{with probability} \frac{\lambda}{1+\lambda}. \end{cases}$$

At a site with at least one active particle, it is *legal* to execute the next unexecuted instruction from its list, which is called *toppling* the site. To execute a left (resp. right) instruction at a site v with an active particle, we subtract 1 from the configuration at v and add 1 at v-1 (resp. v+1), interpreting  $\mathfrak{s}+1$  as 2. To execute a sleep instruction at a site v with an active particle, we alter the configuration at v to  $\mathfrak{s}$  if it is currently 1 and make no change if it is 2 or more. If at each site v we execute instructions from its list at rate equal to  $1 + \lambda$  times the number of active particles at v, the resulting Markov chain is activated random walk as defined previously. The advantage of the sitewise representation is that the long-term state of the system is determined solely by the initial configuration and list of instructions, with no role played by the timing or order of executions. To make this statement precise, fix the instruction lists and the initial configuration and define the odometer for any sequence of legal topplings as the function  $u: \mathbb{Z} \to \mathbb{N}$  where u(v) gives the number of topplings of vertex v. (Note that we will generalize this notion of odometer in Section 2.2.) For any finite set  $V \subseteq \mathbb{Z}$ , we say that a finite sequence of topplings stabilizes V if it leaves a stable configuration on V (i.e., all active particles in V are left sleeping or are driven out of V). While we can stabilize V in more than one order, in the end we arrive at the same place:

**Lemma 2.1** ([Rol20, Lemma 2.4]). All sequences of topplings within a finite set V that stabilize V have the same odometer.

If this odometer exists, we call it the *true odometer stabilizing* V. It is a simple corollary, to be discussed in the next section (see (2)), that all sequences of topplings in V that stabilize V result in the same stable configuration. We call this configuration the *stabilization* of the initial configuration on V. It is also easy to see that with random instruction lists as defined previously, the true odometer stabilizing V exists almost surely. We can always find it by toppling sites in V in any order until all particles have fallen asleep or left V. We can think of this procedure as piling up active vertices on the outer boundary of V or as stabilization with sinks on the outer boundary of V.

2.2. Stable odometers and the least-action principle. Generalizing the odometers derived from sequences of topplings in the previous section, we call any function  $u: \mathbb{Z} \to \mathbb{N}$  an *odometer*. We say that u is an *odometer on*  $V \subseteq \mathbb{Z}$  if it is zero everywhere off V. Whether or not an odometer arises from a sequence of topplings, we still think of it as indicating a quantity of instructions executed at each site. For an odometer u, we write  $\mathcal{L}_v(u)$  and  $\mathcal{R}_v(u)$  to refer to the number of left and right instructions, respectively, executed at site v; that is,

$$\mathcal{L}_v(u) = \sum_{i=1}^{u(v)} \mathbf{1}\{\mathsf{Instr}_v(i) = \mathtt{left}\} \qquad \text{and} \qquad \mathcal{R}_v(u) = \sum_{i=1}^{u(v)} \mathbf{1}\{\mathsf{Instr}_v(i) = \mathtt{right}\}.$$

If u is an odometer derived from a sequence of topplings starting from an initial configuration  $\sigma$ , the number of particles ending at site v is

(2) 
$$|\sigma(v)| + \mathcal{R}_{v-1}(u) + \mathcal{L}_{v+1}(u) - \mathcal{L}_v(u) - \mathcal{R}_v(u).$$

The terms  $\mathcal{R}_{v-1}(u)$  and  $\mathcal{L}_{v+1}(u)$  count the number of times a particle arrives at v, while  $\mathcal{L}_v(u)$  and  $\mathcal{R}_v(u)$  count the number of times a particle departs it. For the true odometer stabilizing V, (a) the quantity (2) is equal to 0 or 1 at each site  $v \in V$ , and (b) it is equal to 1 if and only if the final instruction executed at v is **sleep**. For a general odometer u that need not correspond to any sequence of legal topplings, we still think of (2) as the number of particles left on v by the odometer. With this interpretation in mind, we abstract (a) and (b) for a general odometer as follows:

**Definition 2.2.** Let u be an odometer on  $\mathbb{Z}$  and let  $\sigma$  be an ARW configuration with no sleeping particles. We call u stable on V for the initial configuration  $\sigma$  and instructions  $(\operatorname{Instr}_{v}(i), v \in \mathbb{Z}, i \geq 1)$  if for all  $v \in V$ ,

- (a)  $h(v) := \sigma(v) + \mathcal{R}_{v-1}(u) + \mathcal{L}_{v+1}(u) \mathcal{L}_v(u) \mathcal{R}_v(u) \in \{0, 1\};$
- (b) h(v) = 1 if and only if  $\mathsf{Instr}_v(u(v)) = \mathtt{sleep}$ .

We call u weakly stable on V if for all  $v \in V$  it satisfies (a) and

(b') if h(v) = 1 then  $\operatorname{Instr}_{v}(u(v)) = \operatorname{sleep}$ .

For any odometer u stable or weakly stable on V, we say that  $\sum_{v \in V} h(v)$  is the quantity of particles left on V by u.

The true odometer stabilizing V is always stable on V. Note that this relies on our assumption that  $\sigma$  contains no sleeping particles here, since if it did the true odometer might execute zero instructions at a site starting with a sleeping particle. We could drop this assumption by modifying (b) to allow this, but we have no need to consider such initial configurations in this paper.

There exist other stable odometers besides the true stabilizing odometer. Some of them can be obtained if we permit the toppling of sleeping particles: these are the *acceptable* but non-legal topplings of [Rol20]. But there are even more stable odometers beyond these, which can be thought of as arising from sequences of topplings with particle counts permitted to be negative, say by carrying out all topplings indicated by the odometer except any terminating **sleep** instructions in any order, and then executing the final **sleep** instruction. But as commented in [Rol20, Section 2.2], the abelian property fails if instructions can be executed with no particles present, and hence it is unwise to consider toppling sequences along these lines. We instead view the stable odometers as the fundamental objects, and we do not associate them with any sequences of topplings.

We now give our least-action principle, stating that the true stabilizing odometer is minimal among all weakly stable odometers. This least-action principle differs slightly from the most commonly cited [Rol20, eq. (2.3)], which states that the true odometer is minimal among all odometers obtained from sequences of acceptable topplings, but it is not really new. It is the same as the "strong form of the least action principle" used in [FLP10] for the abelian sandpile model, and it could also be obtained from the very general framework in [BL16]. We give a direct proof here since it is not complicated to do so.

**Lemma 2.3** (Least-action principle). Let u be the true odometer stabilizing finite  $V \subseteq \mathbb{Z}$  with given instructions and initial configuration with no sleeping particles. Let u' be an odometer on  $\mathbb{Z}$  that is weakly stable on V for the same instructions and initial configuration. Then

 $u(v) \le u'(v)$ 

for all  $v \in V$ .

*Proof.* Consider the following toppling procedure: Starting with our initial configuration  $\sigma$ , arbitrarily choose any nonstable site  $v \in V$  that has been toppled fewer than u'(v) times and topple it. Continue until no such sites exist, i.e., all sites  $v \in V$  are stable or have been toppled u'(v) times, which is guaranteed to occur eventually since V is finite and  $u'(v) < \infty$  for all v. Let w be the odometer on V derived from this sequence of topplings. By construction  $w \leq u'$ .

We claim that w = u, which completes the proof. We need only show that our toppling procedure stabilizes V, since then w = u by Lemma 2.1. Suppose that some site v is left unstable. Then w(v) = u'(v), and either multiple particles are left on v or one active particle is left on v. In the first case,

$$\sigma(v) + \mathcal{R}_{v-1}(w) + \mathcal{L}_{v+1}(w) - \mathcal{L}_v(w) - \mathcal{R}_v(w) > 1.$$

But since w(v) = u'(v) and  $w \le u'$ , this means that

$$1 < \sigma(v) + \mathcal{R}_{v-1}(w) + \mathcal{L}_{v+1}(w) - \mathcal{L}_v(w) - \mathcal{R}_v(w)$$
  
$$\leq \sigma(v) + \mathcal{R}_{v-1}(u') + \mathcal{L}_{v+1}(u') - \mathcal{L}_v(u') - \mathcal{R}_v(u'),$$

demonstrating that Definition 2.2(a) fails for u', a contradiction since u' is weakly stable. In the second case,

$$\sigma(v) + \mathcal{R}_{v-1}(w) + \mathcal{L}_{v+1}(w) - \mathcal{L}_v(w) - \mathcal{R}_v(w) = 1$$

but  $\operatorname{Instr}_{v}(w(v)) \neq \operatorname{sleep}$ . This time, from w(v) = u'(v) and  $w \leq u'$  we obtain

$$1 = \sigma(v) + \mathcal{R}_{v-1}(w) + \mathcal{L}_{v+1}(w) - \mathcal{L}_v(w) - \mathcal{R}_v(w)$$
  
$$\leq \sigma(v) + \mathcal{R}_{v-1}(u') + \mathcal{L}_{v+1}(u') - \mathcal{L}_v(u') - \mathcal{R}_v(u')$$

with  $\operatorname{Instr}_{v}(u'(v)) \neq \text{sleep}$ . If  $\sigma(v) + \mathcal{R}_{v-1}(u') + \mathcal{L}_{v+1}(u') - \mathcal{L}_{v}(u') - \mathcal{R}_{v}(u') > 1$  then Definition 2.2(a) fails for u'. If  $\sigma(v) + \mathcal{R}_{v-1}(u') + \mathcal{L}_{v+1}(u') - \mathcal{L}_{v}(u') - \mathcal{R}_{v}(u') = 1$ , then Definition 2.2(b') fails for u'. Either way yields a contradiction since u' is weakly stable.  $\Box$ 

Remark 2.4. We used Lemma 2.1 from [Rol20] in this proof, but in fact we could use this proof to establish Lemma 2.1. First, restate the least-action principle as applying to any odometer u obtained from topplings in V that stabilize V. Then if u and  $\tilde{u}$  are two such odometers, both are stable on V and hence  $u \leq \tilde{u}$  and  $\tilde{u} \leq u$ , thus proving  $u = \tilde{u}$ .

Since the true odometer stabilizing an interval is minimal among weakly stable odometers, it in particular executes the minimal number of instructions on the boundary of the interval. Thus, we can interpret the least-action principle as saying that the true odometer maximizes the number of particles left sleeping on the interval.

**Lemma 2.5.** Let u' be an odometer on  $[\![a,b]\!]$  that is weakly stable on  $[\![a,b]\!]$ , for given initial configuration and instruction lists on the interval. The true odometer stabilizing  $[\![a,b]\!]$  leaves at least as many particles sleeping on  $[\![a,b]\!]$  as does u', in the sense given in Definition 2.2.

*Proof.* The number of particles left by u' is by definition

$$\sum_{v=a}^{b} \left( |\sigma(v)| + \mathcal{R}_{v-1}(u') + \mathcal{L}_{v+1}(u') - \mathcal{L}_{v}(u') - \mathcal{R}_{v}(u') \right)$$

Since all terms  $\mathcal{L}_v(u')$  and  $\mathcal{R}_v(u')$  cancel except for  $\mathcal{R}_{a-1}(u') + \mathcal{L}_{b+1}(u') - \mathcal{L}_a(u') - \mathcal{R}_b(u')$ , and the first two of these terms are zero since we have assumed that u' is zero off of  $[\![a, b]\!]$ , this sum is equal to

(3) 
$$\sum_{v=a}^{b} |\sigma(v)| - \mathcal{L}_{a}(u') - \mathcal{R}_{b}(u'),$$

which is the number of particles in the initial configuration minus the number of particles pushed off the interval by u'. The true number of particles left on the interval is

$$\sum_{v=a}^{b} |\sigma(v)| - \mathcal{L}_a(u) - \mathcal{R}_b(u)$$

where u is the true odometer u stabilizing [a, b], and this quantity is at least (3) since  $u(a) \le u'(a)$  and  $u(b) \le u'(b)$  by the least-action principle.

## 3. Layer percolation

Our approach to activated random walk is to understand the set of stable odometers, given the initial configuration and instructions at each site. Layer percolation encodes this set as an infection process in a (2+1)-dimensional oriented percolation model. At each time step, a two-dimensional set of sites randomly infects sites in the next step. We call the sites *cells* to reserve the term *site* for locations of particles in activated random walk. We refer to the cells at step k as  $(r, s)_k$  for  $r, s \ge 0$ . Typically we will consider  $(0, 0)_0$  to be the lone infected cell at step 0, denoting this singleton set as  $\zeta_0$ . Then we define  $\zeta_1$  as the set of cells at step 1 infected by  $(0, 0)_0$ , then  $\zeta_2$  as the set of cells at step 2 infected by a cell in  $\zeta_1$ , and so on.

An instance of layer percolation can be defined from the instructions in activated random walk; the instructions on site k + 1 of activated random walk will determine the infections in layer percolation going from step k to step k + 1. When activated random walk and layer

FIGURE 1. Each of the fourteen possibilities for (u(0), u(1), u(2)) to make a stable odometer consistent with (4),  $\sigma \equiv 1$ ,  $u_0 = 20$  and  $f_0 = 2$  is represented as a leaf in the tree. For example, the leftmost leaf represents (u(0), u(1), u(2)) = (20, 19, 11), while the rightmost represents (u(0), u(1), u(2)) = (20, 23, 22). The quantity  $s_k$  denotes the number of sites  $1, \ldots, k$  on which the final instruction executed under the odometer is sleep, representing the number of particles left on  $[\![1, k]\!]$  by the odometer.

percolation are coupled in this way, the odometers stable on the interior of [0, n] correspond to length *n* infection paths in layer percolation, sequences of cells each infecting the next starting at  $(0, 0)_0$ . We will not prove this correspondence until Section 4, but in Section 3.1 we give an example to give a sense of the correspondence and motivate layer percolation. We define layer percolation in Section 3.2, and then in Section 3.3 we revisit the example from the perspective of layer percolation.

3.1. Example: finding stable odometers. Consider ARW on an interval [0, n] with initial configuration  $\sigma \equiv 1$  where the instructions at sites 0, 1, and 2 are as follows, with L, R, and S short for left, right, and sleep.

	Site 0:	SRSSL	LRLRL	RRLRR	LRSLR	RLSRR	
(4)	Site 1:	RLSLR	RSSRL	RSLLR	RLRLR	SRSLR	
	Site 2:	SLRRL	SLSRL	LRSLL	SLSRR	SSLLS	

Suppose we want to construct all odometers on [0, n] stable on the interior of the interval. To get started, we choose some  $u_0$  and restrict ourselves to constructing odometers u satisfying  $u(0) = u_0$ . We also make a choice  $f_0$ , representing a net flow from 0 to 1, and further restrict ourselves to odometers satisfying  $\mathcal{R}_0(u) - \mathcal{L}_1(u) = f_0$ . In the following example, we take  $u_0 = 20$  and  $f_0 = 2$ .

From  $u_0$  and the instructions at site 0, we have  $\mathcal{R}_0(u) = 9$  for any odometer in this class. From  $f_0$ , we must have  $\mathcal{L}_1(u) = 7$ , and therefore  $u(1) \in [19, 23]$ . Each choice of u(1) then yields different possibilities for u(2).

### **Case 1:** u(1) = 19.

Then  $\mathcal{R}_1(u) = 8$ , and u leaves no particle sleeping at 1 since the final instruction executed there is left. The net flow from site 0 to site 1 was 2, and therefore the net flow from site 1 to site 2 must be 3 to remove the particle initially at site 1. Hence  $\mathcal{L}_2(u) = 8 - 3 = 5$ , yielding  $u(2) \in [11, 13]$ .

# **Case 2:** u(1) = 20.

Then  $\mathcal{R}_1(u) = 9$ , and u leaves no particle sleeping at 1 since the final instruction executed there is **right**. The net flow from site 0 to site 1 was 2, and therefore the net flow from site 1 to site 2 must be 3 to remove the particle initially at site 1. Hence  $\mathcal{L}_2(u) = 9 - 3 = 6$ , yielding u(2) = 14.

#### **Case 3:** u(1) = 21.

Then  $\mathcal{R}_1(u) = 9$ , and u leaves a particle sleeping at 1 since the final instruction executed there is **sleep**. The net flow from site 0 to site 1 was 2, and therefore the net flow from site 1 to site 2 must also be 2. Hence  $\mathcal{L}_2(u) = 9 - 2 = 7$ , yielding  $u(2) \in [15, 16]$ .

# **Case 4:** u(1) = 22.

Then  $\mathcal{R}_1(u) = 10$ , and u leaves no particle sleeping at 1 since the final instruction executed there is **right**. The net flow from site 0 to site 1 was 2, and therefore the net flow from site 1 to site 2 must be 3 to remove the particle initially at site 1. Hence  $\mathcal{L}_2(u) = 10 - 3 = 7$ , yielding  $u(2) \in [15, 16]$ .

**Case 5:** u(1) = 23.

Then  $\mathcal{R}_1(u) = 10$ , and u leaves a particle sleeping at 1 since the final instruction executed there is **sleep**. The net flow from site 0 to site 1 was 2, and therefore the net flow from site 1 to site 2 must be 2. Hence  $\mathcal{L}_2(u) = 10 - 2 = 8$ , yielding  $u(2) \in [17, 22]$ .

The fourteen possible odometers produced so far are illustrated in decision tree form in Figure 1. Given the instructions at sites  $2, \ldots, n$ , we could continue forming the decision tree to find all stable odometers for our specified  $u_0$  and  $f_0$ . As illustrated by our example, at each step the choice made so far of  $u(0), \ldots, u(k)$  determines  $\mathcal{R}_k(u)$  and the net flow from site k to site k + 1 required to make u stable at k, thus determining  $\mathcal{L}_{k+1}(u)$ . Then  $\mathcal{L}_{k+1}(u)$  determines the possible choices of u(k + 1), ranging from the  $\mathcal{L}_{k+1}(u)$ th left instruction up to but excluding the  $(\mathcal{L}_{k+1}(u) + 1)$ th left instruction.

We have depicted the set of stable odometers in tree form, but different branches of the tree are highly dependent. For example, in Figure 1, the level 1 nodes representing (u(0), u(1)) = (20, 21) and (u(0), u(1)) = (20, 22) have nearly identical children because both are generated from the same range of the site 2 instructions. On the other hand, their grandchildren will not match up. This complex dependency poses an obstacle to analyzing the stable odometers.

The key insight in making sense of the odometers is that we do not need to know the entire past history  $u(0), \ldots, u(k)$  to determine the possible choices for u(k+1). Rather, two pieces of information suffice: The first is  $\mathcal{R}_k(u)$ . The second is the number of sites  $1, \ldots, k$  on which the final instruction executed under u is sleep, a quantity we denote by  $s_k$ . From these two pieces of information, we can find the number of left instructions needed at site k + 1 to make u stable at k, thus determining the range of instructions at site k + 1 that are possible choices for u(k + 1). Each increase of  $\mathcal{R}_k(u)$  forces  $\mathcal{L}_{k+1}(u)$  to increase by one to balance the flow of particles onto site k. Likewise, each increase of  $s_k$  forces  $\mathcal{L}_{k+1}(u)$  to increase by one, since it means that an additional particle sleeps on  $[\![1,k]\!]$  and hence the net flow from site k to site k + 1 must decrease by one. The explanation for why (u(0), u(1)) = (20, 21) and (u(0), u(1)) = (20, 22) lead to the same possible values  $u(2) \in [\![15, 16]\!]$  is that  $\mathcal{R}_1(u) + s_1 = 10$  for both choices of (u(0), u(1)).

FIGURE 2. Each node of the tree in Figure 1 is represented as a *cell* in the above diagram. A node at level k of the tree is plotted at step k of this diagram, with  $\mathcal{R}_k(u)$  plotted on the horizontal axis and  $s_k$  plotted on the vertical axis.

We can thus capture all information in each level of the decision tree in Figure 1 as a collection of pairs ( $\mathcal{R}_k(u), s_k$ ), as depicted in Figure 2. The nodes at level k of the tree become infected *cells*, depicted as black squares, at step k of our layer percolation process. If one node is the parent of another in the tree, we say that the cell corresponding to the parent *infects* the cell corresponding to the child. For example, the cell ( $\mathcal{R}_2(u), s_2$ ) = (4,0) at step 2 is infected by three different cells ( $\mathcal{R}_1(u), s_1$ ) = (8,0), (9,0), (10,0) at step 1. This process in which cells with two-dimensional coordinates infect cells in the next step is *layer percolation*, to be defined formally in the next section.

We can describe the odometer-generating algorithm purely from the perspective of layer percolation. The initial cell  $(\mathcal{R}_0(u), s_0) = (9, 0)$  infects cells according to instructions  $19, \ldots, 23$  at site 1 (LRSRS), starting at the fifth left instruction and ending immediately before the sixth. These five choices correspond to the five infected cells in the middle image in Figure 2. The three non-sleep instructions (i.e., choosing u(1) to be 19, 20, or 22) lead respectively to the infection of three consecutive cells in row 0: the row is 0 because these choices of instructions do not leave a particle sleeping at site 1, and the columns span three cells because each additional right instruction (u(1) = 21 or u(1) = 23) leads to an infection in row 1, since a particle is left sleeping a site 1; the column infected is the same for the first non-sleep instruction prior to the sleep instruction.

We can apply the same analysis to determine the cells infected by any cell  $(\mathcal{R}_k(u), s_k)$ . The infected cells are determined by some string of instructions at site k + 1 starting with a left instruction and ending immediately prior to the next left instruction. A stretch of cells in row  $s_k$  is infected whose length is given by the number of non-sleep instructions in the stretch. And some of the cells above this stretch in row  $s_k+1$  are also infected, depending on the presence of sleep instructions in between successive non-sleep instructions. From (1), the stretch of cells infected in row  $s_k$  has length 1 + Geo(1/2), and each cell in row  $s_k+1$ in the stretch is infected independently with probability  $\lambda/(1 + \lambda)$ . (Here and elsewhere, Geo(p) denotes the geometric distribution on the nonnegative integers with parameter p, i.e., the one placing probability  $(1-p)^k p$  on k for  $k \in \mathbb{N} = \{0, 1, \ldots\}$ . We abuse notation slightly by conflating distributions and random variables to permit an expression like 1 + Geo(1/2).)

Next, we try to unravel the dependence between the infections arising from different cells. First, we observe that two cells at step k with the same value of  $\mathcal{R}_k(u) + s_k$  infect cells according to the same range of instructions at site k+1. The cells they infect have the same shape but are in shifted rows from each other depending on the value of  $s_k$  for each infector (see for example the cells infected by  $(\mathcal{R}_1(u), s_1) = (10, 0)$  and  $(\mathcal{R}_1(u), s_1) = (9, 1)$ ). On the other hand, the infections stemming from cells with values of  $\mathcal{R}_k(u) + s_k$ —in other words, cells in different antidiagonals—are based on distinct ranges of instructions and hence have independent shapes.

In the description so far, we have discussed the width of each infected range of cells while obscuring the exact columns infected, which we consider now. First, all infections from a given antidiagonal occur at the same columns—the infected cells are shifted in rows but not in columns. If we move from one antidiagonal to the next, the range of instructions determining the infections moves ahead by one left instruction. That is, suppose that a given antidiagonal at step k uses instructions from the jth left up to but excluding the (j+1)th left instruction at site k+1. Then the next antidiagonal will use instructions from (j+1)th left instruction up to but excluding the (j+2)th. The final instruction before the (j+1)th left instruction corresponds to the same value of  $\mathcal{R}_{k+1}(u)$  as the (j+1)th left instruction itself. Hence the rightmost column infected from a given antidiagonal is the same as the leftmost column infected from the next. This phenomenon is the reason we call our process layer percolation: each successive antidiagonal at one step infects a layer of cells in the next, and the layers accumulate one after the other.

In the next section, we give a formal description of the layer percolation process, motivated by this discussion but without reference to odometers and instructions. The one notable difference between the process as sketched here and as formally described in the next section is that the first coordinate of cells will not match up exactly with  $\mathcal{R}_k(u)$ . Instead all cells in a given step will be shifted at each step by a constant to put the leftmost infected cell in column 0.

3.2. Definition of layer percolation. We define layer percolation with parameter  $\lambda > 0$ as a process in which cells denoted  $(r, s)_k$  for integers  $r, s, k \ge 0$  infect one or more cells  $(r', s')_{k+1}$ . We say that a cell  $(r, s)_k$  is at step k of layer percolation; since we plot r on the horizontal and s on the vertical axis, we call r the cell's column and s the cell's row. We write  $(r, s)_k \to (r', s')_{k+1}$  to denote the event that  $(r, s)_k$  infects  $(r', s')_{k+1}$ . Formally, layer percolation up to step  $n \le \infty$  is the collection of indicators

$$\left(\mathbf{1}\{(r,s)_{k-1} \to (r',s')_k\}, r,s \ge 0, 1 \le k \le n\right)$$

Note that the process is oriented, in the sense that cells at step k only infect cells at step k+1. The infections  $(\mathbf{1}\{(r,s)_{k-1} \to (r',s')_k\}, r,s \ge 0)$  for different values of k are i.i.d. To define the process, it therefore suffices to state the distribution of  $(\mathbf{1}\{(r,s)_{k-1} \to (r',s')_k\}, r,s \ge 0)$  for any particular  $k \ge 1$ , which we give now.

Take k as fixed. We refer to the j+1 cells  $\{(r,s)_{k-1}: r+s=j\}$  as diagonal j at step k-1. Cells in diagonal j at step k-1 infect cells only in layer j at step k, which we define now. Let  $R_0, R_1, \ldots$  be independent with distribution Geo(1/2). For  $j = 0, 1, \ldots$ , we define layer j at step k as the vertical strip of cells starting at column  $R_0 + \cdots + R_{j-1}$  and ending at column  $R_0 + \cdots + R_j$ , including these endpoints. Let

(5) 
$$\operatorname{layer}(j) = \operatorname{layer}_k(j) = [\![R_0 + \dots + R_{j-1}, R_0 + \dots + R_j]\!],$$

so that layer j at step k consists of all cells  $(r, s)_k$  for  $r \in \text{layer}(j)$ . We call  $1 + R_j$  the width of layer j, the number of columns it spans. More informally, the layer structure at step k is defined as follows. The widths of the layers are independent with distribution 1 + Geo(1/2). Layer 0 is a strip of columns starting at 0 with the given width. Layer 1 begins in the final column of layer 0, overlapping it by one column, and then extends to the right for its given width. Then layer 2 begins in the final column of layer 1, and so on. By the memoryless property of the geometric distribution, we can also imagine forming the layers starting in

FIGURE 3. A cell  $(r, s)_{k-1}$  in diagonal j (i.e., r + s = j) infects an interval of  $R_j + 1$  cells in row s at step k, along with some of the cells above them in row s + 1 as determined by the Bernoulli random variables  $(B_0^j, \ldots, B_{R_j}^j)$ . The example above shows the shape of cells infected when  $R_j = 4$  and  $(B_0^j, \ldots, B_r^j) = (1, 0, 0, 1, 0)$ .

column 0 with layer 0. At each step, with equal probability we extend the current layer by one column, or we remain at the same column and start a new layer, continuing in this way forever to carve up the cells into vertical strips each overlapping the last by one column.

Now, we explain which cells in layer j at step k are infected by each cell in diagonal j at step k-1. For each j, let  $B^j = (B_0^j, \ldots, B_{R_j}^j)$  consist of Bernoulli random variables with  $\mathbf{E}B_i^j = \lambda/(1+\lambda)$ , independent for all i and j. The random variables  $(R_j, B^j)$  encodes the shape of cells infected at step k by a cell in diagonal j at step k-1; see Figure 3. A cell  $(r, s)_{k-1}$  in diagonal j infects all  $1 + R_j$  cells at row s in layer j, and it also infects the ith cell in row s + 1 in layer j if  $B_i^j = 1$  (here we call column  $R_0 + \cdots + R_{j-1}$  the 0th column of layer j). That is, we have  $(r, s)_{k-1} \to (u, t)_k$  if either

- (i)  $u \in layer(r+s)$  and t = s, or
- (ii)  $u \in \text{layer}(r+s)$  and t = s+1 and  $B_i^j = 1$ , where  $i = u (R_0 + \dots + R_{r+s-1})$ .

This completes our description of the infections from step k-1 to step k. As we said before, the infections from other steps are independent with the same distribution, and thus our definition of layer percolation is complete.

Remark 3.1. We defined layer percolation up to step n as the collection of indicators on events  $(r, s)_{k-1} \rightarrow (r', s')_k$  for all  $r, s \ge 0$  and  $1 \le k \le n$ . We note that for any k, this collection of indicators can be generated from  $(R_j)_{j\ge 0}$  and  $(B_0^j, \ldots, B_{R_j}^j)_{j\ge 1}$  and vice versa, and thus layer percolation could equally well be defined by  $(R_j)_{j\ge 0}$  and  $(B_0^j, \ldots, B_{R_j}^j)_{j\ge 1}$ for each  $1 \le k \le n$ .

We take a break from formality now to look back to our example from Section 3.1. The random variables  $R_j$  and  $B^j$  specify the shape of cells infected in step k by a cell in diagonal j at step k-1. In terms of the tree in Figure 1, they describe the children of all nodes at level k-1 with a certain value of  $\mathcal{R}_{k-1}(u) + s_{k-1}$ . The quantity  $R_j$  corresponds to the number of right instructions between a certain pair of left instructions at site k. And the Bernoulli random variables  $B_0^j, \ldots, B_{R_j}^j$  are indicators on the presence of sleep instructions occurring between the non-sleep instructions in the string of instructions from the two left instructions. Our main interest in layer percolation will be the set of infected cells at each step originating from the single infected cell  $(0,0)_0$ , for which we will give notation below. A chain of infections of length n starting at  $(0,0)_0$  will correspond to an odometer on [0,n] stable on [1, n-1], modulo various complications.

Finally, we explain again why we call the process *layer percolation*. Given the infected cells in diagonal j at step k - 1, we can determine the *shape* of the set of cells they infect from  $R_j$  and  $B^j$  alone. But to determine the actual set of cells infected, we must first find the cells infected by diagonals  $0, \ldots, j - 1$ . In effect, we need to find the shapes of the sets of cells infected by diagonals  $0, \ldots, j$  and then paste them together from left to right. Thus

our infection sets are built up layer by layer. This differs from classical (and even modern [HS21]) percolation processes and to us seems essential.

We also mention that layer percolation can be generalized by defining the random variables  $R_0, R_1, \ldots$  to have distribution  $\text{Geo}(\theta)$  for a parameter  $\theta$ . For  $\theta$  other than 1/2, this layer percolation will match up with activated random walk in which particles move as nearest-neighbor random walk with a bias in one direction. This fundamentally alters the behavior of layer percolation by changing  $\mathbf{E}R_i$  from 1, thus making key branching processes subcritical or supercritical rather than critical. We plan to examine this process in future work.

We close the section with some additional notation. We have now defined the event of  $(r, s)_k$  infecting  $(r', s')_{k+1}$ , denoting it by  $(r, s)_k \to (r', s')_{k+1}$ . If we want to say that  $(r, s)_k$  infects  $(r', s')_{k+1}$ , we will often just write  $(r, s)_k \to (r', s')_{k+1}$  rather than "the event  $(r, s)_k \to (r', s')_{k+1}$  holds". We write

$$(r_0, s_0)_k \rightarrow (r_1, s_1)_{k+1} \rightarrow \cdots \rightarrow (r_n, s_n)_{n+k}$$

as a shorthand for the event that  $(r_i, s_i)_{k+i} \to (r_{i+1}, s_{i+1})_{k+i+1}$  for all  $0 \le i < k$ . In this case we call this sequence of cells an *infection path* from  $(r_0, s_0)_k$  to  $(r_n, s_n)_{n+k}$ . For  $k \ge 2$ , we write  $(r, s)_k \to (r', s')_{n+k}$  for the event that there exists an infection path from  $(r, s)_k$  to  $(r', s')_{n+k}$ . For consistency of notation, we say that the event  $(r, s)_k \to (r', s')_k$  holds if and only if r = r' and s = s'.

Define the infection set from  $(r, s)_k$  after n steps, denoted  $\zeta_n^{(r,s)_k}$  (and often abbreviated to  $\zeta_n$ ), as the set of cells at step k + n infected starting from the given cell  $(r, s)_k$ . Formally,

(6) 
$$\zeta_n^{(r,s)_k} = \{(u,t)_{k+n} \colon (r,s)_k \to (u,t)_{k+n} \}.$$

Similarly, the backward infection set from  $(r, s)_k$  after n steps, denoted  $\overline{\zeta}_n^{(r,s)_k}$ , consists of all cells at step k - n that infect  $(r, s)_k$ , or

(7) 
$$\overline{\zeta}_{n}^{(r,s)_{k}} = \left\{ (u,t)_{k-n} \colon (u,t)_{k-n} \to (r,s)_{k} \right\}.$$

As we will see in Section 5.3, layer percolation has a sort of duality that relates the distribution of backward infection sets to forward ones.

3.3. Example: stable odometers from the layer percolation perspective. In Section 3.1, we described an algorithm to find all odometers stable on the interior of an interval given the initial configuration and instructions from activated random walk, the value  $u_0$  of the odometer at site 0, and the net flow  $f_0$  of particles from site 0 to site 1 under the odometer. We sketched a representation of these odometers in terms of layer percolation. Now that we have defined layer percolation and given notation for it, we return to the example from Section 3.1 and show how we construct an instance of layer percolation from the instructions of the activated random walk. We will be informal in this section, trying to get the idea across of the correspondence between activated random walk and layer percolation while saving rigor for Section 4.

Recall that there are two key quantities for an odometer u at each site k. The first is  $\mathcal{R}_k(u)$ , the number of **right** instructions executed at site k under the odometer. The second is  $s_k$ , the number out of the indices  $i \in [\![1,k]\!]$  for which the u(i)th instruction at site i is **sleep**; that is, it represents the number of times the odometer u leaves a particle sleeping at site  $i \in [\![1,k]\!]$ . The importance of  $\mathcal{R}_k(u)$  and  $s_k$  is that they provide enough information to determine all possible extensions of u from  $[\![1,k]\!]$  to  $[\![1,n]\!]$ .

Recall the instructions (4) and that in the example we fix  $u_0 = 20$  and  $f_0 = 2$ . Our goal is to generate an instance of layer percolation that corresponds to Figure 2 and encodes the

stable odometers. To generate  $R_0, R_1, \ldots$  and  $B^0, B^1, \ldots$  for generating the infections from step 0 to step 1 of layer percolation, we first recall that from  $u_0$  and  $f_0$ , the minimum (and only) value that  $\mathcal{L}_1(u)$  could have is 7. Thus we start our generation of layer percolation at the seventh left instruction at site 1. We set  $R_0$  equal to the number of **right** instructions between the 7th and 8th left instructions, then  $R_1$  equal to the number of **right** instructions between the 8th and 9th left instructions, and so on. Since the number of **right** instructions between successive left instructions are independent with distribution Geo(1/2) by the strong Markov property, our random variables  $R_0, R_1, \ldots$  are i.i.d.-Geo(1/2)as desired. In this example,  $R_0 = 2$ .

To determine  $B_0^j, \ldots, B_{R_j}^j$ , we look at the portion of instructions from the (7 + j)th to the (8 + j)th left instruction, which contains  $R_j$  right instructions. We let  $B_i^j$  be an indicator on the presence of a sleep instruction immediately following the *i*th of these right instructions (or following the initial left instruction for i = 0). Thus the instructions LRSRS from the 7th left instruction up to the 8th give us  $(B_0^0, B_1^0, B_2^0) = (0, 1, 1)$  because there is not a sleep instruction following the initial left instructions. Since the instruction following any given instruction is sleep with probability  $\lambda/(1 + \lambda)$ , these random variables  $B_i^j$  are i.i.d.-Bernoulli $(\lambda/(1 + \lambda))$ .

These values  $R_0 = 2$  and  $(B_0^0, B_1^0, B_2^0) = (0, 1, 1)$  represent the shape

To form the infection set at step 1 starting from  $(0,0)_0$ , the cell  $(0,0)_0$  in diagonal 0 infects a set of cells of the shape above, starting at column 0 (because the leftmost cell infected by the diagonal 0 cell is always in column 0) and at row 0 (because a cell in row s always infects cells in row s and s + 1). Thus the infection set at step 1 consists of the following cells  $(r, s)_1$ :

The colors are to be used in illustrating the next step; they correspond to the diagonal of each cell. Note that these infected cells match step 1 in Figure 2 except for being shifted along the horizontal axis.

Next, we form the random variables  $R_0, R_1, \ldots$  and  $B^0, B^1, \ldots$  that generate the infections from step 1 to step 2 of layer percolation. We will form them from the site 2 instructions, setting  $R_j$  equal to the number of **right** instructions between the (m + j)th and (m + j +1)th left instructions and setting  $(B_0^j, \ldots, B_{R_j}^j)$  as indicators on the presence of **sleep** instructions in this span. But we must first determine the value of m, which we can obtain from the index of the first possible instruction that u(2) might take. In this example, the minimal value of u(2) is 11, corresponding to the 5th left instruction, yielding m = 5. In general, to find these minimal odometer values at each step, we follow the leftmost branch of the tree in Figure 1, simply choosing the minimal value of u(k + 1) at each step given our previous choices of  $u(0), \ldots, u(k)$ . The odometer obtained in this way is called the *minimal odometer* and plays an important role in our theory. (But note that while it is minimal among odometers stable on  $[\![1, n-1]\!]$  with a fixed choice of  $u_0$  and  $f_0$ , it is typically not stable at the boundary points 0 and n and hence it is not minimal in the sense of Lemma 2.3).

Counting up the number of right instructions between successive left instructions at site 2 starting at the 5th left instruction,

$$(R_0, R_1, R_2, R_3, \ldots) = (1, 0, 0, 2, \ldots).$$

Examining the presence of **sleep** instructions interspersed between the non-**sleep** instructions,

$$B^0 = (0, 1),$$
  $B^1 = (0),$   $B^2 = (1),$   $B^3 = (1, 0, 1), \dots$ 

Thus the shapes for diagonals  $0, \ldots, 4$  are:

Here the shapes are colored to match up the diagonals in (8). Each cell of a certain color in (8) will infect a block of cells in the shape above with the same color.

Using the formula layer(j) =  $\left[\!\left[\sum_{i=0}^{j-1} R_i, \sum_{i=0}^{j} R_i\right]\!\right]$ , the layers in step 2 consist of the columns

$$layer(0) = [0, 1],$$
  $layer(1) = [1, 1],$   $layer(2) = [1, 1],$   $layer(3) = [1, 3], \dots$ 

A cell  $(r, s)_1$  in diagonal j (i.e., r + s = j) infects cells in the columns found in layer(j). It will infect all cells  $(r, s)_2$  and some of the cells  $(r, s + 1)_2$  for  $r \in \text{layer}(j)$ . Here we show the layers one at a time. Layers 0, 1, and 3 each consist of a single copy of one of the shapes in (9), while layer 2 is formed from two copies of the yellow shape, one starting in row 0 and one in row 1:

The infection set at step 2 is the union of these cells:

This set is the one pictured in step 2 in Figure 2, except that it is shifted to begin in column 0.

## 4. The correspondence between ARW and layer percolation

We are now ready to connect layer percolation to activated random walk, as alluded to in Sections 3.1 and 3.3. The idea is to define layer percolation by constructing the random variables  $R_0, R_1, \ldots$  and  $B^0, B^1, \ldots$  that yield the infections from step k - 1 to step k from the ARW instructions at site k. The layer widths  $R_0, R_1, \ldots$  are given by the counts of right instructions between successive left instructions; the Bernoulli random variables  $B_i^j$  are determined by the presence of sleep instructions.

The end result of this construction will be a correspondence given in Proposition 4.6 between what we call extended odometers in ARW and infection paths in the coupled layer percolation. The correspondence is between a set of extended odometers  $\mathcal{O}_n(\text{instr}, \sigma, u_0, f_0)$  on  $[\![0, n]\!]$  and a set of length n infection paths  $\mathcal{I}_n(\text{instr}, \sigma, u_0, f_0)$  in the coupled layer percolation and is given by a map  $\Phi$  that is a bijection up to identification of odometers that yield the same final configuration. We get started now on the task of defining  $\mathcal{O}_n(\text{instr}, \sigma, u_0, f_0)$ ,  $\mathcal{I}_n(\text{instr}, \sigma, u_0, f_0)$ , and  $\Phi$ . The proof is technical, but the ideas in it are simple and are apparent in the example from Sections 3.1 and 3.3.

4.1. Extended odometers. As we described in Section 3.1, we consider odometers on [0, n] stable on [1, n-1] with a given value  $u_0$  at 0 and given net flow  $f_0$  from site 0 to site 1. Our goal is to relate this set of odometers to the set of infection paths of length n starting from  $(0, 0)_0$  in layer percolation. But there is an obstacle not apparent in our example in Sections 3.1 and 3.3, which is that things can go wrong when  $u_0$  is too small or  $f_0$  is too large. For example, suppose we take  $u_0 = 10$  and  $f_0 = 20$ . Then there are no odometers at all with the given properties, because we cannot have net flow  $\mathcal{R}_0(u) - \mathcal{L}_1(u) = 20$  unless  $\mathcal{R}_0(u) \geq 20$ , which cannot occur if u(0) = 10. Since our odometers are to correspond to a set of infection paths in layer percolation with no dependence on  $u_0$  and  $f_0$ , we need to make its size the same (in distribution) regardless of the choice of  $u_0$  and  $f_0$ .

We carry this out by introducing *extended odometers* that can take negative values. We extend each stack of instructions to be two-sided. We think of negative odometer values as representing the execution of instructions on the negative-index portion of the instruction list, but with the reverse of their normal effects: a left instruction at site 1 takes a particle from 0 to 1 rather than sending a particle from 1 to 0, for example. Thus we can produce an odometer satisfying  $u_0 = 10$  and  $f_0 = 20$  by making the odometer negative at site 1. These extended odometers have no useful interpretation from the perspective of activated random walk, but by allowing them we regularize the set of stable odometers and make them independent of the choice of  $u_0$  and  $f_0$ .

We make this precise now. For  $v \ge 0$ , let  $\operatorname{instr}_v$  denote the two-sided list of instructions at site v, with instruction number i notated as  $\operatorname{instr}_v(i)$  for  $i \in \mathbb{Z}$ , and with  $\operatorname{instr}_v(0) = \operatorname{left}$ for all v. In Section 2.1 we defined  $\operatorname{Instr}_v$  to be a one-sided list of i.i.d. instructions. Here we think of  $\operatorname{instr}_v$  as being any deterministic list of instructions with  $\operatorname{instr}_v(0) = \operatorname{left}$ . The correspondence between ARW and layer percolation is deterministic, and probability plays no role here until Section 4.6.

If  $u(v) \geq 0$ , we define  $\mathcal{L}_v(u)$  and  $\mathcal{R}_v(u)$  as before as the number of left and right instructions, respectively, in  $\mathsf{instr}_v(1), \ldots, \mathsf{instr}_v(u(v))$ . Note that we have  $\mathcal{L}_v(u) = \mathcal{R}_v(u) =$ 0 if u(v) = 0. For u(v) < 0, we define  $\mathcal{L}_v(u)$  and  $\mathcal{R}_v(u)$  as the negative of the number of left and right instructions, respectively, in  $\mathsf{instr}_v(u(v) + 1), \ldots, \mathsf{instr}_v(0)$ . Note that because  $\mathsf{instr}_v(0) = \mathsf{left}$ , we always have  $\mathcal{L}_{-1}(u) = -1$  and  $\mathcal{R}_{-1}(u) = 0$ . This is the point of requiring  $\mathsf{instr}_v(0) = \mathsf{left}$ , since it makes it so that extending our instruction lists to be two-sided does not create new values of i with  $\mathcal{L}_i(u) = 0$ .

We define an *extended odometer* on  $[\![a, b]\!]$  as a function  $u: \mathbb{Z} \to \mathbb{Z}$  that is zero off of  $[\![a, b]\!]$ . We call an extended odometer *stable*, either at a site or a set of sites, by the same criteria given in Definition 2.2 but with our extended definition of  $\mathcal{L}_v(\cdot)$  and  $\mathcal{R}_v(\cdot)$ . And we define  $\mathcal{O}_n(\mathsf{instr}, \sigma, u_0, f_0)$  to be the set of extended odometers u on  $[\![0, n]\!]$  for the instructions instr and initial configuration  $\sigma$  that satisfy  $u(0) = u_0$  and  $\mathcal{R}_0(u) - \mathcal{L}_1(u) = f_0$  and are stable on  $[\![1, n-1]\!]$ . This is the set that we will embed in an instance of layer percolation.

We start by giving a criterion for an extended odometer u on [0, n] to be stable on [1, n-1]. Essentially we are just rewriting Definition 2.2 in a convenient form.

**Lemma 4.1.** Let u be an extended odometer on [[0,n]]. Let  $f_v = \mathcal{R}_v(u) - \mathcal{L}_{v+1}(u)$ , the net flow from v to v + 1 under the odometer. Let  $s_v = \sum_{i=1}^v \mathbf{1}\{\mathsf{instr}_i(u(i)) = \mathsf{sleep}\}$ . Then u is stable on [[1, n-1]] if and only if

(10) 
$$f_v = f_0 + \sum_{i=1}^{v} |\sigma(i)| - s_v \quad \text{for all } v \in [[0, n-1]].$$

*Proof.* Suppose u is stable on [1, n-1]. Then from Definition 2.2,

(11) 
$$f_i - f_{i-1} = |\sigma(i)| - 1\{\operatorname{instr}_i(u(i)) = \operatorname{sleep}\}$$

for all  $i \in [1, n-1]$ . Summing this equation from i = 1 to i = v yields (10).

Conversely, suppose (10) holds. Then (11) holds, which shows that the criteria for stability given in Definition 2.2 hold.  $\Box$ 

4.2. The minimal odometer. Our embedding of  $\mathcal{O}_n(\text{instr}, \sigma, u_0, f_0)$  into layer percolation will take the smallest odometer in  $\mathcal{O}_n(\text{instr}, \sigma, u_0, f_0)$  to the infection path  $(0, 0)_0 \to (0, 0)_1 \to \cdots \to (0, 0)_n$ ; see the discussion of the *minimal odometer* on page 18. We now define this minimal odometer before proving in Lemma 4.3 that it is indeed the minimal element of  $\mathcal{O}_n(\text{instr}, \sigma, u_0, f_0)$ .

**Definition 4.2.** The minimal odometer  $\mathfrak{m}$  of  $\mathcal{O}_n(\operatorname{instr}, \sigma, u_0, f_0)$  is the extended odometer defined by the following inductive procedure. First let  $\mathfrak{m}(0) = u_0$ . Now suppose that  $\mathfrak{m}(v-1)$  has already been defined. We define  $\mathfrak{m}(v)$  to be the minimum integer such that

$$\mathcal{L}_{v}(\mathfrak{m}) = \mathcal{R}_{v-1}(\mathfrak{m}) - f_{0} - \sum_{i=1}^{v-1} |\sigma(i)|.$$

This procedure always makes  $\operatorname{instr}_{v}(\mathfrak{m}(v)) = \operatorname{left}$  for  $v \in \llbracket 1, n \rrbracket$ , since if  $\operatorname{instr}_{v}(\mathfrak{m}(v))$  were anything other than left, we could decrease  $\mathfrak{m}(v)$  by one without changing  $\mathcal{L}_{v}(\mathfrak{m})$  (note that this argument applies even when  $\mathfrak{m}(v) \leq 0$ ).

The idea of the definition is that at each step we are choosing  $\mathfrak{m}(v)$  to be the minimal value making  $\mathfrak{m}$  stable at v-1. If we ever made  $\mathfrak{m}(v)$  a larger value, then we would execute an additional right instruction or cause a particle to sleep at v, either of which would require an additional left instruction at site v + 1.

**Lemma 4.3.** The odometer  $\mathfrak{m}$  constructed in Definition 4.2 is an element of  $\mathcal{O}_n(\operatorname{instr}, \sigma, u_0, f_0)$  satisfying

$$\mathfrak{m}(v) \leq u(v) \text{ for all } v \in \llbracket 0, n \rrbracket$$

for any  $u \in \mathcal{O}_n(\mathsf{instr}, \sigma, u_0, f_0)$ . The net flow from site v to v + 1 under  $\mathfrak{m}$  is

(12) 
$$\mathcal{R}_{v}(\mathfrak{m}) - \mathcal{L}_{v+1}(\mathfrak{m}) = f_{0} + \sum_{i=1}^{v} |\sigma(i)| \quad \text{for } v \in [\![0, n-1]\!].$$

*Proof.* Equation (12) is immediate from the construction of the minimal odometer. With  $s_v = \sum_{i=1}^{v} \mathbf{1}\{\operatorname{instr}_i(\mathfrak{m}(i)) = \mathtt{sleep}\}$ , we have  $s_v = 0$  for all  $v \ge 0$  since  $\operatorname{instr}_i(\mathfrak{m}(i)) = \mathtt{left}$  for  $i \in [\![1, n]\!]$ . Hence (10) is satisfied, and Lemma 4.1 proves that  $\mathfrak{m}$  is stable on

 $\llbracket 1, n-1 \rrbracket$ . By construction, the minimal odometer satisfies  $\mathfrak{m}(0) = u_0$  and by (12) we have  $\mathcal{R}_0(\mathfrak{m}) - \mathcal{L}_1(\mathfrak{m}) = f_0$ . Thus  $\mathfrak{m}$  is an element of  $\mathcal{O}_n(\mathsf{instr}, \sigma, u_0, f_0)$ .

To prove the minimality of  $\mathfrak{m}$ , fix  $u \in \mathcal{O}_n(\operatorname{instr}, \sigma, u_0, f_0)$  and proceed by induction on v. Assume that  $\mathfrak{m}(v) \leq u(v)$  for some  $v \in [0, n-1]$ , and we will prove that  $\mathfrak{m}(v+1) \leq u(v+1)$ . Since u is stable on [1, n-1], Lemma 4.1 gives us

$$\begin{aligned} \mathcal{R}_v(u) - \mathcal{L}_{v+1}(u) &= \mathcal{R}_0(u) - \mathcal{L}_1(u) + \sum_{i=1}^v |\sigma(i)| - \sum_{i=1}^v \mathbf{1}\{\mathsf{instr}_i(u(i)) = \mathtt{sleep}\} \\ &= f_0 + \sum_{i=1}^v |\sigma(i)| - \sum_{i=1}^v \mathbf{1}\{\mathsf{instr}_i(u(i)) = \mathtt{sleep}\} \\ &\leq f_0 + \sum_{i=1}^v |\sigma(i)| = \mathcal{R}_v(\mathfrak{m}) - \mathcal{L}_{v+1}(\mathfrak{m}). \end{aligned}$$

Thus  $\mathcal{L}_{v+1}(u) \geq \mathcal{R}_v(u) - \mathcal{R}_v(\mathfrak{m}) + \mathcal{L}_{v+1}(\mathfrak{m})$ . Since  $u(v) \geq \mathfrak{m}(v)$ , we have  $\mathcal{R}_v(u) - \mathcal{R}_v(\mathfrak{m}) \geq 0$ , proving that  $\mathcal{L}_{v+1}(u) \geq \mathcal{L}_{v+1}(\mathfrak{m})$ . If  $\mathcal{L}_{v+1}(u)$  is strictly greater than  $\mathcal{L}_{v+1}(\mathfrak{m})$ , then  $u(v+1) > \mathfrak{m}(v+1)$ . And if  $\mathcal{L}_{v+1}(u) = \mathcal{L}_{v+1}(\mathfrak{m}) = \ell$ , then since  $\mathfrak{m}(v+1)$  was chosen as the minimum value making  $\mathcal{L}_{v+1}(\mathfrak{m})$  equal to  $\ell$ , we have  $u(v+1) \geq \mathfrak{m}(v+1)$ .

We emphasize that despite being minimal in  $\mathcal{O}_n(\operatorname{instr}, \sigma, u_0, f_0)$ , the minimal odometer is not minimal in the sense of the least-action principle and is not typically the true odometer. While the true odometer stabilizing  $[\![0, n]\!]$  is minimal out of all odometers stable on  $[\![0, n]\!]$ , the minimal odometer of  $\mathcal{O}_n(\operatorname{instr}, \sigma, u_0, f_0)$  is stable only on  $[\![1, n - 1]\!]$  and is usually only an extended odometer, not an odometer.

4.3. Statement of the correspondence. We are nearly ready to state the main result of Section 4. First we construct layer percolation from the ARW instructions. Recall that layer percolation can be represented as random variables  $(R_j)_{j\geq 0}$  and  $(B_0^j, \ldots, B_{R_j}^j)_{j\geq 1}$  for each  $v \in [\![1, n]\!]$  that determine the infections from step v - 1 to v (see Remark 3.1).

**Definition 4.4**  $(\Theta_n)$ . We define a mapping of realizations of ARW to realizations of layer percolation, expressed as

$$\Theta_n : \left( (\mathsf{instr}_v)_{v \in \llbracket 0,n \rrbracket}, \, \sigma, \, u_0, \, f_0 \right) \mapsto \left( (R_j(v))_{j \ge 0}, \, (B_0^j(v), \dots, B_{R_j}^j(v))_{j \ge 1} \right)_{v \in \llbracket 1,n \rrbracket},$$

where  $R_j(v)$  are deterministic nonnegative integers and  $B_0^j(v), \ldots, B_{R_j}^j(v)$  are deterministic values in  $\{0, 1\}$ . So long as we are working with one value of v at a time, we will suppress v from the notation by fixing it and referring to  $(R_j)_{j\geq 0}$  and  $(B_0^j, \ldots, B_{R_j}^j)_{j\geq 0}$  as the component of  $\Theta_n(\text{instr}, \sigma, u_0, f_0)$  for step v.

Given  $(\mathsf{instr}_v)_{v \in [\![0,n]\!]}$ ,  $\sigma$ ,  $u_0$ , and  $f_0$ , let  $\mathfrak{m}$  be the minimal odometer of  $\mathcal{O}_n(\mathsf{instr}, \sigma, u_0, f_0)$ . Fix  $v \in [\![1, n]\!]$  and consider the instruction list

(13) 
$$\operatorname{instr}_{v}(\mathfrak{m}(v)), \operatorname{instr}_{v}(\mathfrak{m}(v)+1), \operatorname{instr}_{v}(\mathfrak{m}(v)+2), \ldots$$

which always starts with left. We define  $\Theta_n(\text{instr}, \sigma, u_0, f_0)$  by setting  $R_0, R_1, \ldots$  for step v as the number of right instructions between successive left instructions in this list. That is, taking the initial left instruction on the list as the 0th left instruction,  $R_j$  is the number of right instructions occurring between the *j*th and (j + 1)th left instruction.

Now fix j and consider this portion of the list from the jth to the (j+1)th left instruction with  $R_j$  many right instructions between them. In the  $R_j + 1$  regions of the string between each of these  $R_j + 2$  many instructions, there might or might not be a string of sleep instructions. We define  $B_0^j, \ldots, B_{R_j}^j$  as indicators on the presence of a sleep instruction in the respective slots. Carrying this out for each v, we have defined  $\Theta_n(\text{instr}, \sigma, u_0, f_0)$ .

Note that this construction matches our example in Section 3.3, where we constructed layer percolation from the sitewise instructions (4). Also note that all objects so far are deterministic. We have constructed a deterministic map from a realization of ARW to a realization of layer percolation, and soon we will establish a deterministic bijection between the extended odometers for the realization of ARW and the infection paths in the realization of layer percolation. Only in Section 4.6 will we add randomness, when we show that the image of  $\Theta_n$  with random instructions is layer percolation as defined in Section 3, i.e., it consists of independent Geo(1/2) and  $\text{Bernoulli}(\lambda/(1 + \lambda))$  random variables for each  $v \in [1, n]$ .

Next we give the map from extended odometers to infection paths:

**Definition 4.5**  $(\mathcal{I}_n(\mathsf{instr}, \sigma, u_0, f_0) \text{ and } \Phi_n)$ . Let  $\mathcal{I}_n(\mathsf{instr}, \sigma, u_0, f_0)$  be the set of infection paths of length n starting from  $(0, 0)_0$  in the realization of layer percolation given by  $\Theta_n(\mathsf{instr}, \sigma, u_0, f_0)$ . And let  $\Phi \colon \mathcal{O}_n(\mathsf{instr}, \sigma, u_0, f_0) \to \mathcal{I}_n(\mathsf{instr}, \sigma, u_0, f_0)$  be defined as follows. For any extended odometer u on  $[\![0, n]\!]$ , we define  $\Phi(u)$  as the sequence of cells  $((r_v, s_v)_v, 0 \le v \le n)$  given by

$$\begin{split} r_v &= \mathcal{R}_v(u) - \mathcal{R}_v(\mathfrak{m}), \\ s_v &= \sum_{i=1}^v \mathbf{1}\{\mathsf{Instr}_i(u(i)) = \mathtt{sleep}\} \end{split}$$

It is not clear that the resulting sequence of cells is an infection path, i.e., that in the realization of layer percolation  $\Theta_n(\text{instr}, \sigma, u_0, f_0)$ , we have  $(r_{v-1}, s_{v-1})_{v-1} \to (r_v, s_v)_v$  in for all  $1 \leq v \leq n$ , but we will prove it as part of Proposition 4.6.

To summarize, we start with a realization of ARW on  $[\![0,n]\!]$ . To form the corresponding realization of layer percolation  $\Theta_n(\operatorname{instr}, \sigma, u_0, f_0)$ , we consider the instruction list at site vstarting at index  $\mathfrak{m}(v)$ , where  $\mathfrak{m}$  is the minimal odometer. We break up the instruction list into blocks separated by left instructions. The layer widths  $R_0(v), R_1(v), \ldots$  are determined by the number of right instructions in each block; the Bernoulli random variables  $(B_i^j(v))$  determining the upward spread of layer percolation are determined by the presence of sleep instructions.

Then, we consider  $\mathcal{O}_n(\mathsf{instr}, \sigma, u_0, f_0)$ , the extended odometers stable on  $[\![1, n-1]\!]$  with given value  $u_0$  at site 0 and given net flow  $f_0$  from site 0 to 1, and  $\mathcal{I}_n(\mathsf{instr}, \sigma, u_0, f_0)$ , the infection paths in the layer percolation  $\Theta_n(\mathsf{instr}, \sigma, u_0, f_0)$ . The map  $\Phi$  goes from  $\mathcal{O}_n(\mathsf{instr}, \sigma, u_0, f_0)$  to  $\mathcal{I}_n(\mathsf{instr}, \sigma, u_0, f_0)$  by taking an extended odometer u to the sequence of cells  $((r_v, s_v)_v, 0 \le v \le n)$  where  $r_v$  gives the number of extra right instructions executed by odometer u at position v compared to the minimal odometer, and  $s_v$  gives the number of particles that the odometer leaves sleeping at positions  $1, \ldots, v$ .

Can we expect  $\Phi$  to be injective? Suppose an extended odometer  $u \in \mathcal{O}_n(\operatorname{instr}, \sigma, u_0, f_0)$ leaves a particle sleeping at site v, i.e., it satisfies  $\operatorname{instr}_v(u(v)) = \operatorname{sleep}$ . Suppose that the instruction at the next index u(v) + 1 at site v is also  $\operatorname{sleep}$ . By our definition of  $\Phi$ , the value of  $\Phi(u)$  is unchanged if we increase u(v) by 1. Thus  $\Phi$  is not injective. On the other hand, it makes sense to identify these two extended odometers, because an odometer may take any index within a string of consecutive  $\operatorname{sleep}$  instructions without altering any of its properties from the perspective of Definition 2.2. The following result shows that if we identify odometers differing in this way, then  $\Phi$  becomes a bijection: **Proposition 4.6.** The map  $\Phi$  is a surjection from  $\mathcal{O}_n(\text{instr}, \sigma, u_0, f_0)$  onto  $\mathcal{I}_n(\text{instr}, \sigma, u_0, f_0)$ . If  $u, u' \in \mathcal{O}_n(\text{instr}, \sigma, u_0, f_0)$  are two extended odometers with  $\Phi(u) = \Phi(u')$ , then for all  $v \in [0, n]$ , either u(v) = u'(v) or u(v) and u'(v) are two indices in  $\text{instr}_v$  in a string of consecutive sleep instructions.

It is a technical but not difficult task to prove this result. The idea of the bijection is more apparent from an example than a proof, and we urge our readers to consult the example from Sections 3.1 and 3.3. The basic idea, visible in the example from Sections 3.1 and 3.3, is to match each choice of odometer value at site v with a collection of infections from step v - 1 to v in layer percolation.

4.4. **Reduced instructions.** When we construct  $\Theta_n(\text{instr}, \sigma, u_0, f_0)$ , we first compute the minimal odometer  $\mathfrak{m}$  from  $\text{instr}_0$ ,  $\sigma$ ,  $u_0$ , and  $f_0$ . Then from the portion of  $\text{instr}_v$  starting at index  $\mathfrak{m}(v)$ , we compute the component of  $\Theta_n(\text{instr}, \sigma, u_0, f_0)$  for step v. It will be helpful to represent this portion of the instruction list in a different form:

**Definition 4.7.** We define the reduced instructions from (instr.  $\sigma$ ,  $u_0$ ,  $f_0$ ) at site  $1 \le v \le n$  as the two sequences  $a_1, a_2, \ldots \in \{ \texttt{left}, \texttt{right} \}$  and  $b_1, b_2, \ldots \in \{ 0, 1 \}$  defined as follows. Let  $\mathfrak{m}$  be the minimal odometer of  $\mathcal{O}_n(\texttt{instr}, \sigma, u_0, f_0)$ . Let  $\mathfrak{m}(v) = i_1 < i_2 < \cdots$  be the indices of the non-sleep instructions in  $\texttt{instr}_v$  starting at index  $\mathfrak{m}(v)$ . We define  $a_1, a_2, \ldots$  to be  $\texttt{instr}_v(i_1), \texttt{instr}_v(i_2), \ldots$ , the subsequence of left and right instructions in  $\texttt{instr}_v$  starting at index  $\mathfrak{m}(v)$ . Note that  $a_1$  is always equal to left. Next, for  $j \ge 1$  we set  $b_j = 1$  if  $\texttt{instr}_v$  contains a sleep instruction between indices  $i_j$  and  $i_{j+1}$  and  $b_j = 0$  otherwise.

It also makes sense to start with layer percolation and arrive at reduced instructions from the other direction.

**Definition 4.8.** Let  $R_0, R_1, \ldots$  and  $B^0, B^1, \ldots$  be the values defining the infections from step v - 1 to step v in a realization of layer percolation (see Remark 3.1). We define the *reduced instructions* corresponding to this step of layer percolation as the two sequences  $a_2, a_3, \ldots \in \{\text{left}, \text{right}\}$  with  $a_1 = \text{left}$  and  $b_1, b_2, \ldots \in \{0, 1\}$  defined as follows. We form  $a_1, a_2, \ldots$  as a left instruction followed by  $R_0$  many right instructions, then a left instruction followed by  $R_1$  many right instructions, and so on. To define  $b_1, b_2, \ldots$ , let  $1 = \ell_0 < \ell_1 < \cdots$  be the indices in  $a_1, a_2, \ldots$  of left instructions. Then for each  $j \ge 0$ , we define

(14) 
$$(b_{\ell_i}, b_{\ell_i+1}, \dots, b_{\ell_{i+1}-1}) = (B_0^j, \dots, B_{R_i}^j).$$

Similarly, we define the step of layer percolation corresponding to reduced instructions  $a_2, a_3, \ldots \in \{ \texttt{left}, \texttt{right} \}$  with  $a_1 = \texttt{left}$  and  $b_1, b_2, \ldots \in \{0, 1\}$  as follows. Let  $1 = \ell_0 < \ell_1 < \cdots$  be the indices in  $a_1, a_2, \ldots$  of left instructions. Let  $R_j$  be the number of right instructions in  $a_1, a_2, \ldots$  between indices  $a_{\ell_j}$  and  $a_{\ell_{j+1}}$ , or equivalently  $R_j = \ell_{j+1} - \ell_j - 1$ . And define  $(B_0^j, \ldots, B_{R_j}^j)$  from  $b_1, b_2, \ldots$  according to (14).

The following lemma is a simple exercise:

**Lemma 4.9.** The maps in Definition 4.8 between  $(R_j)_{j\geq 0}$ ,  $(B^j)_{j\geq 0}$  and  $(a_j)_{j\geq 1}$ ,  $(b_j)_{j\geq 1}$  are inverses. Hence reduced instructions are in bijection with realizations of  $(R_j)_{j\geq 0}$ ,  $(B^j)_{j\geq 0}$  and provide another way to specify a step of layer percolation.

Finally, we observe that Definitions 4.7 and 4.8 are compatible with each other.

**Proposition 4.10.** The reduced instructions from (instr,  $\sigma$ ,  $u_0$ ,  $f_0$ ) at site  $v \in [\![1, n]\!]$  are the same as the reduced instructions corresponding to step v of the layer percolation  $\Theta_n(\text{instr}, \sigma, u_0, f_0)$ .

*Proof.* Let  $a_1, a_2, \ldots$  and  $b_1, b_2, \ldots$  be the reduced instructions from (instr,  $\sigma, u_0, f_0$ ) at site v and let  $a'_1, a'_2, \ldots$  and  $b'_1, b'_2, \ldots$  be the reduced instructions corresponding to step v of  $\Theta_n(\text{instr}, \sigma, u_0, f_0)$ . Let  $R_0, R_1, \ldots$  and  $B^0, B^1, \ldots$  be the component of  $\Theta_n(\text{instr}, \sigma, u_0, f_0)$  for step v.

The sequence  $a_1, a_2, \ldots$  is defined as the subsequence of non-sleep instructions within instr<sub>v</sub> starting at index  $\mathfrak{m}(v)$ . Meanwhile,  $R_0, R_1, \ldots$  are defined as the number of right instructions between successive left instructions in instr<sub>v</sub> starting at  $\mathfrak{m}(v)$ , and then  $(a'_1, a'_2, \ldots) = (a_1, a_2, \ldots)$  by Definition 4.8.

With  $1 = \ell_0 < \ell_1 < \cdots$  the indices in  $a_1, a_2, \ldots$  of left instructions, we have  $B_i^j = b_{\ell_j+i}$  because both are defined as indicators on the presence of a sleep instruction in the same portion of  $instr_v$ . Then  $b'_{\ell_j+i}$  for  $0 \le i \le R_j$  is defined to be equal to  $B_i^j$ , demonstrating that  $(b_1, b_2, \ldots) = (b'_1, b'_2, \ldots)$ .

**Example 4.11.** We return to the example presented in Sections 3.1 and 3.3. We take the positive-index portions of  $instr_0$ ,  $instr_1$ ,  $instr_2$  to be given by (4), and we take  $\sigma \equiv 1$ ,  $u_0 = 20$ , and  $f_0 = 2$ . Here are the site 2 instructions, with the portion starting at the minimal odometer index highlighted:

SLRRLSLSRLLRSLLSLSRRSSLLS...

The reduced instructions from (instr,  $\sigma$ ,  $u_0$ ,  $f_0$ ) at site 2 are

$$\begin{array}{ccc} (15) & a: \quad LRLLLRRLL \dots \\ b: \quad 010110101\dots \end{array}$$

The component of  $\Theta_n(\text{instr}, \sigma, u_0, f_0)$  for site v is

$$(R_0, R_1, \ldots) = (1, 0, 0, 2, 0, \ldots),$$
  
 $B^0 = (0, 1), \ B^1 = (0), \ B^2 = (1), \ B^3 = (1, 0, 1), \ B^4 = (0), \ldots$ 

The reduced instructions corresponding to step 2 of  $\Theta_n(\text{instr}, \sigma, u_0, f_0)$  are also equal to (15). The sequence  $R_0, R_1, \ldots$  gives the length of runs of **right** instructions in  $a_1, a_2, \ldots$ , and  $B^0, B^1, \ldots$  when concatenated form the sequence  $b_1, b_2, \ldots$ .

4.5. **Proof of the correspondence.** To prove Proposition 4.6, we first construct a bijection between infections in a step of layer percolation and locations within the reduced instructions corresponding to this step. We start by defining a set  $\mathsf{Infections}_v$  consisting of all infections from step v - 1 to step v in a realization of layer percolation.

nfections<sub>v</sub> = {
$$(r, s, r', s'): (r, s)_{v-1} \rightarrow (r', s')_v$$
 }.

Taking  $a_1, a_2, \ldots$  and  $b_1, b_2, \ldots$  as the reduced instructions corresponding to this step of layer percolation, we define a set  $\mathsf{Positions}_v$  consisting of every possible position in the reduced instructions, represented as follows:

Positions<sub>v</sub> = { 
$$(i, z): i \ge 1, z \in \{0, 1\}, z \le b_i$$
 }.

In the definition of  $\mathsf{Positions}_v$ , the value of *i* represents an index in the reduced instructions, while *z* represents whether a **sleep** instruction is chosen, if it is available.

To give a sense of the bijection before we rigorously define it, we again consider our running example. In the realization of layer percolation described in Section 3.3, we have  $(1,1)_1 \rightarrow (1,2)_2$ . The infections from  $(1,1)_1$  stem from indices 15 and 16 at site 2 (see Case 3 in Section 3.1), with the infection of  $(1,2)_2$  corresponding to u(2) = 16. Looking at Example 4.11, index 16 in instr<sub>2</sub> is the sleep instruction after the fourth non-sleep instruction starting at index  $\mathfrak{m}(2) = 11$ . Hence index 16 in instr<sub>2</sub> corresponds to  $(4,1) \in$ 

Positions<sub>2</sub>. This will be represented in the following lemma by a map  $\Psi$ : Infections<sub>v</sub>  $\rightarrow$  Positions<sub>v</sub> taking the infection  $(1, 1)_1 \rightarrow (1, 2)_2$  (represented as  $(1, 1, 1, 2) \in$  Infections<sub>2</sub>) to  $(4, 1) \in$  Positions<sub>2</sub>. This map is surjective, but it is not bijective because all of the "parallel" infections from cells along a common diagonal are mapped to the same element of Positions<sub>v</sub>.

**Lemma 4.12.** Let  $a_1, a_2, \ldots$  and  $b_1, b_2, \ldots$  be the reduced instructions corresponding to step v of layer percolation represented by  $(R_j)_{j\geq 0}$  and  $(B_0^j, \ldots, B_{R_j}^j)_{j\geq 0}$ , and consider the associated sets  $\mathsf{Infections}_v$  and  $\mathsf{Positions}_v$ .

(a) For each  $(r, s, r', s') \in \text{Infections}_v$ , there is a unique index j such that  $a_1, \ldots, a_j$  contains r + s + 1 left and r' right instructions and  $b_j \ge s' - s$ .

Thus we can define a map  $\Psi_v$  on  $\mathsf{Infections}_v$  taking (r, s, r', s') to (j, s' - s), where j is the index given in (a).

- (b) The map  $\Psi_v$  is a surjection from  $Infections_v$  to  $Positions_v$ .
- (c) For each  $(j, z) \in \mathsf{Positions}_v$ ,

$$\Psi_{v}^{-1}((j,z)) = \{(r,s,r',s'): r,s,s' \in \mathbb{N} \text{ such that } r+s = q-1 \text{ and } s'-s = z\},\$$

where q and r' are the number of left and right instructions, respectively, in  $a_1, \ldots, a_j$ .

*Proof.* Let  $1 = \ell_0 < \ell_1 < \cdots$  be the indices of left instructions in  $a_1, a_2, \ldots$  For  $j \in [\![\ell_{r+s}, \ell_{r+s+1} - 1]\!]$  and no other values of j, there are exactly r + s + 1 left instructions in  $a_1, \ldots, a_j$ . According to Definition 4.8, the number of right instructions in  $a_1, \ldots, a_{\ell_{r+s}-1}$ , and the number of right instructions in  $a_1, \ldots, a_{\ell_{r+s}-1}$  is  $R_0 + \cdots + R_{r+s-1}$ , and the number of right instructions in  $a_1, \ldots, a_{\ell_{r+s}+1} - 1$  is  $R_0 + \cdots + R_{r+s}$ . Suppose that  $(r, s)_{v-1} \to (r', s')_v$ . Then

$$R_0 + \dots + R_{r+s-1} \le r' \le R_0 + \dots + R_{r+s}$$

by definition of layer percolation. Hence there is a unique  $j \in [\![\ell_{r+s}, \ell_{r+s+1} - 1]\!]$  such that  $a_1, \ldots, a_j$  contains r' right instructions, namely

(16) 
$$j = \ell_{r+s} + r' - (R_0 + \dots + R_{r+s-1}).$$

Thus we have found a unique index j so that  $a_1, \ldots, a_j$  contains r' right instructions, within a unique stretch of indices j so that  $a_1, \ldots, a_j$  contains r+s+1 left instructions. To prove (a), it just remains to prove that for this choice of j we have  $b_j = 1$  when  $s' - s \ge 1$ . By Definition 4.8 we have  $b_j = B_{j-\ell_{r+s}}^{r+s}$ . If  $s'-s \ge 1$ , then  $B_{r'-(R_0+\cdots+R_{r+s-1})}^{r+s} = 1$  by definition of layer percolation, and  $B_{r'-(R_0+\cdots+R_{r+s-1})}^{r+s} = B_{j-\ell_{r+s}}^{r+s}$  by (16). Thus (a) is proven, and  $\Psi_v$ is well defined.

To prove (c), let  $(j, z) \in \text{Positions}_v$ . Let q and r' be the number of left and right instructions, respectively, in  $a_1, \ldots, a_j$ . By Definition 4.8,

$$R_0 + \dots + R_{q-2} \le r' \le R_0 + \dots + R_{q-1},$$

and  $r' - (R_0 + \dots + R_{q-2}) = j - \ell_{q-1}$  Suppose that r + s = q - 1. Then  $r' \in \text{layer}_v(r + s)$ , using the notation given in (5). If z = 0, then we have  $(r, s) \to (r', s)$ . Hence  $(r, s, r', s) \in$ Infections<sub>v</sub>, and  $\Psi_v(r, s, r', s) = (j, 0)$  since  $a_1, \dots, a_j$  contains q = r + s + 1 left instructions and r' right instructions. If z = 1, then  $b_j = 1$  by definition of Positions<sub>v</sub>. By Definition 4.8, we have  $B_{j-\ell_{q-1}}^{q-1} = b_j = 1$ . Hence  $B_{r'-(R_0+\dots+R_{r+s-1})}^{r+s} = 1$ , and so  $(r, s, r', s+1) \in \text{Infections}_v$ and  $\Psi_v(r, s, r', s+1) = (j, 1)$ . This proves that  $\Psi_v^{-1}((j, z))$  contains all (r, s, r', s') such that r + s = q - 1 and s' - s = z. For the converse, observe that if  $r + s \neq q - 1$ , then  $\Psi_v(r, s, r', s') = (j', s' - s)$  with  $j' \neq j$ , since j' is by definition of  $\Psi_v$  an index such that  $a_1, \dots, a_{j'}$  contains r + s + 1 left instructions. And if r + s = q - 1 but  $s' - s \neq z$ , of course  $\Psi_v(r, s, r', s') \neq (j, z)$ , since  $\Psi_v(r, s, r', s') = (j', z')$  where z' = s' - s. This completes the proof of (c).

To prove (b), by (c) we need only assert that for every  $(j, z) \in \mathsf{Positions}_v$ , there exists r, s, r', s' such that r + s = q - 1 and s' - s = z. In fact, with q, r' defined as above, there are exactly q choices of (r, s, r', s'), obtained by taking  $r \in [0, q - 1]$ , then defining s = q - r and s' = z + s. And  $q \ge 1$  since  $a_1 = \mathsf{left}$ .

Proving Proposition 4.6 amounts to repeatedly applying Lemma 4.12. We first need to define a map  $\tau_v$  taking indices for the instructions at site v to indices of the reduced instructions. Let  $a_1, a_2, \ldots$  and  $b_1, b_2, \ldots$  be the reduced instructions from  $(\text{instr}, \sigma, u_0, f_0)$  at site v, and let  $\mathfrak{m}(v) = i_1 < i_2 < \cdots$  be the indices of non-sleep instructions in instr<sub>v</sub> as in Definition 4.7. We now define  $\tau_v(k)$  for  $k \ge \mathfrak{m}(v)$ . If  $\text{instr}_v(k) \in \{\text{left}, \text{right}\}$ , then k is the index of the jth non-sleep instruction at or after index  $\mathfrak{m}(v)$  for some  $j \ge 1$ . Then we define  $\tau_v(k) = (j, 0)$ . If  $\text{instr}_v(k) = \text{sleep}$ , then let k' < k be the first index before k of a left or right instruction. Note that  $k' \ge \mathfrak{m}(v)$  since  $\mathfrak{m}(v)$  is the index of a left instruction. Then  $\tau_v(k')$  has already been defined as (j, 0) for some  $j \ge 1$ , and we define  $\tau_v(k)$  to be (j, 1). It is easy to see that  $\tau_v$  maps  $\{\mathfrak{m}(v), \mathfrak{m}(v+1), \ldots\}$  surjectively onto Positions<sub>v</sub>, and that  $\tau_v(k) = \tau_v(k')$  only when k = k' or k and k' are indices within a string of consecutive sleep instructions in instr<sub>v</sub>.

Proof of Proposition 4.6. First, we demonstrate that  $\Phi$  maps an element  $u \in \mathcal{O}_n(\operatorname{instr}, \sigma, u_0, f_0)$ into  $\mathcal{I}_n(\operatorname{Instr}, \sigma, u_0, f_0)$ . Let  $((r_v, s_v)_v, 0 \leq v \leq n) = \Phi(u)$ . We have  $r_0 = 0$  since  $u(0) = u_0 = \mathfrak{m}(0)$ , and  $s_0 = 0$  by definition. To show that  $\Phi(u) \in \mathcal{I}_n(\operatorname{Instr}, \sigma, u_0, f_0)$ , then, we must show that  $(r_{v-1}, s_{v-1})_{v-1} \to (r_v, s_v)_v$  for each  $v \in [\![1, n]\!]$ . By definition of  $\Phi$ ,

$$\begin{aligned} r_{v-1} &= \mathcal{R}_{v-1}(u) - \mathcal{R}_{v-1}(\mathfrak{m}), \qquad r_v = \mathcal{R}_v(u) - \mathcal{R}_v(\mathfrak{m}), \\ s_v - s_{v-1} &= \mathbf{1}\{\mathsf{Instr}_v(u(v)) = \mathtt{sleep}\}. \end{aligned}$$

Let  $a_1, a_2, \ldots$  and  $b_1, b_2, \ldots$  be the reduced instructions from (instr,  $\sigma, u_0, f_0$ ) at v. Let  $(j, z) = \tau_v(u(v))$ , the element of Positions<sub>v</sub> corresponding to u(v). By definition of  $\tau_v$ , there are  $\mathcal{R}_v(u) - \mathcal{R}_m(u) = r_v$  right instructions and  $\ell_v := \mathcal{L}_v(u) - \mathcal{L}_v(\mathfrak{m}) + 1$  left instructions in  $a_1, \ldots, a_j$ , and  $z = \mathbf{1}\{\operatorname{instr}_v(u(v)) = \mathtt{sleep}\} = s_v - s_{v-1}$ . Putting these facts together,

$$r_{v-1} - \ell_v = \mathcal{R}_{v-1}(u) - \mathcal{L}_v(u) - \left(\mathcal{R}_{v-1}(\mathfrak{m}) - \mathcal{L}_v(\mathfrak{m})\right) - 1$$
  
=  $\left(f_0 + \sum_{i=1}^{v-1} |\sigma(i)| - s_{v-1}\right) - \left(f_0 + \sum_{i=1}^{v-1} |\sigma(i)|\right) - 1 = -s_{v-1} - 1,$ 

applying Lemma 4.1 and (12) to get to the second line. Hence  $r_{v-1} + s_{v-1} = \ell_v - 1$ . By Lemma 4.12(c), we have  $(r_{v-1}, s_{v-1}, r_v, s_v) \in \Psi_v^{-1}((j, z))$ . In particular,  $(r_{v-1}, s_{v-1})_{v-1} \to (r_v, s_v)_v$ . This shows that  $\Phi(u) \in \mathcal{I}_n(\operatorname{instr}, \sigma, u_0, f_0)$ .

Next, we define a map  $\chi$  from  $\mathcal{I}_n(\text{instr}, \sigma, u_0, f_0)$  back to  $\mathcal{O}_n(\text{instr}, \sigma, u_0, f_0)$  that we will use to prove surjectivity of  $\Phi$ . Consider an infection path

(17) 
$$(0,0)_0 = (r_0, s_0)_0 \to \dots \to (r_n, s_n)_n \in \mathcal{I}_n(\mathsf{instr}, \sigma, u_0, f_0).$$

Now we construct an odometer u that we define as the image of this infection path under  $\chi$ . First set  $u(0) = u_0$ . Now fix  $v \in [\![1, n]\!]$ , and again let  $a_1, a_2, \ldots$  and  $b_1, b_2, \ldots$  be the reduced instructions at v. Let  $(j, z) = \Psi_v(r_{v-1}, s_{v-1}, r_v, s_v)$ . Define u(v) as the smallest value making  $\tau_v(u(v)) = (j, z)$ , which exists by surjectivity of  $\tau_v$  onto Positions<sub>v</sub>. By definition of  $\tau_v$ , we have  $\mathsf{instr}_v(u(v)) = \mathsf{sleep}$  if and only if z = 1. By definition of  $\Psi_v$ , we have  $z = s_v - s_{v-1}$ , yielding

(18) 
$$s_v - s_{v-1} = \mathbf{1}\{\mathsf{instr}_v(u(v)) = \mathtt{sleep}\}.$$

Also by definition of  $\Psi_v$ , there are  $r_{v-1}+s_{v-1}+1$  left instructions and  $r_v$  right instructions in  $a_1, \ldots, a_j$ . Since  $\tau_v(u(v)) = (j, z)$ ,

(19) 
$$\mathcal{R}_v(u) = r_v + \mathcal{R}_v(\mathfrak{m}),$$

(20) 
$$\mathcal{L}_v(u) = r_{v-1} + s_{v-1} + \mathcal{L}_v(\mathfrak{m}).$$

These equalities hold for  $v \in [\![1, n]\!]$ , and (19) also holds for v = 0 since  $u(0) = \mathfrak{m}(0)$  and  $r_v = 0$ .

Now we show that  $u \in \mathcal{O}_n(\text{instr}, \sigma, u_0, f_0)$ . For any  $v \in [\![1, n]\!]$ , by (19) and (20)

(21) 
$$\mathcal{R}_{v-1}(u) - \mathcal{L}_v(u) = \mathcal{R}_{\mathfrak{m}}(v-1) - \mathcal{L}_{\mathfrak{m}}(v) - s_{v-1} = f_0 + \sum_{i=1}^{v-1} |\sigma(i)| - s_{v-1},$$

applying Lemma 4.3 for the last equality. By (18), we have

(22) 
$$s_v = \sum_{i=1}^v \mathbf{1}\{\mathsf{instr}_i(u(i)) = \mathtt{sleep}\}$$

in agreement with the definition of  $s_v$  in Lemma 4.1, which we can then apply to show that u is stable on  $[\![1, n-1]\!]$ . We have  $u(0) = u_0$  by construction. By the v = 1 case of (21), we have  $\mathcal{R}_0(u) - \mathcal{L}_1(u) = f_0$ . Hence  $u \in \mathcal{O}_n(\operatorname{instr}, \sigma, u_0, f_0)$ , showing that  $\chi$  does indeed map  $\mathcal{I}_n(\operatorname{instr}, \sigma, u_0, f_0)$  back into  $\mathcal{O}_n(\operatorname{instr}, \sigma, u_0, f_0)$ . From (19) and (22) and the definition of  $\Phi$ , we see that  $\Phi(u)$  is our original infection path (17). That is,  $\Phi \circ \chi$  is the identity on  $\mathcal{I}_n(\operatorname{instr}, \sigma, u_0, f_0)$ . This proves that  $\Phi$  is surjective.

Finally, suppose  $\Phi(u) = \Phi(u') = ((r_v, s_v)_v, 0 \le v \le n)$  for  $u, u' \in \mathcal{O}_n(\mathsf{instr}, \sigma, u_0, f_0)$ . From the definition of  $\Phi$ ,

$$\mathcal{R}_v(u) = \mathcal{R}_v(u') \quad \text{for } v \in \llbracket 0, n \rrbracket,$$

and

$$\operatorname{instr}_{v}(u(v)) = \operatorname{sleep} \text{ if and only if } \operatorname{instr}_{v}(u'(v)) = \operatorname{sleep} \text{ for } v \in [1, n].$$

Using these facts together with the stability of u and u' on  $[\![1, n-1]\!]$ , we have  $\mathcal{L}_v(u) = \mathcal{L}_v(u')$  for  $v \in [\![1, n]\!]$ . Thus at each site in  $[\![1, n]\!]$ , the odometers u and u' execute identical numbers of left and right instructions. Hence u(v) and u'(v) can only differ by pointing to different sleep instructions in a consecutive block of them.

4.6. Layer percolation constructed from ARW is correctly distributed. Extending our definition of  $\text{Instr}_v$  from Section 2.1, we let  $(\text{Instr}_v(k), v \in \mathbb{Z})$  be independent with

$$\mathsf{Instr}_{v}(k) = \begin{cases} \mathsf{left} & \text{with probability } \frac{1/2}{1+\lambda}, \\ \mathsf{right} & \text{with probability } \frac{1/2}{1+\lambda}, \\ \mathsf{sleep} & \text{with probability } \frac{\lambda}{1+\lambda}, \end{cases}$$

for  $k \neq 0$  and  $\operatorname{Instr}_{v}(0) = \operatorname{left}$ . To finish the correspondence, we show now that the layer percolation  $\Theta_n(\operatorname{Instr}, \sigma, u_0, f_0)$  constructed from these random instructions is actually distributed as layer percolation as defined in Section 3. Note that we will leave the instructions at 0 as the arbitrary, deterministic list  $\operatorname{instr}_0$ , which will prove technically helpful later on. **Proposition 4.13.** Let  $(R_j(v))_{j\geq 0}$  and  $(B_i^j(v))_{j\geq 0, 0\leq i\leq R_j}$  be the component of

 $\Theta_n((\mathsf{instr}_0,\mathsf{Instr}_1,\ldots,\mathsf{Instr}_n),\,\sigma,\,u_0,\,f_0)$ 

for step v. For different choices of v, these random variables are independent. For any particular  $v \in [\![1,n]\!]$ , the random variables  $(R_j(v))_{j\geq 0}$  are i.i.d.-Geo(1/2), and conditional on  $(R_j(v))_{j\geq 0}$ , the random variables  $(B_j^j(v))_{j\geq 0,0\leq i\leq R_j}$  are i.i.d.-Bernoulli $(\lambda/(1+\lambda))$ .

*Proof.* For any  $v \ge 0$ , let  $\mathscr{F}_v$  be the  $\sigma$ -algebra generated by  $\mathsf{Instr}_1, \ldots, \mathsf{Instr}_v$ , and observe that the random variables  $(R_j(u))_{j\ge 0}$  and  $(B_i^j(u))_{j\ge 0, 0\le i\le R_j}$  for  $u\le v$  are measurable with respect to  $\mathscr{F}_v$ . Thus it suffices to show that for any  $v\ge 1$ , the distribution of  $(R_j(v))_{j\ge 0}$  and  $(B_i^j(v))_{j\ge 0, 0\le i\le R_j}$  conditional on  $\mathscr{F}_{v-1}$  is as stated.

Let  $\mathfrak{m}$  be the minimal odometer of  $\mathcal{O}_n(\mathsf{Instr}, \sigma, u_0, f_0)$ . We claim that the instructions

(23) 
$$\operatorname{Instr}_{v}(\mathfrak{m}(v)), \operatorname{Instr}_{v}(\mathfrak{m}(v)+1), \operatorname{Instr}_{v}(\mathfrak{m}(v)+2) \dots$$

used to generate  $(R_j(v))_{j\geq 0}$  and  $(B_i^j(v))_{j\geq 0, 0\leq i\leq R_j}$  are distributed conditional on  $\mathscr{F}_{v-1}$  as a left instruction followed by i.i.d. instructions with the usual distribution, namely left and right each with probability  $1/2(1 + \lambda)$  and sleep with probability  $\lambda/(1 + \lambda)$ . The lemma follows, by simple properties of i.i.d. sequences and by definition of  $(R_j(v))_{j\geq 0}$  and  $(B_i^j(v))_{j\geq 0, 0\leq i\leq R_j}$ .

Now we establish the claim. For a two-sided sequence of instructions  $\ldots, x_{-1}, x_0, x_1, \ldots$ with  $x_0 = \texttt{left}$ , for  $\ell \in \mathbb{Z}$  we refer to the  $\ell$ th instance of left in the sequence to mean the  $\ell$ th instance after index 0 when  $\ell$  is positive, the  $|\ell|$ th instance before index 0 when  $\ell$ is negative, and  $x_0$  itself when  $\ell = 0$ . We define  $T_{\ell}(\ldots, x_{-1}, x_0, x_1, \ldots)$  as the shift of the sequence that puts the  $\ell$ th occurrence of left at position 0.

Let  $\ell_v = \mathcal{R}_{v-1}(\mathfrak{m}) - f_0 - \sum_{i=1}^{v-1} |\sigma(i)|$  and recall that  $\mathfrak{m}(v)$  is the index of the  $\ell_v$ th left instruction in  $\mathsf{Instr}_v$ . Since  $\ell_v$  is measurable with respect to  $\mathscr{F}_{v-1}$ , and conditioning on  $\mathscr{F}_{v-1}$ does not alter the distribution of  $\mathsf{Instr}_v$ , the claim is equivalent to showing that the sequence  $\mathsf{Instr}_v$  is invariant under the action of  $T_\ell$  for any deterministic  $\ell$ . By symmetry it suffices to show this claim for  $\ell \geq 1$ , and by iteration it is enough to show it for  $T_1$ . And this is a simple technical fact following from the strong Markov property for an i.i.d. sequence.  $\Box$ 

**Corollary 4.14.** For any initial configuration  $\sigma$  on [[0,n]] and any  $u_0, f_0 \in \mathbb{Z}$ , the set  $\mathcal{I}_n(\mathsf{Instr}, \sigma, u_0, f_0)$  is distributed as the collection of length n infection paths from  $(0,0)_0$  in layer percolation. Furthermore the conclusion holds for random  $u_0$  measurable with respect to  $\mathsf{Instr}_0$ .

*Proof.* Since Proposition 4.13 is stated for deterministic instructions at site 0, we can apply it to show that  $\Theta_n(\text{Instr}, \sigma, u_0, f_0)$  conditional on  $\text{Instr}_0$  is distributed as layer percolation. Hence it is distributed unconditionally as layer percolation, and  $\mathcal{I}_n(\text{Instr}, \sigma, u_0, f_0)$  has the claimed distribution.

Together, Proposition 4.6 and Corollary 4.14 show that the set of extended odometers  $\mathcal{O}_n(\mathsf{Instr}, \sigma, u_0, f_0)$  is (nearly) in bijection with the length *n* infection paths in layer percolation.

Since the distribution of  $\mathcal{I}_n(\mathsf{Instr}, \sigma, u_0, f_0)$  does not depend on  $\sigma$ ,  $u_0$ , and  $f_0$ , it follows from the definition of  $\Phi$  that the distribution of the extended odometers  $\mathcal{O}_n(\mathsf{Instr}, \sigma, u_0, f_0)$ depends on  $\sigma$ ,  $u_0$ , and  $f_0$  only in that they affect the minimal odometer.

We have taken care to allow  $u_0$  to depend on  $\mathsf{Instr}_0$  for the following reason. All extended odometers in  $\mathcal{O}_n(\mathsf{Instr}, \sigma, u_0, f_0)$  are stable on  $[\![1, n - 1]\!]$  by definition. While it will take

quite a bit of work to form odometers stable also at n (see Section 6), we can make them stable at 0 by the right choice of  $u_0$ :

**Proposition 4.15.** Given initial configuration  $\sigma$  on [0,n] and  $f_0 < 0$ , let  $u_0$  be the index of the  $(\sigma(0) - f_0)$ th occurrence of left within  $Instr_0(1), Instr_0(2), \ldots$  Then all  $u \in \mathcal{O}_n(Instr, \sigma, u_0, f_0)$  are stable at 0.

*Proof.* Since u(-1) = 0 by definition for  $u \in \mathcal{O}_n(\mathsf{Instr}, \sigma, u_0, f_0)$ , the stability condition for u at site 0 is that

$$\sigma(0) - \mathcal{L}_0(u) - \mathcal{R}_0(u) + \mathcal{L}_1(u) = \mathbf{1} \{ \mathsf{Instr}_0(u(0)) = \mathsf{sleep} \}.$$

Since  $u(0) = u_0$  and  $\mathcal{R}_0(u) - \mathcal{L}_1(u) = f_0$ , the extended odometer u is stable at 0 if and only if

$$\mathcal{L}_0(u) = \sigma(0) - f_0 - \mathbf{1} \{ \mathsf{Instr}_0(u_0) = \mathtt{sleep} \}$$

The proof is complete since our choice of  $u_0$  makes this equation hold.

## 5. BASIC PROPERTIES OF LAYER PERCOLATION

We establish fundamental properties of infection in layer percolation that we will use throughout the rest of the paper. In Section 5.1, we prove that forward and backward infection sets are connected, in slightly different senses. In Section 5.2, we translate bounds on the rows of an infection path into bounds on the columns. Additionally we give general lower and upper bounds on infection sets. We include a lower bound on the minimal odometer (which is associated with ARW rather than layer percolation), since it uses similar techniques. In Section 5.3 we describe how the law of layer percolation is basically invariant with respect to the starting cell, and we describe a coupling that establishes a duality between forward and reverse infection. In Section 5.4, we stitch together infection paths of locally optimal growth in the second coordinate (the row) and prove growth estimates in both row and column for the resulting paths. Then in Section 5.5, we apply these greedy paths to establish the existence of a limiting speed  $\rho_*$  for the maximum row infected and prove an exponential lower tail bound for it.

5.1. Connectivity of infection sets. At the end of Section 3.2, we define  $\zeta_n^{(r,s)_k}$  as the set of cells at step k + n infected starting from  $(r, s)_k$ , and we define  $\zeta_n^{(r,s)_k}$  as the set of cells at step k - n that infect  $(r, s)_k$ . These sets have geometric properties that are apparent from examples (see Figure 4) but which would be challenging even to state in terms of odometers. We show now that each cell in an infection set other than the most southwestern has a neighbor immediately to its south or west. Hence we can move within an infection set from any cell to any other by taking steps in compass directions.

**Proposition 5.1.** Fix  $(u,t)_0$  and consider the forward infection set  $\zeta_n = \zeta_n^{(u,t)_0}$  as defined in (6). For any  $(r,s)_n \in \zeta_n$  other than the leftmost cell in row t, either  $(r-1,s)_n \in \zeta_n$  or  $(r,s-1)_n \in \zeta_n$ .

*Proof.* We proceed by induction and assume that the connectivity property holds for  $\zeta_{n-1}$ . Now, we consider a cell  $(r, s)_n \in \zeta_n$  and show that  $(r - 1, s)_n \in \zeta_n$  or  $(r, s - 1)_n \in \zeta_n$  or (r, s) is the leftmost cell in row t in  $\zeta_n$ . We break the proof into cases based on the source of infection of  $(r, s)_n$  in  $\zeta_{n-1}$ .

**Case 1:**  $(r, s)_n$  is infected by some  $(r', s - 1)_{n-1} \in \zeta_{n-1}$ .

If  $(r', s-1)_{n-1} \to (r, s)_n$ , then  $(r', s-1)_{n-1} \to (r, s-1)_n$  too. Thus  $(r, s-1)_n \in \zeta_n$ .

FIGURE 4. Examples of forward (blue) and backward (red) infection sets at a step. Proposition 5.1 proves that each cell (except the bottom-left) in the forward infection set has another infected cell to its south or west. Proposition 5.2 proves that each cell (except the top-left) in the backward infection set has another cell to its west or northwest.

In Cases 2–4,  $(r, s)_n$  is infected by a cell in  $\zeta_{n-1}$  in row s. We let  $(r', s)_{n-1} \in \zeta_{n-1}$  be the leftmost such cell.

**Case 2:**  $(r, s)_n$  is infected by  $(r', s)_{n-1} \in \zeta_{n-1}$  and column r is not the minimum value in  $\operatorname{layer}_n(r'+s)$ .

Then  $(r', s)_{n-1} \to (r-1, s)_n$ , and hence  $(r-1, s)_n \in \zeta_n$ .

**Case 3:**  $(r, s)_n$  is infected by  $(r', s)_{n-1} \in \zeta_{n-1}$ , column r is the minimum value in layer<sub>n</sub>(r' + s), and  $(r', s)_{n-1}$  is not the leftmost cell in row t of  $\zeta_{n-1}$ .

Since r is the minimum of  $\operatorname{layer}_n(r'+s)$ , it is the maximum of  $\operatorname{layer}_n(r'+s-1)$ . Thus  $(r'-1,s)_{n-1} \to (r,s)_n$ . Since  $(r',s)_{n-1}$  is the leftmost cell in row s of  $\zeta_{n-1}$  infecting  $(r,s)_n$ , we can conclude that  $(r'-1,s)_{n-1} \notin \zeta_{n-1}$ . And since  $(r',s)_{n-1}$  is not the leftmost cell in row t of  $\zeta_{n-1}$ , the inductive hypothesis yields that  $(r',s-1)_{n-1} \in \zeta_{n-1}$ . And  $(r',s-1)_{n-1} \to (r,s-1)_n$ , because  $r \in \operatorname{layer}_n(r'+s-1)$ . Thus we have shown that  $(r,s-1)_n \in \zeta_n$ .

**Case 4:**  $(r, s)_n$  is infected by  $(r', s)_{n-1} \in \zeta_{n-1}$ , column r is the minimum value in layer<sub>n</sub>(r' + s), and  $(r', s)_{n-1}$  is the leftmost cell in row t of  $\zeta_{n-1}$ .

We have s = t. Infections in row t can only come from cells in row t, since t is the minimum row present in these infections sets. Since r is the minimum value in the layer infected by the leftmost cell in row t at step n - 1, the cell  $(r, t)_n$  is the leftmost cell in  $\zeta_n$  in row t.

Similarly, any cell in the backward infection set other than the top-left one has a neighbor either immediately to its left or upper-left:

**Proposition 5.2.** Fix  $(u,t)_{m+n}$  and consider the backward infection set  $\zeta_n = \zeta_n^{(u,t)_{m+n}}$  as defined in (7). For any  $(r,s)_m \in \zeta_n$  other than the leftmost cell in row t, if r > 0 then either  $(r-1,s)_m \in \zeta_n$  or  $(r-1,s+1)_m \in \zeta_n$ .

Proof. The proof is nearly the same as the previous one. We assume the connectivity property holds for  $\zeta_{n-1}$  and extend it to  $\zeta_n$ . Suppose that  $(r, s)_m \in \zeta_n$ . We must show that  $(r-1, s)_m \in \zeta_n$  or  $(r-1, s+1)_m \in \zeta_n$  or  $(r, s)_m$  is the leftmost cell in row t of  $\zeta_n$ . Again, we consider cases based on the cell in  $\zeta_{n-1}$  that  $(r, s)_m$  infects. We assume throughout that r > 0.

**Case 1:**  $(r, s)_m$  infects some  $(r', s+1)_{m+1} \in \overline{\zeta}_{n-1}$ . We have  $r' \in \operatorname{layer}_{m+1}(r+s)$ . Hence  $(r-1, s+1)_m \to (r', s+1)_{m+1}$ , which makes  $(r-1, s+1)_m \in \overline{\zeta}_n$ .

In Cases 2–4,  $(r, s)_m$  infects a cell in  $\zeta_{n-1}$  in row s. We let  $(r', s)_{m+1} \in \overline{\zeta}_{n-1}$  be the leftmost such cell.

- **Case 2:**  $(r, s)_m \to (r', s)_{m+1} \in \overline{\zeta}_{n-1}$  and column r' is the minimum value in  $\operatorname{layer}_{m+1}(r+s)$ . Then r' is the maximum in  $\operatorname{layer}_{m+1}(r+s-1)$ . Since r > 0, we have a cell  $(r-1, s)_m$  also infecting  $(r', s)_{m+1}$ . Hence  $(r-1, s)_m \in \overline{\zeta}_n$ .
- **Case 3:**  $(r, s)_m \to (r', s)_{m+1} \in \overline{\zeta}_{n-1}$  and column r' is not the minimum value in layer<sub>m+1</sub>(r+s) and  $(r', s)_{m+1}$  is not the leftmost cell in row t in  $\overline{\zeta}_{n-1}$ .

Since r' is not the minimum of  $\operatorname{layer}_{m+1}(r+s)$ , we have r' > 0 and  $(r,s)_m \to (r'-1,s)_{m+1}$ . Since  $(r',s)_{m+1}$  was the leftmost cell in  $\zeta_{n-1}$  infected by  $(r,s)_m$ , we conclude that  $(r'-1,s)_{m+1} \notin \zeta_{n-1}$ . Since  $(r',s)_{m+1}$  is not the leftmost cell in row t in  $\zeta_{n-1}$ , the inductive hypothesis yields  $(r'-1,s+1)_{m+1} \in \zeta_{n-1}$ . And  $(r-1,s+1)_m \to (r'-1,s+1)_{m+1}$  since  $r'-1 \in \operatorname{layer}_{m+1}(r+s)$ , yielding  $(r-1,s+1)_m \in \zeta_m$ .

**Case 4:**  $(r, s)_m \to (r', s)_{m+1} \in \zeta_{n-1}$  and column r' is not the minimum value in layer<sub>m+1</sub>(r+s) and  $(r', s)_{m+1}$  is the leftmost cell in row t in  $\zeta_{n-1}$ .

We have s = t. Since r' is not the minimum value in  $\operatorname{layer}_{m+1}(r+t)$ , we have  $\operatorname{layer}_{m+1}(p+t) \subseteq [\![0,r'-1]\!]$  for all p < r. Since  $(r',t)_{m+1}$  is the leftmost cell in row t in  $\zeta_{n-1}$  and cells  $(p,t)_m$  for p < r only infect cells in columns r'-1 and below, cell  $(r,s)_m = (r,t)_m$  is the leftmost cell in row t of  $\zeta_n$ .

5.2. Bounds on infection paths. Branching processes with migration—where the population size is increased or decreased by a time-dependent but deterministic quantity at each step—feature prominently in our analysis of layer percolation. It is helpful to allow the population size to decrease below zero, so that migration always shifts the population by a given amount and its expectation can be computed. To accomplish this, we define a signed Galton–Watson process with migration, with the following dynamics: The child distribution is as usual on the nonnegative integers. If the population is nonnegative, each member gives birth to a number of children sampled independently from the child distribution as usual, and then the amount of migration (possibly negative) is added to get the size of the next generation. If the population is negative, then each member gives birth to a number of children sampled independently from the child distribution; the size of this next generation is the negative of the resulting quantity of children, plus the amount of migration. We give the formal definition now.

**Definition 5.3.** We call  $(X_j)_{j\geq 0}$  a signed Galton-Watson process with child distribution L and migration  $(e_j)_{j\geq 1}$  if  $X_{j+1}$  is distributed conditional on  $X_j$  as

$$\operatorname{sgn}(X_j) \sum_{i=1}^{|X_j|} L_i + e_{j+1},$$

where  $L_1, L_2, \ldots$  are independent copies of L. The migration  $e_j$  may be positive or negative. If  $e_j \ge 0$  for all j, we call it an *immigration* process. When the migration counts are all negative, we often call it a signed Galton–Watson process with *emigration*  $(f_j)_{j\ge 1}$  where  $f_j = -e_j \ge 0$ . When the child distribution is Geo(1/2), we call the process a *critical geometric branching process*.

The aim of our first two lemmas is to transfer bounds on the rows of an infection path (i.e., their second coordinates) into bounds on the columns.

**Lemma 5.4.** Let  $s_0^{\min}, \ldots, s_n^{\min}$  and  $r_0$  be nonnegative integers. Define  $r_1, \ldots, r_n$  inductively by setting  $r_i$  to be the minimum value in layer<sub>k+i</sub> $(r_{i-1} + s_{i-1}^{\min})$ . Then

- (a) for any infection path  $(u_0, s_0)_k \to \cdots \to (u_n, s_n)_{k+n}$  satisfying  $u_0 \ge r_0$  and  $s_i \ge s_i^{\min}$ for  $0 \le i \le n$ , we have  $u_i \ge r_i$  for  $1 \le i \le n$ ;
- (b) the random sequence  $r_0 + s_0^{\min}, \ldots, r_n + s_n^{\min}$  is a critical geometric branching process with immigration  $s_i^{\min}$  at step *i* for  $i \ge 1$ .

*Proof.* To prove (a), we proceed inductively, assuming that  $u_i \ge r_i$  and showing that  $u_{i+1} \ge r_{i+1}$ . The column of the leftmost cell infected by  $(u_i, s_i)_{k+i}$  is the minimum value in  $\operatorname{layer}_{k+i+1}(u_i + s_i)$ . Since  $u_i \ge r_i$  and  $s_i \ge s_i^{\min}$ , this column is at least the minimum value of  $\operatorname{layer}_{k+i+1}(r_i + s_i^{\min}) = r_{i+1}$ , proving that  $u_{i+1} \ge r_{i+1}$ .

Fact (b) follows from the dynamics of layer percolation, since the minimum value in  $\operatorname{layer}_{k+i+1}(r_i + s_i^{\min})$  is by definition the sum of  $r_i + s_i^{\min}$  independent random variables with distribution  $\operatorname{Geo}(1/2)$ .

The upper bound is nearly the same, and we omit its proof. The only difference is that  $r_i$  must be set to the *maximum* value in layer<sub>i+k</sub>  $(r_{i-1} + s_{i-1}^{\max})$ , which is equal to the minimum value in layer<sub>i+k</sub>  $(r_{i-1} + s_{i-1}^{\max} + 1)$ 

**Lemma 5.5.** Let  $s_0^{\max}, \ldots, s_n^{\max}$  and  $r_0$  be nonnegative integers. Define  $r_1, \ldots, r_n$  inductively by setting  $r_i$  to be the maximum value in  $\operatorname{layer}_{k+i}(r_{i-1} + s_{i-1}^{\max})$ , or equivalently, the minimum value in  $\operatorname{layer}_{k+i}(r_{i-1} + s_{i-1}^{\max} + 1)$ . Then

- (a) for any infection path  $(u_0, s_0)_k \to \cdots \to (u_n, s_n)_{k+n}$  satisfying  $u_0 \leq r_0$  and  $s_i \leq s_i^{\max}$  for  $0 \leq i \leq n$ , we have  $u_i \leq r_i$  for  $1 \leq i \leq n$ ;
- (b) the random sequence  $r_0 + s_0^{\max} + 1, \ldots, r_n + s_n^{\max} + 1$  is a critical geometric branching process with immigration  $s_i^{\max} + 1$  at step i for  $i \ge 1$ .

Suppose we have a sequence of sets  $\xi_0, \ldots, \xi_n$  where  $\xi_i$  contains cells from step k + i (in typical applications these will be infection sets). We say that a sequence of cells  $(r_0, s_0)_k, \ldots, (r_n, s_n)_{k+n}$  is a *lower-left bound* (resp. *upper-right bound*) for  $\xi_0, \ldots, \xi_n$  if  $r_i \leq r'_i$  and  $s_i \leq s'_i$  (resp.  $r'_i \leq r_i$  and  $s'_i \leq s_i$ ) for all  $(r'_i, s'_i)_{k+i} \in \xi_i$  and all  $0 \leq i \leq n$ . Lemmas 5.4 and 5.5 give easy lower-left and upper-right bounds for a sequence of infection sets. For the lower-left bound, define the *minimal infection path from*  $(r, s)_k$  as the infection path

$$(r_0,s)_k \to (r_1,s)_{k+1} \to \dots$$

that always chooses  $(r_n, s)_{n+k}$  to be the leftmost cell in row s infected by  $(r_{n-1}, s)_{n+k-1}$ . That is, set  $r_0 = r$ , and then inductively define  $r_n$  as the minimum value in layer<sub>n+k</sub> $(r_{n-1}+s)$ . This path is very much analogous to the minimal odometer. Indeed, under the bijection to odometers given in Section 4, it corresponds to picking the first permissible left instruction, exactly as is done when defining the minimal odometer. Hence it corresponds to a minimal odometer started at site k for some initial odometer value at k and net flow from k to k+1.

#### Lemma 5.6.

- (a) If  $u \ge r$  and  $t \ge s$ , then the minimal infection path from  $(r, s)_k$  is a lower-left bound for the infection sets  $\zeta_0^{(u,t)_k}, \zeta_1^{(u,t)_k}, \ldots$
- (b) Let  $(r_0, s)_k \to (r_1, s)_{k+1} \to \cdots$  be the minimal infection path from  $(r, s)_k$ . Then the random sequence  $r_0 + s, r_1 + s, \ldots$  is distributed as a critical geometric branching process with constant immigration s.

*Proof.* Since all infection paths from  $(u, t)_k$  have all cells at or above row s, the lemma follows by applying Lemma 5.4 with  $s_i^{\min} = s$  for all  $i \ge 0$ .

For a generic upper-right bound, we define the *upper-right cell sequence from*  $(r, s)_k$  as the sequence of cells

$$(r_0, s)_k, (r_1, s+1)_{k+1}, (r_2, s+2)_{k+2}, \dots$$

where  $r_0 = r$  and  $r_{n+1}$  is the maximum of layer<sub>n+k+1</sub>  $(r_n + s + n)$  for  $n \ge 0$ . This sequence is not an infection path: while  $(r_n, s_n + n)_{n+k}$  infects  $(r_{n+1}, s + n)_{n+k+1}$ , it is not guaranteed to infect  $(r_{n+1}, s + n + 1)_{n+k}$  unless  $\lambda = \infty$ . One might think to modify the sequence into an infection path by incrementing the row only when this infection occurs, but the resulting infection path is not necessarily an upper-right bound for infection sets.

### Lemma 5.7.

- (a) If  $r \ge u$  and  $s \ge t$ , then the upper-right cell sequence from  $(r, s)_k$  is an upper-right bound for the infection sets  $\zeta_0^{(u,t)_k}, \zeta_1^{(u,t)_k}, \ldots$
- (b) Let  $(r_0, s)_k$ ,  $(r_1, s+1)_{k+1}$ ,  $(r_2, s+2)_{k+2}$ ,... be the upper-right cell sequence from  $(r, s)_k$ . Then the random sequence  $(r_n + s + n + 1)_{n\geq 0}$  is distributed as a critical geometric branching process with immigration  $e_n = s + n + 1$  for  $n \geq 1$ .

*Proof.* Let  $s_n^{\max} = s + n$  for  $n \ge 0$ . Since the row in an infection path can increase by at most one at each step, any infection path starting at  $(u, t)_k$  has its row dominated by  $s_0^{\max}, s_1^{\max}, \ldots$  at each step. Then an application of Lemma 5.5 proves the lemma.

Finally, we give a bound on the minimal odometer. We sneak the proof into this section even though it applies directly to odometers and not to layer percolation because it uses the same idea as all the other bounds of this section.

**Proposition 5.8.** For a given initial configuration  $\sigma$  on  $[\![0,n]\!]$ , initial odometer value  $u_0$  at site 0, and net flow  $f_0$  from site 0 to site 1, let  $\mathfrak{m}$  be the minimal odometer of  $\mathcal{O}_n(\operatorname{Instr}, \sigma, u_0, f_0)$ . Let

$$e_i = -f_0 - \sum_{v=1}^i |\sigma(v)|$$

and suppose that  $|e_i| \leq e_{\max}$  for some  $e_{\max} \geq 1$ . For some constants c, C > 0 depending only on  $\lambda$ , it holds for all  $t \geq 4e_{\max}$  that

(24) 
$$\mathbf{P}\left[\left|\mathcal{R}_{j}(\mathfrak{m}) - \left(\frac{u_{0}}{2(1+\lambda)} + \sum_{i=1}^{j} e_{i}\right)\right| \ge t\right] \le C \exp\left(-\frac{ct^{2}}{n(ne_{\max} + u_{0} + t)}\right)$$

for all  $1 \leq j \leq n$ .

Proof. Let  $Z_j = \mathcal{R}_j(\mathfrak{m}) + e_j$ . First, we claim that  $Z_0, \ldots, Z_n$  is a critical geometric signed branching process with migration  $(e_j)_{j\geq 1}$ . Suppose that  $Z_j$  is positive. By definition of the minimal odometer,  $\mathfrak{m}(j+1)$  is equal to the index of the  $Z_j$ th left instruction at site j+1, and  $\mathcal{R}_{j+1}(\mathfrak{m})$  is equal to the number of right instructions prior to this left instruction. Since the counts of right instructions prior to each left instruction are independent with distribution  $\operatorname{Geo}(1/2)$ , this makes the distribution of  $Z_{j+1}$  given  $Z_j$  equal to the sum of  $Z_j$ independent copies of  $\operatorname{Geo}(1/2)$  plus an additional  $e_{j+1}$ . If  $Z_j = 0$ , then  $\mathfrak{m}(j+1) = 0$  by the definition of the minimal odometer (this is a consequence of our insistence that  $\operatorname{Instr}_{j+1}(0)$ always be equal to left). Thus  $Z_{j+1} = \mathcal{R}_{j+1}(\mathfrak{m}) + e_{j+1} = e_{j+1}$ , again consistent with a signed Galton–Watson process with migration  $e_{j+1}$  at this step. And if  $Z_j < 0$ , then  $\mathfrak{m}(j+1)$ is equal to the index of the  $|Z_j|$ th occurence of left prior to index 0. Then  $\mathcal{R}_{j+1}(\mathfrak{m})$  is equal to the negative of the number of right instructions at indices  $\mathfrak{m}(j+1)+1,\ldots,-1$ , which is distributed as the sum of  $|Z_j|$  copies of  $\operatorname{Geo}(1/2)$ , which again gives  $Z_{j+1}$  the correct distribution given  $Z_j$ .

Let  $\mu_j = Z_0 + \sum_{i=1}^j e_i$ . We can now invoke Proposition A.1 conditional on  $Z_0$  to obtain

$$\mathbf{P}\left[|Z_j - \mu_j| \ge t \mid Z_0\right] \le C \exp\left(-\frac{ct^2}{j(je_{\max} + |Z_0| + t)}\right)$$

Applying the bounds  $|Z_0| \leq u_0 + e_{\max}$  and  $j \leq n$  and taking expectations,

(25) 
$$\mathbf{P}\left[|Z_j - \mu_j| \ge t\right] \le C \exp\left(-\frac{ct^2}{n\left((n+1)e_{\max} + u_0 + t\right)}\right).$$

Now we have

$$P\left[\left|\mathcal{R}_{j}(\mathfrak{m}) - \left(\frac{u_{0}}{2(1+\lambda)} + \sum_{i=1}^{j} e_{i}\right)\right| \geq t\right]$$

$$= \mathbf{P}\left[\left|Z_{j} - \mu_{j} - e_{j} + \mathcal{R}_{0}(\mathfrak{m}) + e_{0} - \frac{u_{0}}{2(1+\lambda)}\right| \geq t\right]$$

$$\leq \mathbf{P}\left[\left|Z_{j} - \mu_{j} - e_{j}\right| \geq \frac{t}{2}\right] + \mathbf{P}\left[\left|\mathcal{R}_{0}(\mathfrak{m}) + e_{0} - \frac{u_{0}}{2(1+\lambda)}\right| \geq \frac{t}{2}\right]$$

$$\leq \mathbf{P}\left[\left|Z_{j} - \mu_{j}\right| \geq \frac{t}{4}\right] + \mathbf{P}\left[\left|\mathcal{R}_{0}(\mathfrak{m}) - \frac{u_{0}}{2(1+\lambda)}\right| \geq \frac{t}{4}\right].$$

We use  $t \ge 4e_{\text{max}}$  to arrive at the final inequality above. We then bound the first summand with (25) with t/4 substituted for t. And by Hoeffding's inequality, we bound the second by  $2e^{-t^2/8u_0}$ . Combining the two bounds with modified constants proves (24).

Typically  $e_{\max} = n$  and  $u_0 \leq c' n^2$  for some constant c', in which case the previous proposition yields

$$\mathbf{P}\left[\left|\mathcal{R}_{j}(\mathfrak{m}) - \left(\frac{u_{0}}{2(1+\lambda)} + \sum_{i=1}^{j} e_{i}\right)\right| \ge tn^{3/2}\right] \le C \exp\left(-\frac{ct^{2}}{1+c'+t/\sqrt{n}}\right),$$

which shows that  $\mathcal{R}_i(\mathfrak{m})$  has fluctuations on the order of  $n^{3/2}$ .

5.3. Shifts and reversals. How does the distribution of the infection set  $\zeta_n^{(r,s)_0}$  depend on the cell  $(r, s)_0$ ? And how do backward infection sets relate to forward ones? In both cases, we can connect the different infection sets to each other by a coupling

To address the first question, the lower-left cell of  $\zeta_n^{(r,s)_0}$  lies on the minimal infection path starting from  $(r, s)_0$ . But in fact this is the only dependence: all infection sets  $\zeta_n^{(r,s)_0}$ have the same distribution once we shift the column by the minimal infection path. We prove this by constructing a coupling between  $\zeta_n^{(r,s)_0}$  and  $\zeta_n^{(0,0)_0}$ . When we work with two different instances of layer percolation, we use the symbol  $\rightarrow$  to denote infection as usual in the first instance and use  $\rightarrow$  to denote infection in the second.

**Proposition 5.9.** Let  $\zeta_n^{(0,0)_0}$  as usual denote the infection set from  $(0,0)_0$  in layer percolation with parameter  $\lambda > 0$ , and let  $\widetilde{\zeta}_n^{(r,s)_0}$  denote the infection set from  $(r,s)_0$  in a second instance of layer percolation. Let

(26) 
$$(r,s)_0 = (r_0,s)_0 \twoheadrightarrow (r_1,s)_1 \twoheadrightarrow (r_2,s)_2 \to \cdots$$

be the minimal infection path starting from  $(r, s)_0$  in the second layer percolation. There exists a coupling of the two instances such that (26) is independent of the first layer percolation and

(27) 
$$\widetilde{\zeta}_n^{(r,s)_0} = \left\{ (r'+r_n, s'+s)_n \colon (r',s')_n \in \zeta_n^{(0,0)_0} \right\}$$

for all n > 0.

*Proof.* Observe that  $\tilde{\zeta}_0^{(r,s)_0} = \{(r,s)_0\}$  and  $\zeta_0^{(0,0)_0} = \{(0,0)_0\}$ , consistent with (27) for n = 0. Proceeding inductively, we suppose we have a coupling such that (27) holds for n, and we extend the coupling to step n+1. We write  $(a,b)_n \to (a',b')_{n+1}$  to denote infection in the first layer percolation and  $(a, b)_n \twoheadrightarrow (a', b')_{n+1}$  to denote infection in the second.

Let  $R_0, R_1, \ldots$  and  $B^0, B^1, \ldots$  be the random variables from Section 3.2 used to define the infections in the first layer percolation from step n to step n+1 (see Remark 3.1). To form the analogous random variables  $\overline{R}_0, \overline{R}_1, \ldots$  and  $\overline{B}^0, \overline{B}^1, \ldots$  for the second layer of percolation, we just insert new independent random variables to the beginning of  $R_0, R_1, \ldots$  and  $B^0, B^1, \ldots$ More specifically, for  $i < r_n + s$  we let  $\overline{R}_i$  be a random variable independent of all else with distribution  $\operatorname{Geo}(1/2)$  and we let  $\overline{B}^i = (\overline{B}^i_0, \ldots, \overline{B}^i_{\overline{R}_i})$  be independent with common distribution Bernoulli $(\lambda/(1+\lambda))$ . For  $i \ge r_n + s$ , let  $\overline{R}_i = R_{i-r_n-s}$  and  $\overline{B}^i = B^{i-r_n-s}$ .

Now, we claim that

(28) 
$$(r',s')_n \to (r'',s'')_{n+1} \iff (r'+r_n,s'+s)_n \twoheadrightarrow (r''+r_{n+1},s''+s)_{n+1}.$$

Indeed, we have

$$r_{n+1} = \overline{R}_0 + \dots + \overline{R}_{r_n+s-1},$$

since  $r_{n+1}$  is the first column in layer  $r_n + s$  at step n+1 in the second layer percolation. Thus layer  $r' + s' + r_n + s$  in the second layer percolation is equal to layer r' + s' in the first layer percolation shifted by  $r_{n+1}$ . Since  $\overline{B}^{r'+s'+r_n+s} = B^{r_n+s}$ , the cell  $(r', s')_n$  in the first layer percolation infects the same cells as  $(r' + r_n, s' + s)_n$ , shifted to the right by  $r_{n+1}$  and upward by s, confirming (28).

Combining (27) with (28) shows that (27) holds with n replaced by n+1, thus extending the induction. 

Combining Lemma 5.6(b) with the previous proposition yields
**Corollary 5.10.** Fix a cell  $(r, s)_0$  and let  $(Z_n)_{n\geq 0}$  be a critical geometric branching process with constant immigration s starting from  $Z_0 = r+s$ , independent of layer percolation. Then

$$\zeta_n^{(r,s)} \stackrel{d}{=} \{ (r' - s + Z_n, s' + s)_n \colon (r', s')_n \in \zeta_n^{(0,0)_0} \}.$$

Next, we describe the backward infection set  $\zeta_n^{(u,t)_m}$  as a transformed version of the forward infection set  $\zeta_n^{(0,0)_0}$ . The coupling connecting these two infection sets can hold only for a finite time, unlike the coupling in Proposition 5.9, since for a fixed u and t, the set  $\zeta_n^{(u,t)_m}$  will be empty for sufficiently large n.

The key idea for the coupling making one layer percolation the reverse of another is to swap left and right instructions. Using the material of Section 4 to interpret the two coupled instances of layer percolation in terms of odometers, the original instance represents odometers stable on the interior of an interval with a fixed initial value  $u_0$  and left-to-right net flow  $f_0$  on the left endpoint, while the second represents odometers with fixed initial value and right-to-left net flow on the right endpoint.

**Coupling 5.11.** Fix  $u, t, m \ge 0$ . Consider layer percolation together with an independent signed critical geometric branching process  $(Z_k)_{k\ge 0}$  with emigration t at each step and  $Z_0 = u$ . We couple these processes with another instance of layer percolation, with infections from step n to step n+1 in the first layer percolation coupled with those from step m-n-1 to step m-n in the second, for all  $0 \le n < m$ .

Suppose we have constructed the coupling up to step n in the first layer percolation and step m - n - 1 in the second. Now we construct the coupling for the next step. If  $Z_n < 0$ , then we just allow the two layer percolations and the branching process  $Z_{n+1}$  to evolve independently When  $Z_n \ge 0$ , we construct the coupling as follows. Start with the reduced instructions  $a_1, a_2, \ldots$  and  $b_1, b_2, \ldots$  corresponding to step n + 1 of the first layer percolation (see Definition 4.8). To make reduced instructions corresponding to step m-n for the second layer percolation, prepend random instructions left or right with equal probability one at a time to the left of the list starting with  $a_1, a_2, \ldots$  until  $Z_n$  left instructions have been added. (If  $Z_n = 0$ , then no instructions are added.) Let A be the number of added instructions. Note that our new list always starts with a left instruction, since we stop prepending instructions followed by  $a_1, a_2, \ldots$ , and for all but the first instruction change left instructions to right instructions and vice versa to produce our new list  $a'_1, a'_2, \ldots$ . From the construction it is evident that  $a'_1 = \text{left}$  and that  $a'_2, a'_3, \ldots$  consists of independent uniformly random instructions left and right.

Define  $Z_{n+1}$  as the number of left instructions contained in  $a'_2, \ldots, a'_A$  minus t. Since the A instructions added to the beginning of  $a_1, a_2, \ldots$  were independent of  $a_1, a_2, \ldots$ , the value of  $Z_{n+1}$  is independent of  $a_1, a_2, \ldots$  as desired. And since the number of left instructions contained in  $a'_2, \ldots, a'_A$  was the number of added right instructions prior to the left-right swap before the  $Z_n$ th left instruction, the value of  $Z_{n+1}$  is the next step in a branching process distributed as desired.

Finally, we define  $b'_1, b'_2, \ldots$  by prepending A random Bernoulli $(\lambda/(1 + \lambda))$  random variables to the left of  $b_1, b_2, \ldots$  Now define step m - n of the second layer percolation from  $a'_1, a'_2, \ldots$  and  $b'_1, b'_2, \ldots$  (see Lemma 4.9). This creates a valid coupling of the two layer percolations and  $(Z_j)_{j=0}^{n+1}$ .

**Proposition 5.12.** Consider Coupling 5.11 for given  $u, t, m \ge 0$ . Let  $\zeta_n = \zeta_n^{(0,0)_0}$  denote the infection set for the first layer percolation and  $\zeta_n = \zeta_n^{(u,t)_m}$  the backward infection set

for the second layer percolation. For all  $0 \le n \le m$ ,

(29) if 
$$Z_n \ge 0$$
, then  $\overline{\zeta}_n = \{ (Z_n + r + s, t - s)_{m-n} : (r, s)_n \in \zeta_n, s \le t \}.$ 

*Proof.* Let  $\rightarrow$  indicate infection in the first layer percolation and  $\rightarrow$  in the second. We claim that the following statement holds for all  $0 \le n < m$ : if  $Z_{n+1} \ge 0$ , then for all  $r, r' \ge 0$  and  $0 \le s, s' \le t$ ,

$$(30) (r,s)_n \to (r',s')_{n+1}$$

if and only if

(31) 
$$(Z_{n+1} + r' + s', t - s')_{m-n-1} \twoheadrightarrow (Z_n + r + s, t - s)_{m-n}.$$

Indeed, suppose that (30) holds. Let

$$\Psi$$
: Infections<sub>n+1</sub>  $\rightarrow$  Positions<sub>n+1</sub> and  $\Psi'$ : Infections'<sub>m-n</sub>  $\rightarrow$  Positions'<sub>m-n</sub>

be the maps from infections to reduced instruction locations defined in Lemma 4.12, based on the first layer percolation for  $\Psi$  and the second for  $\Psi'$ . Let  $(a_j)_{j\geq 1}$ ,  $(b_j)_{j\geq 1}$  and  $(a'_j)_{j\geq 1}$ ,  $(b'_j)_{j\geq 1}$ be the reduced instructions corresponding to the coupled steps of the two layer percolations, as in Coupling 5.11. Let  $(i, z) = \Psi((r, s, r', s'))$ . By definition of  $\Psi$ , there are r + s + 1 left instructions and r' right instructions in  $a_1, \ldots, a_i$ , and z = s' - s.

Now consider location (A + i, z), which is a valid location in  $\mathsf{Positions}'_{m-n}$  since  $z \leq b_i = b'_{A+i}$ . We claim that there are  $Z_{n+1} + r' + t + 1$  left instructions and  $Z_n + r + s$  right instructions in  $a'_1, \ldots, a'_{A+i}$ . First, we dispense with the special case A = 0, which by our assumption  $Z_{n+1} \geq 0$  can happen only when  $t = Z_n = 0$ . In this case we also have  $Z_{n+1} = 0$ . The instructions  $a'_1, \ldots, a'_{A+i}$  are obtained by swapping  $a_1, \ldots, a_i$  except for the first instruction, giving us r' + 1 left instructions and r + s right instructions.

When A > 0, we break the computation into four pieces, the number of left and right instructions in each of  $a'_1, \ldots, a'_A$  and  $a'_{A+1}, \ldots, a'_{A+i}$ :

- (i)  $1 + Z_{n+1} + t$  left instructions in  $a'_1, \ldots, a'_A$ By definition of  $Z_{n+1}$ , there are  $Z_{n+1} + t$  left instructions in  $a'_2, \ldots, a'_A$ . And also  $a'_1 =$  left.
- (ii) r' left instructions in  $a'_{A+1}, \ldots, a'_{A+i}$ This comes from the number of right instructions in  $a_1, \ldots, a_i$ .
- (iii)  $Z_n 1$  right instructions in  $a'_1, \ldots, a'_A$ We constructed  $a'_1, \ldots, a'_A$  by adding random instructions until we obtained  $Z_n$  left instructions and then swapping all but one of them to be right instructions.

(iv) 
$$r + s + 1$$
 right instructions in  $a'_{A+1}, \ldots, a'_{A+1}$ 

This is the number of left instructions in  $a_1, \ldots, a_i$ .

This completes the proof that there are  $Z_{n+1} + r' + t + 1$  left and  $Z_n + r + s$  right instructions in  $a'_1, \ldots, a'_{A+i}$ .

By Lemma 4.12(c),

$$(Z_{n+1} + r' + s', t - s', Z_n + r + s, t - s) \in \Psi'^{-1}(A + i, z).$$

Thus we have shown that (31) holds.

In the other direction, suppose that (31) holds and let

$$(j,z) = \Psi' \big( (Z_{n+1} + r' + s', t - s', Z_n + r + s, t - s) \big).$$

Thus  $a'_1, \ldots, a'_j$  contains  $Z_{n+1}+r'+t+1$  left instructions and  $Z_n+r+s$  right instructions. Let i = j - A. We claim that there are r+s+1 left instructions and r' right instructions in  $a_1, \ldots, a_i$ .

If A = 0, then as before  $t = Z_n = Z_{n+1} = 0$ . The instructions  $a'_2, \ldots, a'_j$  are swapped versions of  $a_2, \ldots, a_i$  while  $a_1 = a'_1 = \texttt{left}$ , giving us r + s + 1 left instructions and r' right instructions in  $a_1, \ldots, a_i$ . If A > 0, then we subtract off the number of left and right instructions in  $a'_1, \ldots, a'_A$  (see (i) and (iii)) from the number in  $a'_1, \ldots, a'_j$  to find that there are  $Z_{n+1} + r' + t + 1 - (1 + Z_{n+1} + t) = r'$  left and  $Z_n + r + s - (Z_n - 1) = r + s + 1$  right instructions in  $a'_{A+1} + \cdots + a'_j$ . The instructions  $a_1, \ldots, a_i$  are these instructions swapped, proving the claim.

Now we have shown that there are r + s + 1 left instructions and r' right instructions in  $a_1, \ldots, a_i$ . Also, since  $b_i = b'_j$  and  $z \le b'_j$ , we have  $z \le b_i$  which shows (i, z) is a valid position in the image of  $\Psi$ . By Lemma 4.12(c),

$$(r, s, r', s') \in \Psi^{-1}(i, z),$$

proving that (30) holds.

Now that the equivalence of (30) and (31) is shown, we prove (29). We proceed by induction. The statement holds for n = 0. Now suppose it holds for n, and we will extend it to n + 1. If  $Z_{n+1} < 0$ , there is nothing to prove. If  $Z_{n+1} \ge 0$ , then  $Z_n \ge 0$  as well by the dynamics of signed branching processes with emigration, and thus

(32) 
$$\tilde{\zeta}_n = \{ (Z_n + r + s, t - s)_{m-n} \colon (r, s)_n \in \zeta_n, s \le t \}$$

by the inductive hypothesis. Let  $(r', s')_{n+1} \in \zeta_{n+1}$ . Then there exists some  $(r, s)_n \in \zeta_n$  such that  $(r, s)_n \to (r', s')_{n+1}$ . We have  $(Z_n + r + s, t - s)_{m-n} \in \zeta_n$  by (32), and  $(Z_{n+1} + r' + s', t - s')_{m-n-1} \in \zeta_{n+1}$  by (31). Thus

$$\left\{ (Z_{n+1} + r' + s', t - s')_{m-n-1} \colon (r', s')_{n+1} \in \zeta_{n+1}, \, s' \le t \right\} \subseteq \overleftarrow{\zeta}_{n+1}$$

Conversely, consider a cell  $(v, w)_{m-n-1} \in \overline{\zeta}_{n+1}$ . Then  $(v, w)_{m-n-1} \twoheadrightarrow (v', w')_{m-n}$  for some cell  $(v', w')_{m-n} \in \overline{\zeta}_n$ . We claim that

$$(33) v \ge Z_{n+1} + t - w$$

Claim (35) holds because all cells in  $\zeta_i$  are in row t or below for all i. Claim(34) holds because by (32), we have  $v' + w' = Z_n + r + t$  for some  $r \ge 0$ . For (33), let  $(i, z) = \Psi'(v, w, v', w')$ . The smallest j such that  $a'_1, \ldots, a'_j$  contains  $Z_n$  right instructions is j = A + 1 (see (iii) and observe that  $a'_{A+1} =$ right except when A = 0, in which case  $Z_n = 0$ ). Since the number of right instructions in  $a'_1, \ldots, a'_i$  is v' by definition of  $\Psi'$  and  $v' \ge Z_n + t - w' \ge Z_n$ , we have  $i \ge A + 1$ . There are thus at least  $1 + Z_{n+1} + t$  left instructions in  $a'_1, \ldots, a'_i$  by (i), and by definition of  $\Psi'$  we have  $v + w + 1 \ge 1 + Z_{n+1} + t$ , which rearranges to show that  $v \ge Z_{n+1} + t - w$ .

Let s' = t - w,  $r' = v - Z_{n+1} - s'$ , s = t - w', and  $r = v' - Z_n - s$ . By inequalities (33)-(35), all are nonnegative. Now  $(v, w)_{m-n-1} = (Z_{n+1} + r' + s', t - s')_{m-n-1}$  and  $(v', w')_{m-n} = (Z_n + r + s, t - s)_{m-n}$ . Since  $(v, w)_{m-n-1} \twoheadrightarrow (v', w')_{m-n}$ , we have  $(r', s')_{n+1} \in \zeta_{n+1}$  by (30). Thus

$$\dot{\zeta}_{n+1} \subseteq \left\{ (Z_{n+1} + r' + s', t - s')_{m-n-1} : (r', s')_{n+1} \in \zeta_{n+1}, s' \le t \right\}.$$

This extends the inductive hypothesis from n to n + 1 and completes the proof.

We mention that we could have used Proposition 5.12 to prove Proposition 5.2 from Proposition 5.1, but then the statement would only hold until the coupling breaks down when  $Z_n < 0$ .

5.4. Greedy infection paths. In the correspondence between odometers and infection paths, the number of sleeping particles left by the odometer is equal to the ending row of the infection path. Since the true odometer leaves the most particles sleeping of any stable odometer by Lemma 2.5, infection paths that reach high rows will play a special role for us. A simple way to get infection paths reaching rows close to the highest possible is to construct them greedily, k steps at a time. We fix a large integer k and choose an infection path of length k from a starting cell that reaches the highest row possible, then from there we choose an infection path of length k reaching the highest row possible, and so on:

**Definition 5.13.** The k-greedy infection path is a sequence of cells  $(r_0, s_0)_0$ ,  $(r_1, s_1)_1$ ,... defined by the following inductive procedure: From a given starting point  $(r_0, s_0)_0$ , which we take to be  $(0, 0)_0$  unless otherwise mentioned, choose some cell  $(r_k, s_k)_k \in \zeta_k^{(r_0, s_0)_0}$  with  $s_k$ maximal, and let  $(r_0, s_0)_0 \to \cdots \to (r_k, s_k)_k$  be any infection path leading to  $(r_k, s_k)_k$ . Then choose  $(r_{2k}, s_{2k})_{2k}$  from  $\zeta_k^{(r_k, s_k)_k}$  with  $s_{2k}$  maximal, and take  $(r_k, s_k)_k \to \cdots \to (r_{2k}, s_{2k})_{2k}$ to be any infection path from  $(r_k, s_k)_k$  to  $(r_{2k}, s_{2k})_{2k}$ , and so on. The choice of  $(r_{jk}, s_{jk})_{jk}$ in each step of the process and the choice of infection path  $(r_{(j-1)k}, s_{(j-1)k})_{(j-1)k} \to \cdots \to (r_{jk}, s_{jk})_{jk}$  is not important to us, so long as it only depends on information up to step jkof layer percolation.

Because it will be useful later to have a specific procedure for choosing the k-greedy infection path, let us specify that given  $(r_{(j-1)k}, s_{(j-1)k})_{(j-1)k}$ , we take  $(r_{jk}, s_{jk})_{jk}$  to be the rightmost cell in the maximal row of  $\zeta_k^{(r_{(j-1)k}, s_{(j-1)k})_{(j-1)k}}$ . Then, out of all infection paths from  $(r_{(j-1)k}, s_{(j-1)k})_{(j-1)k}$  to  $(r_{jk}, s_{jk})_{jk}$ , select  $(r_{jk-1}, s_{jk-1})_{jk-1}$  by first maximizing  $s_{jk-1}$  and then  $r_{jk-1}$ . Then out of all infection paths from  $(r_{(j-1)k}, s_{(j-1)k})_{(j-1)k}$  to  $(r_{jk-1}, s_{jk-1})_{jk-1}$ , select  $(r_{jk-2}, s_{jk-2})_{jk-2}$  by first maximizing  $s_{jk-2}$  and then  $r_{jk-2}$ , and so on.

For the k-greedy path, the row reached at step jk is the sum of j i.i.d. random variables and is hence easy to analyze. Its growth rate is the following constant  $\rho_*^{(k)}$ :

**Definition 5.14.** Let  $X_k = \max\{s: (r, s)_k \in \zeta_k^{(0,0)_0}\}$  be the highest row contained in the infection set at step k of layer percolation with sleep rate  $\lambda > 0$ . Then define

$$\rho_*^{(k)} = \frac{1}{k} \mathbf{E} X_k$$

Note that  $0 \le \rho_*^{(k)} \le 1$ , since  $0 \le X_k \le k$  for all k.

In this section, we seek estimates on the *n*th cell  $(r_n, s_n)_n$  of the *k*-greedy infection path. We take  $r_0 = s_0 = 0$ , since for other starting points we can simply shift the path using Proposition 5.9. As we mentioned,  $s_n \approx \rho_*^{(k)} n$ . We will also show that

(37) 
$$r_n \approx \rho_*^{(k)} n^2 / 2.$$

We can heuristically derive the asymptotics for  $r_n$  by estimating  $r_{(j+1)k} - r_{jk}$  using Lemmas 5.6 and 5.7. The sequence  $r_{jk}, \ldots, r_{(j+1)k}$  lies between critical Galton–Watson processes with immigration  $s_{jk}$  and with immigration  $s_{jk} + k$ . Thus  $r_{(j+1)k} - r_{jk} \approx s_{jk}k \approx jk^2 \rho_*^{(k)}$ .

We are neglecting the difference of k between the upper and lower bounds because k will be held fixed while j is taken to infinity, and thus it will be negligible. Summing these increments, we have  $r_{jk} \approx \frac{1}{2}j^2k^2\rho_*^{(k)}$ . Since k will be O(1), this statement will also hold for  $r_n$  when n lies between between jk and (j+1)k, explaining (37).

The complication in making this heuristic exact is that the sequences  $s_k, s_{2k}, \ldots$  and  $r_k, r_{2k}, \ldots$  are dependent, and we cannot condition on the first sequence and then apply the heuristic analysis. Instead, we do the proof in two steps. First, we choose deterministic sequences  $s_1^{\min}, s_2^{\min}, \ldots$  and  $s_1^{\max}, s_2^{\max}, \ldots$  with  $s_j^{\min} = j\rho_*^{(k)} - O(\sqrt{n})$  and  $s_j^{\max} = j\rho_*^{(k)} + O(\sqrt{n})$ . A classical estimate ensures that  $s_j^{\min} \leq s_j \leq s_j^{\max}$  holds for all  $1 \leq j \leq n$  with high probability. Second, we apply Lemmas 5.4 and 5.5 to obtain (random) sequences that almost surely bound the columns of all infection paths  $(r'_0, s'_0)_0 \to \cdots \to (r'_n, s'_n)_n$  for which  $s'_1, \ldots, s'_n$  lies between the bounding sequences  $s_1^{\min}, \ldots, s_n^{\min}$  and  $s_1^{\max}, \ldots, s_n^{\max}$ . We then complete the proof by bounding the deviations of our stochastic upper and lower bounds using branching processes.

We start by constructing our bounding sequences.

**Lemma 5.15.** For fixed t > 0 and positive integers k and n, define  $s_0^{\min}, \ldots, s_n^{\min}$  by

$$s_{jk+i}^{\min} = \max\left(0, \lfloor \rho_*^{(k)} jk - \frac{t}{2}\sqrt{n} \rfloor\right) \text{ for integers } 0 \le j \le n/k,$$
  
$$s_{jk+i}^{\min} = s_{jk}^{\min} \text{ for integers } 0 \le j \le n/k \text{ and } 1 \le i < k.$$

Define  $s_0^{\max}, \ldots, s_n^{\max}$  by

$$s_{jk}^{\max} = \lceil \rho_*^{(k)} jk + \frac{t}{2}\sqrt{n} \rceil \text{ for integers } 0 \le j < n/k + 1$$
$$s_{ik-i}^{\max} = s_{ik}^{\max} \text{ for integers } 1 \le j < n/k + 1 \text{ and } 1 \le i < k$$

Then for the k-greedy infection path  $(0,0)_0 \rightarrow (r_1,s_1)_1 \rightarrow (r_2,s_2)_2 \rightarrow \cdots$ ,

$$\mathbf{P}\left[s_i^{\min} \le s_i \le s_i^{\max} \text{ for all } 0 \le i \le n\right] \ge 1 - 2e^{-t^2/3k}$$

*Proof.* Let  $\mathscr{F}_i$  be the  $\sigma$ -algebra generated by layer percolation up to step i. The random variable  $s_{(j+1)k} - s_{jk}$  is independent of  $\mathscr{F}_{jk}$  by Proposition 5.9. Thus the random variables  $s_{(j+1)k} - s_{jk}$  for  $j = 0, 1, \ldots$  are i.i.d. with mean  $\rho_*^{(k)}k$  and maximum value k. Let n' be the smallest multiple of k greater than or equal to n. By the maximal version of Hoeffding's inequality [Roc24, Theorem 3.2.1], for any  $t \ge 0$ 

$$\mathbf{P}\left[\max_{0 \le j \le n'/k} |s_{jk} - \rho_*^{(k)} jk| \ge \frac{t}{2}\sqrt{n}\right] \le 2\exp\left(-\frac{t^2 n}{2n'k}\right) \le 2e^{-t^2/3k}.$$

If  $s_i < s_i^{\min}$ , then with i' the largest multiple of k less than or equal to i, we have  $s_{i'} \leq s_i < s_i^{\min} = s_{i'}^{\min}$ . And if  $s_i > s_i^{\max}$ , then with i' the smallest multiple of k greater than or equal to i, we have  $s_{i'} \geq s_i > s_i^{\max} = s_{i'}^{\max}$ . Hence the probability that  $s_i$  lies outside of  $[s_i^{\min}, s_i^{\max}]$  for some  $0 \leq i \leq n$  is bounded by the probability that  $s_{i'}$  lies outside of  $[s_{i''}^{\min}, s_i^{\max}]$  for some  $i' \in \{0, k, 2k, \ldots, n'\}$ , completing the proof.

**Proposition 5.16.** Let  $(0,0)_0 = (u_0, s_0)_0 \rightarrow (u_1, s_1)_1 \rightarrow \cdots$  be the k-greedy infection path. There exist constants C, c depending only on  $\lambda$  and k such that for all n and all  $t \geq 5$ ,

(38) 
$$\mathbf{P}\left[\left|u_n - \frac{\rho_*^{(k)} n^2}{2}\right| \ge t n^{3/2}\right] \le C \exp\left(-\frac{ct^2}{1 + \frac{t}{\sqrt{n}}}\right),$$

and

(39) 
$$\mathbf{P}\left[\left|s_{n}-\rho_{*}^{(k)}n\right| \geq t\sqrt{n}\right] \leq 2e^{-ct^{2}}$$

*Proof.* For the bound on  $s_n$ , first let n' be the greatest multiple of k less than or equal to n. Since  $s_{n'}$  differs from  $s_n$  and  $\rho_*^{(k)}n'$  differs from  $\rho_*^{(k)}n$  by at most k,

$$\mathbf{P}\left[|s_n - \rho_*^{(k)}n| \ge t\sqrt{n}\right] \le \mathbf{P}\left[|s_{n'} - \rho_*^{(k)}n'| \ge t\sqrt{n} - 2k\right]$$

As in the proof of Lemma 5.15, the random variable  $s_{n'}$  is the sum of n'/k independent random variables with mean  $\rho_*^{(k)}k$  and upper bound k. By Hoeffding's inequality,

$$\mathbf{P}\Big[|s_{n'} - \rho_*^{(k)}n'| \ge t\sqrt{n} - 2k\Big] \le 2\exp\left(-\frac{2(t\sqrt{n} - 2k)^2}{n'k}\right) \le 2e^{-c_1t^2}$$

for a constant  $c_1$  depending on k and  $\lambda$ .

Next we turn to the tail bounds on  $u_n$ . Fix t > 0 and let  $s_0^{\min}, \ldots, s_n^{\min}$  and  $s_0^{\max}, \ldots, s_n^{\max}$  be as in Lemma 5.15. We start with the lower tail bound on  $u_n$ . Apply Lemma 5.4 with  $s_0^{\min}, \ldots, s_n^{\min}$  as we have defined it and with  $r_0 = u_0 = 0$  to generate a lower-bounding infection path  $(r_0, s_0)_0 \to \cdots \to (r_n, s_n)_n$ . First, we give lower bounds on  $r_n$ . Let  $X_i = r_i + s_i^{\min}$ . Since  $X_0, \ldots, X_n$  is a critical geometric branching process with immigration  $s_i^{\min}$  at step i, we have

$$\mathbf{E}X_n = r_0 + s_0^{\min} + \sum_{i=1}^n s_i^{\min} \ge \sum_{j=0}^{\lfloor n/k \rfloor} (\rho_*^{(k)} jk - \frac{t}{2}\sqrt{n} - 1)k$$
$$\ge \rho_*^{(k)} \frac{1}{2} (n/k)^2 k^2 - (\frac{t}{2}\sqrt{n} + 1)(n/k + 1)k$$
$$= \frac{\rho_*^{(k)} n^2}{2} - \frac{t}{2} (n^{3/2} + O_k(n)).$$

Here we use the notation  $O_k(f(n))$  to denote an expression bounded by a constant times f(n) for all  $n \ge 1$ , with the constant permitted to depend on k. Preparing to apply Proposition A.1, we rewrite the deviations of  $r_n$  in terms of the the deviations of  $X_n$ :

$$\mathbf{P}\left[r_n - \frac{\rho_*^{(k)}n^2}{2} \le -tn^{3/2}\right] = \mathbf{P}\left[X_n - \mathbf{E}X_n \le -tn^{3/2} + s_n^{\min} + \frac{t}{2}\left(n^{3/2} + O_k(n)\right)\right]$$
$$\le \mathbf{P}\left[X_n - \mathbf{E}X_n \le -\frac{t}{2}\left(n^{3/2} - O_k(n)\right)\right].$$

Here we have incorporated  $s_n^{\min}$  into the  $\frac{t}{2}O_k(n)$ , since  $s_n^{\min} \leq n$  and t is bounded away from 0. Now we apply Proposition A.1 to obtain

(40) 
$$\mathbf{P}\left[r_n - \frac{\rho_*^{(k)}n^2}{2} \le -tn^{3/2}\right] \le C_2 \exp\left(-\frac{c_2 t^2 n^3}{n(n^2 + tn^{3/2})}\right) = C_2 \exp\left(-\frac{c_2 t^2}{1 + \frac{t}{\sqrt{n}}}\right)$$

for some constants  $c_2 = c_2(k)$  and  $C_2 = C_2(k)$ .

By Lemma 5.4, we have  $u_n \ge r_n$  so long as  $u_i \ge s_i^{\min}$  for  $0 \le i \le n$ . Thus,

$$\mathbf{P}\left[u_{n} - \frac{\rho_{*}^{(k)}n^{2}}{2} \le -tn^{3/2}\right] \le \mathbf{P}\left[r_{n} - \frac{\rho_{*}^{(k)}n^{2}}{2} \le -tn^{3/2}\right] + \mathbf{P}\left[u_{i} < s_{i}^{\min} \text{ for some } 0 \le i \le n\right]$$
$$\le C_{3} \exp\left(-\frac{c_{3}t^{2}}{1 + \frac{t}{\sqrt{n}}}\right)$$

42

for altered  $c_3 = c_3(k)$  and  $C_3 = C_3(k)$ , applying (40) and Lemma 5.15. The upper tail bound on  $u_n$  is obtained by a nearly identical argument using Lemma 5.5 and  $s_0^{\max}, \ldots, s_n^{\max}$  in place of Lemma 5.4 and  $s_0^{\min}, \ldots, s_n^{\min}$ .

In Section 6, we will consider the k-greedy infection path capped at row s, defined as following the k-greedy infection path until it reaches row s and then following the minimal infection path started at that point.

**Proposition 5.17.** Let  $(0,0)_0 = (u'_0,s'_0)_0 \to (u'_1,s'_1)_1 \to \cdots$  be a k-greedy infection path capped at row s starting from  $(0,0)_0$ . Assume that  $s/m \le \rho_*^{(k)} - \epsilon$  for some  $\epsilon > 0$ . Then

(41) 
$$\mathbf{P}\left[\left|u'_{m}-\left(m-\frac{s}{2\rho_{*}^{(k)}}\right)s\right| \ge tm^{3/2}\right] \le C\exp\left(-\frac{ct^{2}}{1+\frac{t}{\sqrt{m}}}\right),$$

and

(42) 
$$\mathbf{P}[s'_m \neq s] \le e^{-cm},$$

where c and C are constants depending only on k,  $\lambda$ , and  $\epsilon$ .

*Proof.* If  $s'_m \neq s$ , then the greedy infection path failed to reach s by step m. This event occurs with probability bounded by  $\mathbf{P}[s_m - \rho_*^{(k)}m < -\epsilon m]$ , which by Proposition 5.16 occurs with exponentially vanishing probability, with the rates depending on k,  $\lambda$ , and  $\epsilon$ , thus proving (42)

Echoing Lemma 5.15, let

$$\tilde{s}_{jk}^{\min} = \max\left(0, \lfloor\min(\rho_*^{(k)}jk, s) - \frac{t}{2}\sqrt{m}\rfloor\right) \text{ for integers } 0 \le j \le m/k,$$
$$\tilde{s}_{jk+i}^{\min} = s_{jk}^{\min} \text{ for integers } 0 \le j \le m/k \text{ and } 1 \le i < k.$$

Now, following the proof of Proposition 5.16 using  $\tilde{s}_1^{\min}, \ldots, \tilde{s}_n^{\min}$  in place of  $s_1^{\min}, \ldots, s_n^{\min}$ , we apply Lemma 5.4 with this capped lower bound and with  $r_0 = u_0 = 0$  to generate a lower-bounding infection path  $(r_0, s_0)_0 \to \cdots \to (r_m, s_m)_m$ . Let  $X_i = r_i + \tilde{s}_i^{\min}$ . Just as in Proposition 5.16 but with a slightly different calculation, setting  $\rho = s/m$ 

$$\mathbf{E}X_{m} = r_{0} + \tilde{s}_{0}^{\min} + \sum_{i=1}^{m} \tilde{s}_{i}^{\min} \geq \sum_{j: jk \leq \rho m/\rho_{*}^{(k)}} (\rho_{*}^{(k)}jk - \frac{t}{2}\sqrt{m} - 1)k + \sum_{j: \rho m/\rho_{*}^{(k)} \leq jk \leq m} (s - \frac{t}{2}\sqrt{m} - 1)k \\ \geq \left(1 - \frac{\rho}{2\rho_{*}^{(k)}}\right)\rho m^{2} - \frac{t}{2}(m^{3/2} + O_{k}(m)),$$

where  $O_k(f(m))$  denotes an expression bounded by a constant times f(m) for all  $m \ge 1$  with the constant permitted to depend on k. Now we can prove (41) by the same argument as in Proposition 5.16 of applying Proposition A.1 and Lemma 5.15. And the upper bound follows similarly.

5.5. The critical density. We now are ready to define the critical density  $\rho_* = \rho_*(\lambda)$  for layer percolation. Recall from Definition 5.14 that  $X_n$  is the highest row infected at step n starting at 0 and  $\rho_*^{(n)}$  is defined as  $\mathbf{E}X_n/n$ . We define

$$\rho_* = \limsup_{n \to \infty} \rho_*^{(n)} = \limsup_{n \to \infty} \frac{1}{n} \mathbf{E} X_n.$$

It follows from  $0 \le \rho_*^{(n)} \le 1$  that  $0 \le \rho_* \le 1$ .

We will show that  $X_n/n$  converges to this constant and satisfies an exponential lower tail bound:

### Proposition 5.18.

(43) 
$$\lim_{n \to \infty} \rho_*^{(n)} = \rho_*$$

and

(44) 
$$\frac{X_n}{n} \xrightarrow{\text{prob}} \rho$$

and there exist constants c, C > 0 depending only on  $\lambda$  and  $\epsilon$  for which the following onesided tail bound holds:

(45) 
$$\mathbf{P}\left[\rho_* - \frac{1}{n}X_n > \epsilon\right] \le Ce^{-cn}.$$

Theorem 8.4 will provide the corresponding upper tail bound

$$\mathbf{P}\left[\frac{1}{n}X_n - \rho_* > \epsilon\right] \le Ce^{-cn},$$

implying that the convergence is almost sure as well as in probability.

The random variables  $X_n$  are superadditive in the following sense: Choose some cell  $(r, s)_n$  from the highest row in the infection set  $\zeta_n^{(0,0)_0}$ . Now choose a cell  $(r', s')_{n+m}$  in the highest row of the infection set  $\zeta_m^{(r,s)_n}$ . Then  $(r', s')_{n+m}$  belongs to  $\zeta_{n+m}^{(0,0)_0}$ , and by Proposition 5.9, we have  $s' \stackrel{d}{=} X_n + X_m$ , where  $X_n$  and  $X_m$  are independent. Thus  $X_{n+m}$  is stochastically larger than the sum of independent copies of  $X_n$  and  $X_m$ . Proposition 5.18 will be a straightforward consequence of this superadditivity.

Proof of Proposition 5.18. We start by proving (45), for which we have already done most of the work. Fix  $\epsilon > 0$  and choose k large enough that that  $\rho_*^{(k)} > \rho_* - \epsilon/2$ . Let  $(r_n, s_n)_n$ be the nth step in the k-greedy infection path from  $(0,0)_0$ . We have  $X_n \ge s_n$ , and so by Proposition 5.16,

$$\mathbf{P}\left[\frac{1}{n}X_n \le \rho_* - \epsilon\right] \le \mathbf{P}\left[\frac{1}{n}s_n \le \rho_*^{(k)} - \epsilon/2\right] \le 2e^{-cn}$$

for some c depending on  $\epsilon$ ,  $\lambda$ , and k, proving (45). As a consequence,  $\liminf_{n\to\infty} \mathbf{E}X_n/n \geq \rho_*$ , proving (43). To prove (44), if  $\limsup_{n\to\infty} \mathbf{P}[X_n/n > \rho_* + \epsilon]$  is greater than 0, then from (45) we would have  $\frac{1}{n}\mathbf{E}X_n > \rho_*$  along a subsequence, contradicting the definition of  $\rho_*$ . Hence  $\mathbf{P}[X_n/n > \rho_* + \epsilon] \to 0$ , which combined with (45) proves (44).

# 6. The box Lemma

In this section we prove the *box lemma* (Lemma 6.1), which gives a deterministic region of cells almost certainly infected by layer percolation. By Proposition 4.6 and Corollary 4.14, any infection path in layer percolation ending at row  $\rho n$  corresponds to an extended odometer on [0, n] stable on [1, n - 1] leaving density  $\rho$  of sleeping particles. By Proposition 5.18, it is likely that such infection paths exist for any  $\rho < \rho_*$ , i.e., there is some cell infected starting from  $(0, 0)_n$  in row  $\rho n$ . The box lemma goes one step further, telling us that there is not just one infected cell in row  $\rho n$  but an entire interval of length on the order of  $n^2$ . One application is to construct odometers stable not only on [1, n-1] but also at n. Another is to prove an exponential upper bound on the probability that layer percolation infects a cell in

44

row  $(\rho_* + \epsilon)n$ , which we carry out in Section 7. Heuristically, the idea is that the box lemma asserts that layer percolation behaves predictably in the bulk. Thus no stretch of steps has a large effect on what row is reached by the infection set, giving rise to concentration for the highest row reached.

To give the idea of the box lemma before we state it, let  $\rho < \rho_*$  and imagine we set out to infect a cell in row  $\rho n$  at step n. Suppose we choose an infection path  $(0,0)_0 =$  $(r_0, s_0)_0 \to \cdots \to (r_n, s_n)_n$  with  $s_j \approx \rho j$ . Then according to Lemmas 5.4 and 5.5, the sequence  $r_0, \ldots, r_n$  is approximately a critical branching process with immigration  $s_j \approx \rho j$ at step j, and  $r_n$  should be close to  $\sum_{j=1}^n \rho j \approx \rho n^2/2$ . Thus some cell in the vicinity of  $(\rho n^2/2, \rho n)_n$  is likely infected starting from  $(0,0)_0$ , for any  $\rho < \rho_*$ . The box lemma states that something much stronger is true: all cells in a box of order  $n^2 \times n$  around  $(\rho n^2/2, \rho n)_n$ are infected with high probability.

**Lemma 6.1** (Box lemma). Suppose that  $0 < \epsilon \le \rho \le \rho_* - \epsilon$ . There exist constants  $\delta = \delta(\epsilon)$ ,  $c = c(\lambda, \epsilon)$ , and  $C = C(\lambda, \epsilon)$  such that the following statement holds: Define the box

$$\mathcal{R}_n(\rho,\delta) := \left[ \left[ \frac{\rho}{2} (1-\delta) n^2, \, \frac{\rho}{2} (1+\delta) n^2 \right] \right] \times \left[ \rho(1-\delta) n, \, \rho(1+\delta) n \right].$$

Then

(46) 
$$\mathbf{P}\Big[\mathcal{R}_n(\rho,\delta) \subseteq \zeta_n^{(0,0)_0}\Big] \ge 1 - Ce^{-cn}$$

We can take  $\delta$  as  $\eta \epsilon^2$  for a sufficiently small absolute constant  $\eta > 0$ .

6.1. Tools for establishing infection. To prove that some cell  $(r, s)_t$  is infected starting from  $(0, 0)_0$ , it suffices to show that the forward infection set from  $(0, 0)_0$  and the backward infection set from  $(r, s)_t$  at some step have a cell in common. Using the connectivity of infection sets (see Section 5.1), the following lemma gives us an easy way to show that a forward and backward infection set cross each other:

**Lemma 6.2.** Let  $\zeta = \zeta_{n-m}^{(r,t)_m}$  and  $\tilde{\zeta} = \tilde{\zeta}_{m'}^{(r',t')_{m'+n}}$  with  $t \leq t'$ . Suppose that  $(x_1,t)_n, (y_1,t')_n$  are cells in  $\zeta$  and  $(x_2,t')_n, (y_2,t)_n$  are cells in  $\tilde{\zeta}$  with  $x_1 \leq y_2$  and  $x_2 \leq y_1$  (see Figure 5). Then  $\zeta \cap \tilde{\zeta} \neq \emptyset$ .

Proof. We make paths as depicted in Figure 5 and show that they cross. To match the figure, call a cell *blue* if it is an element of  $\zeta$  and *red* if it is an element of  $\zeta$ . By Proposition 5.1, each blue cell except for the leftmost one in row t has a blue neighbor one cell to its left or below it. Thus, we can make a path of blue cells from  $(y_1, t')_n$  to the leftmost blue cell in row t by moving left or down at each step, choosing arbitrarily when both are possible. The cells in the blue path in a given row form an interval, and the start of an interval in some row s + 1 is the final column of the interval in row s. Likewise, by Proposition 5.2 we can form a path of red cells starting from  $(y_2, t)_n$  that moves to the left or upper-left in each step, terminating either at the leftmost red cell in row t' or at some red cell  $(0, t_0)_n$  where  $t \leq t_0 < t'$ . Call the ending cell  $(x_0, t_0)_n$  in either case, with  $x_0 \leq x_2$  and  $t_0 = t'$  in the first case and  $x_0 = 0$  and  $t_0 < t'$  in the second. In either case, the blue path has a cell in row  $t_0$  at or to the right of column  $x_0$ , in the first case because  $x_0 \leq x_2 \leq y_1$  and in the second because  $x_0 = 0$ . The cells in the red path in a given row form an interval, and the interval in some row s - 1 starts one column after the end of the interval in row s.

We claim that the red and blue paths contain a common cell. Suppose not. Then in each row, either the blue path is entirely to the left of the red path or the red path is entirely to the left of the blue. In row t, the blue path contains the leftmost blue cell in the row.

FIGURE 5. Let  $\zeta$  be an infection set from some cell in row t, and let  $\overline{\zeta}$  be a backward infection set from some cell in row t' for  $t' \geq t$ , both at step n. If  $(x_1, t)_n, (y_1, t') \in \zeta$  and  $(x_2, t')_n, (y_2, t)_n \in \overline{\zeta}$  and  $x_1 \leq y_2$  and  $x_2 \leq y_1$ , then the two infection sets must cross, as proven in Lemma 6.2. The blue and red shaded regions indicate the forward and backward infections sets, respectively, with their overlap shaded purple. The cells with highlighted outlines are the paths (which are not infection paths) constructed starting at  $(y_1, t')_n$  and  $(y_2, t)_n$  in the proof of Lemma 6.2. It is shown that these two paths must intersect, and in this case they do so at cell  $(26, 6)_n$ .

Since  $(x_1,t)_n$  is blue and  $(y_2,t)_n$  is red and  $x_1 \leq y_2$ , the blue path must be to the left of the red path. As we move to higher rows, the blue path must remain to the left. Indeed, suppose the blue path in some row s covers columns  $[\![a,b]\!]$  and the red path covers columns  $[\![c,d]\!]$  with b < c. Then in row s + 1, the blue path has b as its left endpoint while the red path has c-1 as its right endpoint; the blue path cannot lie entirely to the right of the red path since  $b \leq c-1$ . Thus the blue path is entirely to the left of the red path in all rows. But this is a contradiction, since in row  $t_0$  the red path contains  $(x_0, t_0)$  and the blue path contains some cell at or to the right of  $x_0$ . Therefore the red and blue paths have a common element, proving that  $\zeta \cap \overline{\zeta} \neq \emptyset$ .

In Section 5, we defined minimal and greedy infection paths. When we prove the box lemma, we will need backward versions of these paths:

**Definition 6.3.** The reverse minimal infection path from  $(r, s)_m$  is the infection path

$$(r_m, s)_0) \to (r_{m-1}, s_{m-1})_1 \to \dots \to (r_1, s)_{m-1} \to (r_0, s)_m = (r, s)_m$$

in which  $(r_{k+1}, s)_{m-k-1}$  is the leftmost cell in row s infecting  $(r_k, s)_{m-k}$  for each  $k \in [0, m-1]$ .

The reverse k-greedy path from  $(r, s)_m$  is defined analogously to the k-greedy path (Definition 5.13), with  $(r_{jk}, s_{jk})_{m-jk}$  chosen from the cells in the minimum row of  $\zeta_k^{(r_{(j-1)k}, s_{(j-1)k})_{m-(j-1)k}}$  for each j and some infection path chosen from  $(r_{jk}, s_{jk})_{m-jk}$  to  $(r_{(j-1)k}, s_{(j-1)k})_{m-(j-1)k}$ . Again, it only really matters that our choice of cell  $(r_{jk}, s_{jk})_{m-jk}$  and path from  $(r_{jk}, s_{jk})_{m-jk}$  to  $(r_{(j-1)k}, s_{(j-1)k})_{m-(j-1)k}$  is made using only the information contained in the infections from steps m - jk to m, but we give a concrete procedure that will be dual to the one from Definition 5.13 (see Lemma 6.4). Given  $(r_{(j-1)k}, s_{(j-1)k})_{m-(j-1)k}$ , choose  $(r_{jk}, s_{jk})_{m-jk}$  to be the rightmost cell in the minimal row of  $\zeta_k^{(r_{(j-1)k},s_{(j-1)k})_{m-(j-1)k}}$ . Then out of all infection paths from  $(r_{jk},s_{jk})_{m-jk}$  to  $(r_{(j-1)k},s_{(j-1)k})_{m-(j-1)k}$ , choose  $(r_{jk-1},s_{jk-1})_{m-jk+1}$  by first minimizing  $s_{jk-1}$  and then maximizing  $r_{jk-1}$ . Then out of all infection paths from  $(r_{jk-1},s_{jk-1})_{m-jk+1}$  to  $(r_{(j-1)k},s_{(j-1)k})_{m-(j-1)k}$  choose  $(r_{jk-2},s_{jk-2})_{m-jk+2}$  by first minimizing  $s_{jk-2}$  and then maximizing  $r_{jk-2}$ .

The reverse k-greedy path from  $(r, s)_m$  capped at row t for  $t \leq s$  is defined analogously to forward capped k-greedy paths, as the infection path that follows the reverse k-greedy infection path from  $(r, s)_m$  until it descends to row t, and then follows the reverse minimal infection path from that point on.

Recall that Proposition 5.12 yields a coupling of two layer percolations such that when the coupling is valid, the backward infection set  $\zeta_n^{(u,t)_m}$  in one layer percolation is the image of the infection set  $\zeta_n^{(0,0)_0}$  in the other under the transformation  $(r,s)_n \mapsto (Z_n+r+s,t-s)_{m-n}$ , where  $Z_n$  is a branching process defined in Coupling 5.11. It is evident from the definitions that this transformation takes minimal and k-greedy infection paths to reverse minimal and reverse k-greedy infection paths:

**Lemma 6.4.** Suppose two layer percolations are coupled by Coupling 5.11 and that  $Z_n \ge 0$  so that Proposition 5.12 is in effect and infection sets from  $(0,0)_0$  in the first layer percolation are transformed versions of backward infection sets from  $(u,t)_n$  in the second layer percolation. Then an infection path

$$(0,0)_0 = (r_0, s_0)_0 \to \cdots (r_n, s_n)_n$$

in the first layer percolation is the minimal infection path (resp. the k-greedy infection path, the k-greedy infection path capped at  $s' \ge s$ ) from  $(0,0)_0$  if and only if the infection path

$$(Z_n + r_n + s_n, t - s_n)_0 \twoheadrightarrow \dots \twoheadrightarrow (Z_0 + r_0 + s_0, t - s_0)_n = (u, t)_n$$

is the reverse minimal infection path (resp. the reverse k-greedy infection path, the reverse k-greedy infection path capped at t - s') from  $(u, t)_n$ .

### 6.2. Sketch of the proof of Lemma 6.1. Suppose that $t = \rho n$ is an integer and

$$u \in \left[ \left[ \frac{\rho}{2} (1 - \delta') n^2, \frac{\rho}{2} (1 + \delta') n^2 \right] \right]$$

for  $\delta' > 0$  to be chosen. It will be enough by a union bound to show that  $\mathbf{P}[(u,t)_n \in \zeta_n^{(0,0)_0}] \ge 1 - Ce^{-cn}$ . Our strategy is to show that the forward infection set from  $(0,0)_0$  and the backward infection set from  $(u,t)_n$  are likely to intersect at step n/2. Let  $n_0 \approx (1/2 - \alpha)n$  for a small constant  $\alpha > 0$ , and let  $s \approx \beta n/2$  for  $\beta$  slightly smaller than  $\rho$ .

Step 0 to step  $n_0: (0,0)_0 \to (R_1,s)_{n_0}$ . Run the greedy infection path from  $(0,0)_0$  capped at row s until step  $n_0$ , when it will be at a cell  $(R_1,s)_{n_0}$ .

Step  $n - n_0$  to step  $n: (R_2, t - s)_{n-n_0} \to (u, t)_n$ . Symmetrically to the previous step, run the reverse greedy infection path from  $(u, t)_n$  capped at row t - s until step  $n - n_0$ , when it will be at some some cell  $(R_2, t - s)_{n-n_0}$ .

Step  $n_0$  to step n/2:  $(R_1, s)_{n_0} \to (X_1, s)_{n/2}$  and  $(R_1, s)_{n_0} \to (Y_1, t - s)_{n/2}$ . From  $(R_1, s)_{n_0}$ , run the minimal infection path to  $(X_1, s)_{n/2}$  and the greedy infection path capped at row t-s to  $(Y_1, t - s)_{n/2}$ .

FIGURE 6. The step (horizontal axis) in layer percolation versus the row (vertical axis) for the paths constructed in the proof of Lemma 6.1. The black line from step 0 to step  $n_0$  is a greedy infection path capped at row s, and the black line from step  $n - n_0$  to step n is a reverse greedy infection path capped at row t - s. The dark and light blue arrows represent a minimal infection path and a greedy infection path capped at row t - s, respectively, started from the same cell. The dark and light red arrows represent a reverse minimal infection path and a reverse greedy infection path capped at row s, respectively, started from the same cell. The dark and light red arrows represent a reverse minimal infection path and a reverse greedy infection path capped at row s, respectively, started from the same cell. The infection sets at step n/2 are depicted in Figure 7.

Step n/2 to step  $n - n_0$ :  $(X_2, t - s)_{n/2} \to (R_2, t - s)_{n-n_0}$  and  $(Y_2, s)_{n/2} \to (R_2, t - s)_{n-n_0}$ . Symmetrically to the previous step, from  $(R_2, t - s)_{n-n_0}$  run the reverse minimal infection path to  $(X_2, t - s)_{n/2}$  and the reverse greedy infection path capped at row s to  $(Y_2, s)_{n/2}$ .

These steps are illustrated in Figure 6. In the end, we will have produced cells  $(X_1, s)_{n/2}$ and  $(Y_1, t - s)_{n/2}$  in  $\zeta_{n/2-n_0}^{(R_1, s)_{n_0}}$  and cells  $(X_2, t - s)_{n/2}$  and  $(Y_2, s)_{n/2}$  in  $\overline{\zeta}_{n/2-n_0}^{(R_2, t - s)_{n-n_0}}$ . With  $\alpha$ ,  $\beta$ , and  $\delta'$  chosen correctly, we will find that these four cells are arranged as in Figure 7, with  $X_1 \leq Y_2$  and  $X_2 \leq Y_1$ , thus producing a cell in  $\zeta_{n/2-n_0}^{(R_1, s)_{n_0}} \cap \overline{\zeta}_{n/2-n_0}^{(R_2, t - s)_{n-n_0}}$  by Lemma 6.2 and proving that

$$(0,0)_0 \to (R_1,s)_{n_0} \to (R_2,t-s)_{n-n_0} \to (u,t)_n.$$

To put this idea into practice, we choose a suitable  $\alpha$  and  $\beta$  and use Lemma 5.6 and Proposition 5.17 to estimate  $R_1$ ,  $X_1$ , and  $Y_1$ , pinpointing each one to a window of order  $n^2$ . With an additional application of Proposition 5.12, we can do the same with  $R_2$ ,  $X_2$ , and  $Y_2$ . At this point we will have proven that  $X_1 \leq Y_2$  and  $X_2 \leq Y_1$  with high probability, allowing us to conclude that  $(u, t)_n$  is in  $\zeta_n^{(0,0)_0}$  with high probability. The technical complexity comes in picking the appropriate values of  $\alpha$  and  $\beta$  and then making the statements about  $R_1$ ,  $R_2$ ,  $X_1$ ,  $Y_1$ ,  $X_2$ , and  $Y_2$  precise.

6.3. Estimates on the box lemma paths. In this section, we consider a cell  $(u, t)_n$  and construct and bound the infection paths described in the previous section used to show that  $(0,0)_0 \rightarrow (u,t)_n$  with exponentially vanishing probability. Throughout this section, we make the following assumptions: As in the statement of Lemma 6.1, we have  $0 < \epsilon \leq \rho \leq \rho_* - \epsilon$ . We assume that  $t := \rho n$  is an integer. We take n to be even and choose k large enough that  $\rho_*^{(k)} > \rho_* - \epsilon/4$ , so that

(47) 
$$\epsilon \le \rho \le \rho_* - \epsilon < \rho_* - \epsilon / 4 < \rho_*^{(k)} \le \rho_*$$

FIGURE 7. Two infection sets at step n/2. In blue is  $\zeta_{n/2-n_0}^{(R_1,s)_{n_0}}$  and in red is  $\zeta_{n/2-n_0}^{(R_2,t-s)_{n-n_0}}$ , with their intersection in purple. The four cells represented by the arrow tips in Figure 6 are outlined. Since the paths are constructed to make  $X_2 \leq Y_1$  and  $X_1 \leq Y_2$ , these four cells satisfy the conditions of Lemma 6.2, demonstrating that that the two infection sets overlap.

Define

(48) 
$$\begin{aligned} \alpha &= \epsilon/16, \qquad n_0 = n/2 - \lfloor \alpha n \rfloor, \\ \beta &= \rho - \left(\rho_* - \frac{\epsilon}{2}\right)\alpha, \qquad s = \lfloor \beta n/2 \rfloor, \end{aligned}$$

whose roles are laid out in the sketch. We let  $\delta' = \alpha^2/4$ . Assume that

(49) 
$$u \in \left[ \frac{\rho}{2} (1 - \delta') n^2, \frac{\rho}{2} (1 + \delta') n^2 \right].$$

We also define  $\delta_0 = \rho \delta'/100$ , to be used in some error bounds. We say that a statement holds with overwhelming probability (w.o.p.) if it fails with probability at most  $Ce^{-cn}$  where c and C are constants that depend only on  $\lambda$  and  $\epsilon$ .

The following lemma proves several important facts about the quantities defined in (48). Equation (50) shows in particular that  $0 < \beta < 1$ . Bounds (51) and (52) confirm that  $\alpha$  and  $\beta$  were chosen appropriately so that the greedy paths described in the sketch can reach the rows that they need to: (51) shows that the capped k-greedy paths used from steps 0 to  $n_0$  and from steps  $n - n_0$  to n progress fast enough to reach their caps; and (52) shows that the capped k-greedy paths used from steps n/2 to  $n - n_0$  reach their caps.

**Lemma 6.5.** For n larger than some constant depending only on  $\epsilon$ ,

(50) 
$$\epsilon/2 \le \beta \le \rho$$
,

(51) 
$$\frac{s}{n_0} \le \rho_*^{(k)} - \epsilon/2,$$

and

(52) 
$$\frac{t-2s}{n/2-n_0} \le \rho_*^{(k)} - \epsilon/5.$$

*Proof.* The upper bound in (50) is immediate from the definition of  $\beta$ . For the lower bound, we have  $\rho \ge \epsilon$  and  $\rho_* - \epsilon/2 \le 1$ , yielding  $\beta \ge \epsilon - \epsilon/16 \ge \epsilon/2$ .

For (51), we let  $q = (\rho_* - \epsilon/2)/\rho$  and have

(53) 
$$\frac{s}{n_0} \le \frac{\beta}{1-2\alpha} = \frac{\rho(1-q\alpha)}{1-2\alpha}.$$

Now we prove a bound on  $(1 - q\alpha)/(1 - 2\alpha)$ . Observe that  $q \ge 1$  by (47). If  $q \le 2$ , then a bit of calculus shows that  $(1 - qx)/(1 - 2x) \le 1 + 2(2 - q)x$  for  $x \le 1/4$ , yielding  $(1 - qx)/(1 - 2x) \le 1 + 2x$  for  $x \le 1/4$ . If q > 2, then  $(1 - qx)/(1 - 2x) \le 1$  for all  $x \le 1/4$ . Hence  $(1 - qx)/(1 - 2x) \le 1 + 2x$  for  $x \le 1/4$  holds in all cases. Since  $\alpha = \epsilon/16$  and  $\epsilon \le 1$ ,

$$\frac{1-q\alpha}{1-2\alpha} \le 1+\epsilon/8 \le \frac{\rho+\epsilon/8}{\rho} \le \frac{\rho_*-7\epsilon/8}{\rho}.$$

Together with (53) and (47), this yields

$$\frac{s}{n_0} \le \rho_* - 7\epsilon/8 < \rho_*^{(k)} - 5\epsilon/8,$$

proving (51).

For (52), just using (47) and (48) we have

(54) 
$$\frac{t-2s}{n/2-n_0} = \frac{t-2s}{\lfloor \alpha n \rfloor} \le \frac{\rho-\beta+1/n}{\alpha-1/n} = \frac{\left(\rho_* - \frac{\epsilon}{2}\right)\alpha + 1/n}{\alpha-1/n} < \frac{\rho_*^{(k)} - \frac{\epsilon}{4} + 1/\alpha n}{1-1/\alpha n}.$$

For large enough n, the right-hand side is bounded by  $\rho_*^{(k)} - \epsilon/5$ , proving (52).

Next, we start defining and giving estimates on the cells from our sketch. We write  $x + [\![a, b]\!]$  to denote  $[\![a + x, b + x]\!]$ .

**Proposition 6.6.** Define the following cells:

- (i)  $(R_1, S_1)_{n_0}$  lies on the k-greedy infection path from  $(0, 0)_0$  capped at row s;
- (ii)  $(R_2, S_2)_{n-n_0}$  lies on the reverse k-greedy infection path from  $(u, t)_n$  capped at row t-s.

It holds with overwhelming probability that

(55) 
$$S_1 = s, \qquad R_1 \in \left(\frac{2 - \beta/\rho_*^{(k)}}{4} - \alpha\right) \frac{\beta n^2}{2} + \left[ -\delta_0 n^2, \delta_0 n^2 \right],$$

(56) 
$$S_2 = t - s, \quad R_2 \in u - \left(\frac{1}{2} - \alpha\right)\rho n^2 + \left(\frac{2 - \beta/\rho_*^{(\kappa)}}{4} - \alpha\right)\frac{\beta n^2}{2} + \left[-2\delta_0 n^2, 2\delta_0 n^2\right].$$

*Proof.* By (51) from Lemma 6.5, we can apply Proposition 5.17 to estimate  $R_1$  and  $S_1$ . Equation (42) shows that the first equality in (55) holds w.o.p. Using (41) and applying (48), we have concentration of  $R_1$  around

$$\left(n_0 - \frac{s}{2\rho_*^{(k)}}\right)s = \left(\frac{2 - \beta/\rho_*^{(k)}}{4} - \alpha\right)\frac{\beta n^2}{2} + O(n/\epsilon).$$

(The factor of  $\epsilon^{-1}$  in the error term comes from from  $\rho_*^{(k)}$ , which is bounded below by  $\epsilon$ .) Then (41) proves that the second part of (55) holds w.o.p.

To prove (56), we must first invoke Proposition 5.12 to couple  $\zeta_{n_0}^{(u,t)_n}$  with  $\zeta_{n_0}^{(0,0)_0}$  in a different layer percolation. Let  $(Z_k)_{k\geq 0}$  be the branching process from Coupling 5.11, which is a critical geometric branching process starting from u with constant emigration t. According to Proposition 5.12 and Lemma 6.4, we have

(57) 
$$(R_2, S_2)_{n-n_0} = (Z_{n_0} + R'_1 + S'_1, t - S'_1)_{n-n_0} \quad \text{if } Z_{n_0} \ge 0,$$

where  $(R'_1, S'_1)_{n_0}$  lies on the k-greedy infection path from  $(0, 0)_0$  capped at row s in the coupled layer percolation. In particular,  $(R'_1, S'_1)$  has the same distribution as  $(R_1, S_1)$ , which we have already analyzed. By Proposition A.1, we have  $Z_{n_0}$  concentrated around  $u - tn_0$ , yielding

(58) 
$$Z_{n_0} \in u - (\frac{1}{2} - \alpha)\rho n^2 + [-\delta_0 n^2, \delta_0 n^2]$$
w.o.p.

Since  $u - \frac{1}{2}\rho n^2 \ge -\frac{1}{2}\rho \delta' n^2$  by (49),

$$Z_{n_0} \ge -\frac{\rho \delta' n^2}{2} + \alpha \rho n^2 - \delta_0 n^2 = \left(1 - \frac{51\alpha}{400}\right) \rho \alpha n^2 > 0$$
 w.o.p.,

since  $\alpha \leq 1/16$ . Thus the coupling is valid w.o.p., and from (57) and  $S'_1 = s$  w.o.p. we obtain the first part of (56). And (58) together with (55) and (57) prove the second part of (56).

Next we give estimates on the cells at step n/2 that we use for applying Lemma 6.2.

# **Proposition 6.7.** Define the following cells:

- (i)  $(X_1, S_1)_{n/2}$  lies on the minimal infection path from  $(R_1, S_1)_{n_0}$ ;
- (ii)  $(Y_1, T_1)_{n/2}$  lies on the k-greedy infection path from  $(R_1, S_1)_{n_0}$  capped at row t s;
- (iii)  $(X_2, S_2)_{n/2}$  lies on the reverse minimal infection path from  $(R_2, S_2)_{n-n_0}$ ;
- (iv)  $(Y_2, T_2)_{n/2}$  lies on the reverse k-greedy infection path from  $(R_2, S_2)_{n-n_0}$  capped at row s.

It holds with overwhelming probability that

(59) 
$$X_1 \in \left(\frac{2-\beta/\rho_*^{(k)}}{4}\right) \frac{\beta n^2}{2} + [-3\delta_0 n^2, 3\delta_0 n^2],$$
  
(60)  $Y_n \in \left(\frac{2-\beta/\rho_*^{(k)}}{4}\right) \frac{\beta n^2}{2} + \left(\alpha - \frac{\rho-\beta}{4}\right) (\alpha - \beta) n^2 + [-4\delta_n n^2],$ 

(60) 
$$Y_1 \in \left(\frac{2-\beta/\rho_*^{(r)}}{4}\right) \frac{\beta n^2}{2} + \left(\alpha - \frac{\rho - \beta}{2\rho_*^{(k)}}\right) (\rho - \beta) n^2 + \left[-4\delta_0 n^2, 4\delta_0 n^2\right].$$

 $(61) \qquad T_1 = t - s,$ 

(62) 
$$X_2 \in u - \frac{\rho n^2}{2} + \left(\frac{2 - \beta/\rho_*^{(k)}}{4}\right) \frac{\beta n^2}{2} + \left[-4\delta_0 n^2, 4\delta_0 n^2\right],$$

(63) 
$$Y_2 \in u - \frac{\rho n^2}{2} + \left(\frac{2 - \beta/\rho_*^{(k)}}{4}\right) \frac{\beta n^2}{2} + \left(\alpha - \frac{\rho - \beta}{2\rho_*^{(k)}}\right) (\rho - \beta) n^2 + \left[-6\delta_0 n^2, 6\delta_0 n^2\right],$$

$$(64) T_2 = s.$$

*Proof.* For (59), we observe that  $X_1 + s$  is the  $\lfloor \alpha n \rfloor$ th step of a critical geometric branching process from  $R_1 + s$  with constant immigration s by Lemma 5.6. An application of Proposition A.1 conditional on  $R_1$  shows that  $X_1 + s$  is contained in  $R_1 + s \lfloor \alpha n \rfloor + \llbracket -\delta_0 n^2, \delta_0 n^2 \rrbracket$  w.o.p. Applying (55) from Proposition 6.6 together with  $s \lfloor \alpha n \rfloor = \alpha \beta n^2/2 + O(n)$  yields (59).

To prove (60) and (61), we first consider a k-greedy infection path from  $(0,0)_0$  capped at row t-2s. Let  $(Y', S')_{\lfloor \alpha n \rfloor}$  lie on this infection path. We claim that

(65) 
$$Y' = \left(\alpha - \frac{\rho - \beta}{2\rho_*^{(k)}}\right)(\rho - \beta)n^2 + \left[-\delta_0 n^2, \delta_0 n^2\right] \text{ w.o.p.},$$

(66) S' = t - 2s w.o.p.

By (52) from Lemma 6.5, the conditions of Proposition 5.17 are satisfied. We can apply it to prove (66) and to conclude that Y' is concentrated around

$$\left(\lfloor \alpha n \rfloor - \frac{t - 2s}{2\rho_*^{(k)}}\right)(t - 2s) = \left(\alpha - \frac{\rho - \beta}{2\rho_*^{(k)}}\right)(\rho - \beta)n^2 + O_\epsilon(n),$$

which proves (65).

By Proposition 5.9, there exists a coupling of Y' and S' with our layer percolation so that  $(Y_1, T_1)_{n/2} = (X_1 + Y', S' + S_1)_{\lfloor \alpha n \rfloor}$ . Since S' = t - 2s w.o.p. and  $S_1 = s$  w.o.p. by (55), we obtain (61). And from (59) and (65), we prove (60).

The proof of (62)–(64) goes just like the proof of (59)–(61) but with an application of Proposition 5.12. This time, we couple  $\zeta_{\lfloor \alpha n \rfloor}^{(R_2,S_2)_{n-n_0}}$  with a forward infection set  $\zeta_{\lfloor \alpha n \rfloor}^{(0,0)_0}$  and branching process  $(\overline{Z}_k)_{k\geq 0}$  starting from  $R_2$  with constant emigration  $S_2$ . Applying Proposition A.1 conditional on  $R_2$  and  $S_2$ ,

$$\overline{Z}_{\lfloor \alpha n \rfloor} \in R_2 - \lfloor \alpha n \rfloor S_2 + \llbracket -\delta_0 n^2, \delta_0 n^2 \rrbracket$$
 w.o.p.

By (56) from Proposition 6.6 together with  $\lfloor \alpha n \rfloor (t-s) = \alpha \rho n^2 - \alpha \beta n^2/2 + O(n)$ , it holds with overwhelming probability that

$$R_{2} - \lfloor \alpha n \rfloor S_{2} \in u - \left(\frac{1}{2} - \alpha\right) \rho n^{2} + \left(\frac{2 - \beta/\rho_{*}^{(k)}}{4} - \alpha\right) \frac{\beta n^{2}}{2} - \lfloor \alpha n \rfloor (t - s) + \left[\!\left[ -2\delta_{0}n^{2}, 2\delta_{0}n^{2} \right]\!\right]$$
$$\subseteq u - \frac{\rho n^{2}}{2} + \left(\frac{2 - \beta/\rho_{*}^{(k)}}{4}\right) \frac{\beta n^{2}}{2} + \left[\!\left[ -3\delta_{0}n^{2}, 3\delta_{0}n^{2} \right]\!\right].$$

Hence

(67) 
$$\overline{Z}_{\lfloor \alpha n \rfloor} \in u - \frac{\rho n^2}{2} + \left(\frac{2 - \beta/\rho_*^{(k)}}{4}\right) \frac{\beta n^2}{2} + \left[-4\delta_0 n^2, 4\delta_0 n^2\right] \text{ w.o.p.}$$

Since  $u - \frac{1}{2}\rho n^2 \ge -\frac{1}{2}\rho \delta' n^2$  by (49) and  $\epsilon/2 \le \beta \le \rho \le \rho_*^{(k)}$  by (47) and (50) from Lemma 6.5,

$$\overline{Z}_{\lfloor \alpha n \rfloor} \ge -\frac{\rho \delta' n^2}{2} + \frac{1}{4} \frac{\epsilon n^2}{4} - 4\delta_0 n^2 = \left(1 - \frac{27\rho\epsilon}{3200}\right) \frac{\epsilon n^2}{16} \ge 0 \text{ w.o.p.},$$

since  $\rho$  and  $\epsilon$  are both bounded by 1. Hence by Proposition 5.12 the coupling of  $\zeta_{\lfloor \alpha n \rfloor}^{(R_2,S_2)_{n-n_0}}$ and  $\zeta_{\lfloor \alpha n \rfloor}^{(0,0)_0}$  is in effect w.o.p. The minimal infection path from  $(0,0)_0$  is simply  $(0,0)_0 \rightarrow$  $(0,0)_1 \rightarrow \cdots$ , and the image of this path under the transformation  $(r,s)_m \mapsto (\overline{Z}_m + r + s, S_2 - s)_m$  is the reverse minimal infection path from  $(R_2, S_2)_{n-n_0}$  under the coupling by Lemma 6.4. Hence (67) together with  $S_2 = t - s$  w.o.p. from Proposition 6.6 proves (62).

For (63) and (64), we consider a k-greedy infection path from  $(0,0)_0$  capped at s - 2t, whose location after  $\lfloor \alpha n \rfloor$  steps we have already determined in (65) and (66). The image of this path under the transformation  $(r, s)_m \mapsto (\overline{Z}_m + r + s, S_2 - s)_m$  is a reverse k-greedy infection path from  $(R_2, S_2)_{n-n_0}$  capped at  $S_2 - (s-2t) = t$  w.o.p. by (56). Then  $T_2 = S_2 - S'$ w.o.p., which by (56) and (66) proves (64). In the same way,  $Y_2 = \overline{Z}_{\lfloor \alpha n \rfloor} + Y' + S'$  w.o.p., and combining (67), (65), and (66) proves (63).

6.4. **Proof of Lemma 6.1.** First, we apply the results from the previous section to prove the likely infection of a single cell  $(u, t)_n$ .

**Proposition 6.8.** Let n be even. Let t be an integer and  $\rho = t/n$ . Suppose that  $0 < \epsilon \le \rho \le \rho_* - \epsilon$ . Let  $\delta' = \epsilon^2/1024$ . Suppose that

$$u \in \left[ \frac{\rho}{2} (1 - \delta') n^2, \frac{\rho}{2} (1 + \delta') n^2 \right].$$

For some constants  $c = c(\lambda, \epsilon)$  and  $C = C(\lambda, \epsilon)$ ,

$$\mathbf{P}\big[(0,0)_0 \to (u,t)_n\big] \ge 1 - Ce^{-cn}.$$

Proof. Define  $k, \alpha, \beta, n_0, s$ , and  $\delta_0$  as in Section 6.3, and note that our definition of  $\delta'$  agrees with the definition  $\delta' = \alpha^2/4$  in Section 6.3. We consider the cells  $(X_1, S_1)_{n/2}, (Y_1, T_1)_{n/2}, (X_2, S_2)_{n/2}$ , and  $(Y_2, T_2)_{n-n_0}$  from Proposition 6.7. By construction, cells  $(X_1, S_1)_{n/2}$  and  $(Y_1, T_1)_{n/2}$  are in  $\zeta_{n/2-n_0}^{(R_1, S_1)_{n_0}}$  and cells  $(X_2, S_2)_{n/2}$  and  $(Y_2, T_2)_{n/2}$  are in  $\zeta_{n/2-n_0}^{(R_2, S_2)_{n-n_0}}$ . Our goal is to show these cells are likely to satisfy the criteria of Lemma 6.2. Then  $(R_1, S_1)_{n_0} \rightarrow (R_2, S_2)_{n-n_0}$ , which then proves  $(0, 0)_0 \rightarrow (u, t)_n$ .

In Propositions 6.6 and 6.7, we showed that  $S_1 = T_2 = s$  and  $S_2 = T_1 = t - s$  w.o.p. We now show that  $X_1 \leq Y_2$  and  $X_2 \leq Y_1$  w.o.p. From Proposition 6.7,

$$Y_2 - X_1 \ge \left(u - \frac{\rho n^2}{2}\right) + \left(\alpha - \frac{\rho - \beta}{2\rho_*^{(k)}}\right)(\rho - \beta)n^2 - 9\delta_0 n^2 \text{ w.o.p.},$$
  
$$Y_1 - X_2 \ge \left(\frac{\rho n^2}{2} - u\right) + \left(\alpha - \frac{\rho - \beta}{2\rho_*^{(k)}}\right)(\rho - \beta)n^2 - 8\delta_0 n^2 \text{ w.o.p.},$$

By our choice of u, we have  $|u - \rho n^2/2| \le \rho \delta' n^2/2$ . Considering the next term in the bounds,

$$\left(\alpha - \frac{\rho - \beta}{2\rho_*^{(k)}}\right)(\rho - \beta)n^2 = \left(1 - \frac{\rho_* - \epsilon/2}{2\rho_*^{(k)}}\right)\left(\rho_* - \epsilon/2\right)\alpha^2 n^2.$$

Since  $1 - (\rho_* - \epsilon/2)/2\rho_*^{(k)} \ge 1/2$  and  $\rho_* - \epsilon/2 \ge \rho$ ,

$$\left(\alpha - \frac{\rho - \beta}{2\rho_*^{(k)}}\right)(\rho - \beta)n^2 \ge \frac{\rho\alpha^2 n^2}{2} = 2\rho\delta' n^2.$$

Hence  $Y_2 - X_1 \ge (2 - 1/2 - 9/100)\rho\delta'n^2 > 0$  w.o.p., and  $Y_1 - X_2 \ge (2 - 1/2 - 8/100)\rho\delta'n^2 > 0$ w.o.p. Now Lemma 6.2 applies to prove that  $\zeta_{n/2-n_0}^{(R_1,S_1)_{n_0}}$  and  $\overline{\zeta}_{n/2-n_0}^{(R_2,S_2)_{n-n_0}}$  contain a common cell, proving that  $(R_1, S_1)_{n_0} \to (R_2, S_2)_{n-n_0}$  w.o.p. Since  $(0, 0)_0 \to (R_1, S_1)_{n_0}$  and  $(R_2, S_2)_{n-n_0} \to (u, t)_n$  by construction, this proves that  $(0, 0) \to (u, t)_n$  w.o.p.  $\Box$ 

All that remains is to apply the previous proposition for all cells  $(u, t)_n$  in a box.

Proof of Lemma 6.1. Without loss of generality we can take n to be even, since  $(0,0)_0 \rightarrow (0,0)_1$  always holds and then we can apply the result starting at step 1. We may also assume that  $0 < 2\epsilon \leq \rho \leq \rho_* - 2\epsilon$  rather than  $0 < \epsilon \leq \rho \leq \rho_* - \epsilon$ . Take  $\delta = \epsilon^2/2048$ . Let  $\rho_t := t/n$ , and observe that  $\epsilon \leq \rho_t \leq \rho_* - \epsilon$  for  $t \in [\rho(1-\delta)n, \rho(1+\delta)n]$ . As before, we say that an event happens with overwhelming probability if it occurs with probability  $1 - Ce^{-cn}$  for constants c, C > 0 that may depend on  $\epsilon$  and  $\lambda$ . Applying Proposition 6.8 over a range of  $O(n^2)$  choices of u and O(n) choices of t, it holds with overwhelming probability that

$$\left\{ (u,t)_n \colon t \in \left[ \!\!\left[ \rho(1-\delta)n, \, \rho(1+\delta)n \right] \!\!\right], \, u \in \left[ \!\!\left[ \frac{\rho_t}{2}(1-\delta')n^2, \, \frac{\rho_t}{2}(1+\delta')n^2 \right] \!\!\right] \right\} \subseteq \zeta_n^{(0,0)_0},$$

where  $\delta' = \epsilon^2 / 1024 = 2\delta$ . To prove (46), it suffices to show that for  $t \in \left[ \rho(1-\delta)n, \rho(1+\delta)n \right]$ ,

$$\left[\!\left[\frac{\rho}{2}(1-\delta)n^2,\,\frac{\rho}{2}(1+\delta)n^2\right]\!\right] \subseteq \left[\!\left[\frac{\rho_t}{2}(1-\delta')n^2,\,\frac{\rho_t}{2}(1+\delta')n^2\right]\!\right]$$

And this holds because  $\delta' = 2\delta'$  and hence for  $t \in \llbracket \rho(1-\delta)n, \rho(1+\delta)n \rrbracket$ ,

$$\rho_t(1-\delta') \le \rho(1+\delta)(1-\delta') \le \rho(1-\delta)$$

and

$$\rho_t(1+\delta') \ge \rho(1-\delta)(1+\delta') \ge \rho(1+\delta).$$

#### 7. Upper tail bounds around the critical density

Let  $X_n$  be the highest row infected by layer percolation at step n, as in Definition 5.14. In Section 5.5, we proved that  $X_n/n \to \rho_*$  in probability and gave an exponential bound on the lower tail of  $X_n$ . In this section we complete the picture by proving an upper tail bound on  $X_n$ .

**Proposition 7.1.** Consider layer percolation with parameter  $\lambda > 0$ , and fix  $\rho > \rho_*(\lambda)$ . There exist C, c > 0 depending only on  $\lambda$  and  $\rho$  such that

$$\mathbf{P}[X_n \ge \rho n] \le C e^{-cn}.$$

In Section 8.2, we will translate this bound to odometers, thus proving that activated random walk on an interval rarely stabilizes with a density above  $\rho_*$ .

Let  $\mathsf{BadCell}_n^\rho(r,s)_k$  denote the event that  $(r,s)_k$  infects a cell  $\rho n$  rows above it in n steps, i.e., the infection set  $\zeta_n^{(r,s)_k}$  contains a cell  $(r',s')_{n+k}$  with  $s'-s \ge \rho n$ . Let  $\mathsf{BadBox}_n^\rho(r,s)_k$ denote the event that  $\mathsf{BadCell}_n^\rho(r',s')_k$  holds for some  $(r',s')_k$  with  $r \le r' < r + n^2$  and  $s \le s' < s + n$ . The probabilities of both events depend on  $\rho$ ,  $\lambda$ , and n but not on the cell  $(r,s)_k$ : the step k is irrelevant since the infections at different steps of layer percolation are i.i.d., and r and s are irrelevant by Proposition 5.9. We write  $\mathsf{BadCell}_n^\rho$  and  $\mathsf{BadBox}_n^\rho$  as abbreviations for  $\mathsf{BadCell}_n^\rho(0,0)_0$  and  $\mathsf{BadBox}_n^\rho(0,0)_0$ .

We start with a sketch of the proof of Proposition 7.1. Our goal is to produce an exponential bound on the probability of  $\mathsf{BadCell}_n^{\rho}$ . From the convergence in probability of  $X_n/n$  to  $\rho_*$ , we have the weaker statement

(68) 
$$\lim_{n \to \infty} \mathbf{P} \big[ \mathsf{BadCell}_n^\rho \big] = 0.$$

Our first step is to prove Lemma 7.2, which improves this to

(69) 
$$\lim_{n \to \infty} \mathbf{P} \left[ \mathsf{BadBox}_n^{\rho} \right] = 0.$$

We cannot use a union bound here since we have no rate of convergence for (68), but the result is an easy consequence of the regularity established by Lemma 6.1.

Next, we take k to be a large but fixed constant, and we partition the cells at each level into boxes of size  $k^2 \times k$ . We fix a sequence of boxes at steps  $k, 2k, \ldots, jk$  for  $j = \lfloor n/k \rfloor$ , say with lower-left corners  $(r_i, s_i)_{ik}$  for  $1 \le i \le j$ . We consider the event that there exists an infection path from  $(0,0)_0$  through these boxes ending beyond row  $\rho n$ . This event can only occur if  $\mathsf{BadBox}_k^{\rho'}(r_i, s_i)_{ik}$  occurs for a positive proportion of  $i \in [\![1, j]\!]$ , where  $\rho'$  is some fixed value between  $\rho_*$  and  $\rho$ . Since these events  $\mathsf{BadBox}_k^{\rho'}(r_i, s_i)_{ik}$  are independent, the probability of this occurring is exponentially small in j, and by (69) we can control the rate by increasing k.

This exponential bound applies only to a single, fixed sequence of boxes. We would like to apply it in a union bound over all possible sequences of boxes, but there are too many. Using the tools provided in Section 5.2, however, we can show that most sequences of boxes are unlikely to have infection paths through them, since the infection set from any particular box after k steps is concentrated on a  $k^2 \times k$  set of cells, i.e., on O(1) many boxes. Thus there are effectively only  $C^j$  sequences of boxes to consider, with C independent of k. Increasing k until our exponential probability bound beats this rate of growth  $C^j$ , we prove Proposition 7.1.

We start now on the proof now, first extending (68) to boxes of size  $n^2 \times n$ .

**Lemma 7.2.** For any fixed  $\rho > \rho_*$  and  $\lambda > 0$ ,

$$\lim_{n \to \infty} \mathbf{P} \left[ \mathsf{BadBox}_n^{\rho} \right] = 0.$$

*Proof.* For  $\theta > 0$  to be specified, let  $\theta$ -BadBox $_n^{\rho}(r, s)_k$  denote the same event as  $\mathsf{BadBox}_n^{\rho}(r, s)_k$ , except that the box has dimensions  $\theta n^2 \times \theta n$  rather than  $n^2 \times n$ . That is,  $\theta$ -BadBox $_n^{\rho}(r, s)_k$  denotes the event that there exist  $r' \in [\![r, r + \theta n^2 - 1]\!]$  and  $s' \in [\![s, s + \theta n - 1]\!]$  such that  $\mathsf{BadCell}_n^{\rho}(r', s')_k$  holds. By a union bound, for any  $0 < \theta < 1$ ,

(70) 
$$\mathbf{P}\left[\mathsf{BadBox}_{n}^{\rho}\right] \leq \left[\frac{1}{\theta^{2}}\right] \mathbf{P}\left[\theta - \mathsf{BadBox}_{n}^{\rho}(0,0)_{0}\right].$$

Thus it suffices to show  $\mathbf{P}[\theta$ -BadBox $_{n}^{\rho}(r,s)_{k}] \to 0$  for some  $\theta > 0$  not depending on n.

For some r, s, k, and  $\theta$  to be given, consider the events  $\theta$ -BadBox<sup> $\rho$ </sup><sub>n</sub> $(r, s)_k$  and

$$\theta\text{-InfectedBox}(r,s)_k := \Big\{ (r',s')_k \in \zeta_k^{(0,0)_0} \text{ for all } r \le r' < r + \theta n^2 \text{ and } s \le s' < s + \theta n \Big\}.$$

If  $\theta$ -InfectedBox $(r, s)_k$  and  $\theta$ -BadBox $_n^{\rho}(r, s)_k$  both occur, then all cells in  $[\![r, r + \theta n^2 - 1]\!] \times [\![s, s + \theta n - 1]\!]$  are infected from  $(0, 0)_0$  at step k, and some cell in this box infects a cell at step n+k at or above row  $s+\rho n$ . Hence BadCell $_{n+k}^{\rho'}(0, 0)_0$  occurs for any  $\rho' \leq (s+\rho n)/(n+k)$ . Restating this conclusion symbolically, for any  $\rho' \leq (s+\rho n)/(n+k)$ ,

(71) 
$$\theta$$
-BadBox $_{n}^{\rho}(r,s)_{k} \subseteq (\theta$ -InfectedBox $(r,s)_{k})^{c} \cup$ BadCell $_{n+k}^{\rho'}(0,0)_{0}$ .

Now, to bound the probability of  $\theta$ -BadBox $_{n}^{\rho}(r,s)_{k}$ , we will bound the failure probability of  $\theta$ -InfectedBox $(r,s)_{k}$  with Lemma 6.1 and bound the probability of BadCell $_{n+k}^{\rho'}(0,0)_{0}$  with (68).

We choose r, s, k, and  $\theta$  now and carry out the proof. First choose  $\eta > 0$  small enough that  $\rho' := \rho/(1+\eta) > \rho_*$ , and let  $k = \lfloor \eta n \rfloor$ . Let  $\pi = \rho_*/2$ . Applying Lemma 6.1 with  $\pi$  playing the role of  $\rho$  and with  $\epsilon = \rho_*/2$ , all cells at step k in the box

$$\mathcal{R}(\pi,\delta) := \left[\!\left[\frac{\pi}{2}(1-\delta)k^2, \, \frac{\pi}{2}(1+\delta)k^2\right]\!\right] \times \left[\!\left[\pi(1-\delta)k, \, \pi(1+\delta)k\right]\!\right]$$

are infected with probability approaching 1 as  $k \to \infty$ , where  $\delta$  is a constant depending only on  $\lambda$  (which determines  $\epsilon$  here). Thus, we set

$$r = \left\lceil \frac{\pi}{2}(1-\delta)k^2 \right\rceil, \quad s = \left\lceil \pi(1-\delta)k \right\rceil, \quad \text{and} \quad \theta = \frac{\delta\pi\eta^2}{2}.$$

Note that r, s, and k depend on n but  $\theta$  is fixed. We have

$$\llbracket r, r + \theta n^2 - 1 \rrbracket \times \llbracket s, s + \theta n - 1 \rrbracket \subseteq \mathcal{R}(\pi, \delta),$$

and hence  $\mathbf{P}[\theta$ -InfectedBox $(r, s)_k] \to 1$  as  $n \to \infty$ . And since  $\rho' > \rho_*$ , we have  $\mathbf{P}[\mathsf{BadCell}_{n+k}^{\rho'}] \to 0$ 0 as  $n \to \infty$ . Since  $\rho' \leq (s + \rho n)/(n + k)$ , we can apply (71) to conclude that

$$\lim_{n \to \infty} \mathbf{P} \big[ \theta \text{-}\mathsf{Bad}\mathsf{Box}_n^\rho(r,s)_k \big] = 0$$

Noting that the probability of  $\theta$ -BadBox $_{n}^{\rho}(r, s)_{k}$  does not depend on  $(r, s)_{k}$  and applying (70) completes the proof. 

Fix a positive integer k and  $\rho_* < \rho' < \rho$  and consider a sequence of cells

(72) 
$$(r_0, s_0)_0, (r_1, s_1)_1, \dots, (r_{jk}, s_{jk})_{jk}$$

that might or might not be an infection path. Typically we let j = |n/k|, so that our potential infection path is a sequence of cells nearly of length n. We will associate with this sequence an object (a, b, c) with  $a = (a_1, \ldots, a_j)$ ,  $b = (b_1, \ldots, b_j)$ , and  $c = (c_1, \ldots, c_j)$  that we call the k-signature of the possible infection path; note that it will also depend on  $\rho'$ .

To summarize the k-signature before we define it, imagine partitioning the cells at step ikof layer percolation into boxes

$$\mathcal{B}_k^i(x,y) = [\![xk^2,(x+1)k^2 - 1]\!] \times [\![yk,(y+1)k - 1]\!], \qquad x \ge 0, \ y \ge 0.$$

For  $i = 0, \ldots, j$ , let  $x_i = \lfloor r_{ik}/k^2 \rfloor$  and  $y_i = \lfloor s_{ik}/k^2 \rfloor$ , so that  $\mathcal{B}_k^i(x_i, y_i)$  specifies the box that (72) goes through at step ik.

- $a_1, \ldots, a_j$  encodes the same information as  $x_1, \ldots, x_j$ , normalized so that the columns of each box are specified relative to the minimal infection path from the previous box:
- $b_1, \ldots, b_j$  encodes the same information as  $y_1, \ldots, y_j$ , normalized as above;
- each  $c_i$  encodes whether the infection path increases in row by an unusual amount from step (i-1)k to step ik, i.e., whether  $s_{ik} - s_{(i-1)k}$  is unusually large.

Eventually, we will bound the probability of the existence of an infection path with a given k-signature. Then, considering all possible choices of  $a_i$  and  $b_i$  and all choices of  $c_i$  consistent with an infection path confirming  $\mathsf{BadCell}_n^{\rho}$ , we will take a union bound over k-signatures. In principle we could work directly with  $x_0, \ldots, x_j$  and  $y_0, \ldots, y_j$  rather than transforming them to define the k-signature, but it will be simpler to work with the transformed version.

Let us define the k-signature now. Fix  $i \in \{1, \ldots, j\}$ . Let  $u_0 = x_{i-1}k^2$  and  $t_0 = y_{i-1}k$ , so that  $(u_0, t_0)_{(i-1)k}$  is the lower-left corner of the box  $\mathcal{B}_k^{i-1}(x_{i-1}, y_{i-1})$  containing cell  $(r_{(i-1)k}, s_{(i-1)k})_{(i-1)k}$ . Let

(73) 
$$(u_0, t_0)_{(i-1)k} \to (u_1, t_0)_{(i-1)k+1} \to \dots \to (u_k, t_0)_{ik}$$

be the minimal infection path starting from  $(u_0, t_0)_{(i-1)k}$ , as defined in Section 5.2. Let  $x_i^{\min} = \lfloor u_k/k^2 \rfloor$  and  $y_i^{\min} = \lfloor t_0/k \rfloor = y_{i-1}$ . Thus  $\mathcal{B}_k^i(x_i^{\min}, y_i^{\min})$  is the lower-left box at step *ik* containing a cell infected starting from within  $\mathcal{B}_k^{i-1}(x_{i-1}, y_{i-1})$  by Lemma 5.6(a). We now define  $a_i = x_i - x_i^{\min}$  and  $b_i = y_i - y_i^{\min} = y_i - y_{i-1}^{\perp}$ . Finally, define  $(c_1, \ldots, c_j)$  by

$$a_i = \mathbf{1}\{s_{ik} - s_{(i-1)k} > \rho'k\} \in \{0, 1\}$$

An arbitrary sequence of cells (72) could have any  $a_1, \ldots, a_n$  and  $b_1, \ldots, b_n$  in its ksignature. But if (72) is truly an infection path, we must have  $a_i \ge 0$  and  $0 \le b_i \le 1$  for all i:

**Lemma 7.3.** If (a, b, c) is the k-signature of an infection path

$$(0,0)_0 = (r_0, s_0)_0 \to (r_1, s_1)_1 \to \cdots \to (r_{jk}, s_{jk})_{jk},$$

then  $a_i \ge 0, b_i \in \{0, 1\}$ , and  $c_i \in \{0, 1\}$  for all  $i \in [1, j]$ .

Proof. Fix *i* and consider the minimal infection path (73) starting from the lower-left corner of the box containing  $(r_{(i-1)k}, s_{(i-1)k})_{(i-1)k}$ . We have  $(r_{ik}, s_{ik})_{ik} \in \zeta_k^{(r_{(i-1)k}, s_{(i-1)k})_{(i-1)k}}$ , and hence  $r_{ik} \ge u_k$  and  $s_{ik} \ge t_0$  by Lemma 5.6(a). By definition of  $a_i$  and  $b_i$ , we have  $a_i \ge 0$ and  $b_i \ge 0$ . And  $b_i \le 1$  because an infection path can move up at most one row in each step, and hence  $s_{ik} - s_{(i-1)k} \le k$ . And  $c_i \in \{0, 1\}$  since it is an indicator by definition.  $\Box$ 

Next, we apply Lemmas 5.6 and 5.7 to show that an infection path starting from a box is unlikely to move too far from the minimal infection path from the box. The point of this is to show that it is unlikely for there to exist an infection path whose k-signature has an especially large  $a_i$ .

**Lemma 7.4.** Given  $x, y \ge 0$ , let  $\mathcal{B}_k^1(x_{\min}, y)$  be the box at step k containing the minimal infection path starting from  $(xk^2, yk)_0$ , the lower-left corner of  $\mathcal{B}_k^0(x, y)$ . For any  $t \ge 0$ , the probability that there is an infection path starting within  $\mathcal{B}_k^0(x, y)$  and ending in some box  $\mathcal{B}_k^1(x', y')$  with  $x' - x_{\min} \ge t$  is at most  $Ce^{-ct}$  for absolute constants c, C > 0.

Proof. Let U be the maximum column infected at step k starting within  $\mathcal{B}_k^0(x, y)$ , and let  $(u_n, yk)_k$  lie on the minimal infection path from  $(xk^2, yk)_0$ . Suppose there is an infection path starting within  $\mathcal{B}_k^0(x, y)$  and ending in box  $\mathcal{B}_k^1(x', y')$  with  $x' - x_{\min} \ge t$ . Then there are at least t-1 boxes strictly between the ones containing columns U and  $u_n$ , and hence  $U-u_n \ge (t-1)k^2$ . Thus it suffices to show that  $\mathbf{P}[U-u_n \ge (t-1)k^2] \le Ce^{-ct}$  for absolute constants c, C. By Proposition 5.9, this can be shown by demonstrating that with U' the maximum column infected starting within  $\mathcal{B}_k^0(0, 0)$ ,

(74) 
$$\mathbf{P}[U' \ge (t-1)k^2] \le Ce^{-ct}.$$

To show this, let

$$(k^2, k)_0 = (r_0, k)_0, \ (r_1, k+1)_1, \ (r_2, k+2)_2, \dots, \ (r_k, 2k)_k$$

be the upper-right cell sequence from  $(k^2, k)_0$ , defined prior to Lemma 5.7. By Lemma 5.7(a), all infection paths starting within  $\mathcal{B}_k^0(0,0)$  arrive in step k at a column bounded by  $r_k$ . And by Lemma 5.7(b), the sequence  $(r_j + j + 1)_{0 \le j \le k}$  is a critical geometric branching process with immigration  $j + 1 \le k + 1$  after each step  $1 \le j \le k$ . Hence  $\mathbf{E}[r_k + k + 1] = k^2 + k(k+1)/2 + k = 3(k^2 + k)/2$ , and

$$\begin{aligned} \mathbf{P}[r_k \ge tk^2] &= \mathbf{P}[r_k + k + 1 - \mathbf{E}[u_k + k + 1] \ge tk^2 + k + 1 - 3(k^2 + k)/2] \\ &\leq \mathbf{P}[r_k + k + 1 - \mathbf{E}[u_k + k + 1] \ge (t - 2)k^2] \\ &\leq C \exp\left(-\frac{c(t - 2)^2k^4}{k(k(k + 1) + k^2 + k + 1 + (t - 2)k^2)}\right) \le C'e^{-c'tk} \le C'e^{-c't} \end{aligned}$$

by Proposition A.1, for absolute constants c' and C', thus establishing (74).

For given sequences  $a = (a_1, \ldots, a_j)$ ,  $b = (b_1, \ldots, b_j)$ , and  $c = (c_1, \ldots, c_j)$ , we write  $\operatorname{Sig}_j(a, b, c)$  (with implicit dependence on k and  $\rho'$ ) to denote the event that there exists an infection path starting from  $(0, 0)_0$  with k-signature (a, b, c) in an underlying layer percolation with parameter  $\lambda > 0$ . We will sometimes write  $\operatorname{Sig}_j(a, b, c)$  with sequences a, b, and c of length greater than j, interpreting them as being truncated at their jth terms. For convenience we interpret  $\operatorname{Sig}_0(a, b, c)$  as the entire probability space.

Our next lemma bounds the probability of  $\text{Sig}_j(a, b, c)$ . Eventually, we will apply this bound via a union bound over all possible k-signatures to complete the proof of Proposition 7.1.

**Proposition 7.5.** Let  $p_k = \mathbf{P}[\mathsf{BadBox}_k^{\rho'}]$ . For absolute constants  $C, \kappa > 0$ , it holds for all sequences a, b, and c satisfying  $a_i \ge 0$  and  $b_i, c_i \in \{0, 1\}$  for all i that

(75) 
$$\mathbf{P}\left[\operatorname{Sig}_{j}(a,b,c)\right] \leq \prod_{i=1}^{j} \min\left(Ce^{-\kappa a_{i}}, p_{k}^{c_{i}}\right).$$

*Proof.* Let  $\mathscr{F}_i$  denote the  $\sigma$ -algebra generated by all information in the underlying layer percolation up to level i, i.e., the  $\sigma$ -algebra generated by the random variables  $R_0, R_1, \ldots$  and  $B^0, B^1, \ldots$  defining the infections from level  $\ell - 1$  to  $\ell$ , for all  $\ell$  from 1 up to i. We will show that

(76) 
$$\mathbf{P}\left[\mathsf{Sig}_{j+1}(a,b,c) \mid \mathscr{F}_{jk}\right] \le \min\left(Ce^{-\kappa a_{j+1}}, p_k^{c_{j+1}}\right),$$

from which the proposition will follow by induction. First, we observe that the information in  $\mathscr{F}_{jk}$  determines the boxes on levels  $1, k, 2k, \ldots, jk$  that an infection path must go through if it is to have k-signature (a, b, c). That is, there is a unique sequence  $(x_1, y_1), \ldots, (x_j, y_j)$ measurable with respect to  $\mathscr{F}_{jk}$  such that if  $(r_{ik}, s_{ik})_{ik}$  is not in  $\mathscr{B}_k^i(x_i, y_i)$  for any  $i \in 1, j$ , then

$$(r_0, s_0)_0, \ldots, (r_{(j+1)k}, s_{(j+1)k})_{(j+1)k}$$

does not have k-signature (a, b, c).

To bound the left-hand side of (76) by  $p_k^{c_{j+1}}$ , we assume  $c_{j+1} = 1$  and must show that

(77) 
$$\mathbf{P}\left[\mathsf{Sig}_{j+1}(a,b,c) \mid \mathscr{F}_{jk}\right] \le p_k.$$

Since  $\operatorname{Sig}_{j+1}(a, b, c)$  can only occur if  $\operatorname{BadBox}_{k}^{\rho'}(x_{j}k^{2}, y_{j}k)_{jk}$  occurs, and this event still has probability  $p_{k}$  after conditioning on  $\mathscr{F}_{jk}$ , we obtain (77).

For the other bound on (75), we observe that if  $\operatorname{Sig}_{j+1,k}(a, b, c)$  occurs, then some cell in  $\mathcal{B}_k^j(x_j, y_j)$  infects a cell at step (j+1)k in a box that is at least  $a_{j+1}$  boxes beyond the box infected by the minimal infection path from  $(x_jk^2, y_jk)_{jk}$ . By Lemma 7.4, the probability of this decays exponentially in  $a_{j+1}$ , completing the proof of (76).

Finally, we observe that if  $\operatorname{Sig}_{j+1,k}(a, b, c)$  holds, then  $\operatorname{Sig}_{j,k}(a, b, c)$  holds. Since  $\operatorname{Sig}_{j,k}(a, b, c)$  is measurable with respect to  $\mathscr{F}_{jk}$ , it follows from (76) that

$$\mathbf{P}\left[\mathsf{Sig}_{j+1,k}(a,b,c)\right] \le \mathbf{P}\left[\mathsf{Sig}_{j,k}(a,b,c)\right] \min\left(Ce^{-\kappa a_{j+1}}, p_k^{c_{j+1}}\right),$$

and now the proposition follows by induction.

We are nearly ready to prove Proposition 7.1, which we will accomplish by summing the bound (75) over all k-signatures that would allow  $\mathsf{BadCell}_n^{\rho}(0,0)_0$  to occur. First we give a technical lemma obtained by summing the right-hand the sum of (75) over all choices of  $a = (a_1, \ldots, a_j)$ .

Lemma 7.6. Let 
$$p_k = \mathbf{P}\left[\mathsf{BadBox}_k^{\rho'}\right]$$
. For fixed  $b, c \in \{0, 1\}^j$ ,  
$$\sum_{a \in \mathbb{N}^j} \mathbf{P}\left[\mathsf{Sig}_{j,k}(a, b, c)\right] \le A^j \left(Bp_k \log\left(\frac{1}{p_k}\right)\right)^{|c|},$$

where A and B are absolute constants and |c| denotes  $\sum_{j=1}^{j} c_j$ .

*Proof.* Applying Proposition 7.5, we bound

$$\sum_{a \in \mathbb{N}^j} \mathbf{P} \big[ \mathsf{Sig}_{j,k}(a,b,c) \big] \le \sum_{a \in \mathbb{N}^j} \prod_{i=1}^j \min \big( Ce^{-\kappa a_i}, p_k^{c_i} \big) = \prod_{i=1}^j \sum_{\ell=0}^\infty \min \big( Ce^{-\kappa\ell}, p_k^{c_i} \big)$$

Regardless of  $c_i$ ,

$$\sum_{\ell=0}^{\infty}\min\left(Ce^{-\kappa\ell},\,p_k^{c_i}\right)\leq \sum_{a_i=0}^{\infty}Ce^{-\kappa\ell}\leq A,$$

where  $1 \leq A < \infty$  is an absolute constant. If  $c_i = 1$ , then we let  $L = \lceil \log(C/p_k)/\kappa \rceil$  and break the sum in two parts at L to obtain

(78) 
$$\sum_{\ell=0}^{\infty} \min\left(Ce^{-\kappa\ell}, p_k^{c_i}\right) \le Lp_k + \sum_{\ell=L}^{\infty} Ce^{-\kappa\ell} \le Lp_k + \frac{p_k}{1 - e^{-\kappa}} \le Bp_k \log(1/p_k)$$

for an absolute constant B. Thus we obtain

$$\sum_{a \in \mathbb{N}^j} \mathbf{P} \left[ \mathsf{Sig}_{j,k}(a,b,c) \right] \le A^{j-|c|} (Bp_k \log(1/p_k))^{|c|}.$$

Proof of Proposition 7.1. If  $\rho > 1$ , then the proposition holds trivially since the infection set can move upward by at most one row per step, and hence  $X_n \leq n$  a.s. Thus we can assume that  $\rho_* < \rho \leq 1$ .

First, we choose  $\rho' \in (\rho_*, \rho)$  and  $\beta \in (0, 1)$  sufficiently small that  $(1 - \beta)\rho' + \beta < \rho$ . To be concrete, take  $\rho' = (\rho_* + \rho)/2$  and  $\beta = (\rho - \rho_*)/(4 - 2\rho - 2\rho_*)$ , which yields

$$(1-\beta)\rho' + \beta = \frac{\rho_* + 3\rho}{4} < \rho.$$

Fix an integer k to be specified later, and let  $j = \lfloor n/k \rfloor$ .

Suppose an infection path of length jk starting from  $(0,0)_0$  has k-signature (a, b, c) with  $|c| \leq \beta j$ . From step (i-1)k to ik, the infection path increases in row by at most  $\rho'k$  if  $c_i = 0$  and by at most k if  $c_i = 1$ . Thus at step jk, the infection path is at row at most

$$(j - |c|)\rho'k + |c|k \le (1 - \beta)\rho'n + \beta n \le \frac{\rho_* + 3\rho}{4}n.$$

If the infection path continues to step n, it can reach at most k rows higher, which is still less than  $\rho n$  assuming  $n \ge n_0(\rho, k)$ . Thus we conclude that  $\mathsf{BadCell}_n^{\rho}(0,0)_0$  can occur only if  $\mathsf{Sig}_{i,k}(a,b,c)$  occurs for  $|c| > \beta j$ . Now by a union bound,

$$\mathbf{P}\left[\mathsf{BadCell}_{n}^{\rho}(0,0)_{0}\right] \leq \sum_{\substack{c \in \{0,1\}^{j} \\ |c| > \beta j}} \sum_{b \in \{0,1\}^{j}} \sum_{a \in \mathbb{N}^{j}} \mathbf{P}\left[\mathsf{Sig}_{j,k}(a,b,c)\right] \leq \sum_{\substack{c \in \{0,1\}^{j} \\ |c| > \beta j}} 2^{j} A^{j} \left(Bp_{k} \log\left(\frac{1}{p_{k}}\right)\right)^{|c|},$$

applying Lemma 7.6 and summing over the  $2^j$  values of  $b \in \{0, 1\}^j$ . By Lemma 7.2, we can choose k large enough that

$$4A\left(Bp_k\log\left(\frac{1}{p_k}\right)\right)^{\beta} \le 1/2.$$

Applying this bound and summing over the at most  $2^j$  values of  $c \in \{0, 1\}^j$  with  $|c| > \beta j$ ,

$$\mathbf{P}\left[\mathsf{BadCell}_n^{\rho}(0,0)_0\right] \le (4A)^j \left(Bp_k \log\left(\frac{1}{p_k}\right)\right)^{\beta j} \le 2^{-j} \le 2^{-n/k}$$

for all  $n \ge n_0(\rho, k)$ . Since our choice of k depended only on  $\rho$  and  $\lambda$ , we have proven the theorem.

#### 8. Establishing the critical values

We now translate our results on layer percolation back to odometers to prove the paper's main results. We prove lower bounds on critical values by constructing stable odometers leaving density  $\rho_* - \epsilon$ , and we prove upper bounds by showing nonexistence of stable odometers leaving a density of  $\rho_* + \epsilon$ . For the constructions, the proof is slightly different for each model. In Section 8.1, we prove a few simple lemmas that we will use together with Lemma 6.1 to construct odometers. Next in Section 8.2 we prove a very general nonexistence proof, from which the upper bounds for each individual model follow easily. Then in Section 8.3 we apply these results to the different models of ARW. Once we are done proving equality of all the critical values, we prove upper and lower bounds on  $\rho_*$  in Section 8.4 that hence extend to  $\rho_{\text{DD}}$ ,  $\rho_{\text{FE}}$ , and  $\rho_{\text{CY}}$ .

8.1. Odometer construction tools. Any extended odometer on  $[\![0,n]\!]$  obtained from a length n infection path in layer percolation is automatically stable on  $[\![1, n-1]\!]$ . In the next lemma, we give a criterion for stability at n.

**Lemma 8.1.** Consider an extended odometer  $u \in \mathcal{O}_n(\operatorname{Instr}, \sigma, u_0, f_0)$  on [0, n] corresponding to an infection path  $(0, 0)_0 = (r_0, s_0)_0 \to \cdots (r_n, s_n)_n$  in  $\mathcal{I}_n(\operatorname{Instr}, \sigma, u_0, f_0)$  under the map  $\Phi$ from Section 4. Let  $\mathfrak{m}$  be the minimal odometer of  $\mathcal{O}_n(\operatorname{Instr}, \sigma, u_0, f_0)$ . Then u is stable at n if and only if

(79) 
$$r_n = f_0 + \sum_{v=1}^n |\sigma(v)| - \mathcal{R}_n(\mathfrak{m}) - s_n.$$

*Proof.* Let  $f_v = \mathcal{R}_v(u) - \mathcal{L}_{v+1}(u)$ . Since u is stable on  $[\![1, n-1]\!]$ , we have

(80) 
$$f_v = f_0 + \sum_{i=1}^{v} |\sigma(i)| - s_v$$

for all  $v \in [0, n-1]$  by Lemma 4.1 together with the definition of  $\Phi$ . By Lemma 4.1 again, it is stable at n as well if and only if (80) also holds for v = n. Here  $f_n = \mathcal{R}_n(u)$  since u(n+1) = 0, and so (80) for v = n states that

$$\mathcal{R}_n(u) = f_0 + \sum_{i=1}^n |\sigma(i)| - s_n$$

And since  $\mathcal{R}_n(u) = \mathcal{R}_n(\mathfrak{m}) + r_n$  under the correspondence given by  $\Phi$ , this statement holds if and only if (79) does.

Reordering and labeling (79) makes its similarity to Definition 2.2 more apparent:

$$\sum_{v=1}^{n} |\sigma(v)| + \underbrace{f_0}_{B} - \underbrace{\left(r_n + \mathcal{R}_n(\mathfrak{m})\right)}_{C} = \underbrace{s_n}_{D}$$

Term A is the number of particles starting on  $[\![1,n]\!]$ . Terms B and C record the flow into  $[\![1,n]\!]$  from 0 and the flow out  $[\![1,n]\!]$  from n, respectively. And term D is the number of particles ending on  $[\![1,n]\!]$ .

Layer percolation produces extended odometers that may include meaningless negative values. We will use the following lemmas to show that the ones we generate do not take negative values and hence can be used to invoke the least-action principle. **Lemma 8.2.** Suppose that u is an extended odometer on [0, n] stable on [1, n - 1]. Let  $f_v = \mathcal{R}_v(u) - \mathcal{L}_{v+1}(u)$ , the net flow from v to v + 1 under the odometer, as in Lemma 4.1.

- (a) For any  $v \in [0, n-1]$ , if  $u(v) \le 0$  and  $f_v \ge 1$  then u(v+1) < 0.
- (b) For any  $v \in [\![1,n]\!]$ , if u(v) < 0 and  $f_{v-1} \le 0$ , then u(v-1) < 0.

*Proof.* Suppose  $u(v) \leq 0$  and  $f_v \geq 1$  for some  $v \in [[0, n-1]]$ . Then  $\mathcal{R}_v(u) \leq 0$  and  $\mathcal{R}_v(u) - \mathcal{L}_{v+1}(u) \geq 1$ . Thus  $\mathcal{L}_{v+1}(u) \leq \mathcal{R}_v(u) - 1 \leq -1$ , implying u(v+1) < 0 and proving (a).

Similarly, suppose u(v) < 0 and  $f_{v-1} \leq 0$  for some  $v \in [\![1,n]\!]$ . Then  $\mathcal{L}_v(u) \leq -1$ (recall that  $\mathcal{L}_v(u)$  is strictly negative whenever u(v) is), and  $\mathcal{R}_{v-1}(u) - \mathcal{L}_v(u) \leq 0$ , yielding  $\mathcal{R}_{v-1}(u) \leq -1$ . Thus u(v-1) < 0, proving (b).

Now we show that if an extended odometer is nonnegative at its endpoints and can be broken up into an interval of negative flow followed by an interval of positive flow, then it is nonnegative everywhere.

**Lemma 8.3.** Let u be an extended odometer on [0,n] stable on [1, n-1] with  $u(0) \ge 0$  and  $u(n) \ge 0$ . Let  $f_v = \mathcal{R}_v(u) - \mathcal{L}_{v+1}(u)$ . Suppose there exists k such that  $f_v \le 0$  for  $0 \le v < k$  and  $f_v \ge 1$  for  $k \le v \le n$ . Then  $u(v) \ge 0$  for all  $v \in [0,n]$ .

*Proof.* Suppose u(v) < 0 for some  $v \in [\![1, n-1]\!]$ . If  $v \ge k$ , then repeated application of Lemma 8.2(a) shows that u(i) < 0 for all  $v \le i \le n$ , a contradiction since  $u(n) \ge 0$ . If v < k, then repeated application of Lemma 8.2(b) shows that u(i) < 0 for all  $0 \le i \le v$ , a contradiction since  $u(0) \ge 0$ .

8.2. Nonexistence of stable odometers above the critical density. In this section we obtain an exponential bound on the probability of activated random walk leaving a high density of particles on an interval, starting from *any* initial configuration:

**Theorem 8.4.** Consider activated random walk with sleep rate  $\lambda > 0$ . Let  $\sigma$  be an initial configuration with no sleeping particles on [0,n]. Let  $Y_n$  be the number of particles left sleeping on [0,n] in the stabilization of  $\sigma$  on [0,n]. For any  $\rho > \rho_*(\lambda)$ ,

$$\mathbf{P}[Y_n \ge \rho n] \le C e^{-cn}$$

where C, c are positive constants depending on  $\lambda$  and  $\rho$  but not on n or  $\sigma$ .

*Proof.* Proposition 7.1 establishes that it is unlikely there is an infection set starting at  $(0,0)_0$  going beyond row  $\rho_*n$  in n steps. Such infection paths correspond to odometers in  $\mathcal{O}_n(\mathsf{Instr},\sigma,u_0,f_0)$  leaving more than  $\rho_*n$  sleeping particles on  $[\![1,n]\!]$ , according to Proposition 4.6. The idea of this proof is to take a union bound on the existence of such an odometer over all choices of  $u_0$  and  $f_0$ , applying Proposition 7.1 when  $u_0$  is small and using an alternate bound when  $u_0$  is large.

To start, we may assume without loss of generality that  $\sigma$  places 0 or 1 particle at each site, since we can topple each site with two or more particles until no such sites exist.

For any integer  $f_0$ , nonnegative integer  $u_0$ , and configuration  $\sigma$  in which all particles are active, let  $\mathsf{Stable}_{n,\rho}(\sigma, u_0, f_0)$  be the event that there exists an odometer u on  $\llbracket 0, n \rrbracket$  stable on  $\llbracket 1, n-1 \rrbracket$  for initial configuration  $\sigma$  with  $u(0) = u_0$  and  $\mathcal{R}_0(u) - \mathcal{L}_1(u) = f_0$  and

$$\sum_{v=1}^n \mathbf{1}\big\{\mathsf{Instr}_v(u(v)) = \mathtt{sleep}\big\} \geq \rho n,$$

with  $(\mathsf{Instr}_v)_{v \in [0,n]}$  the instructions for activated random walk with sleep rate  $\lambda > 0$ .

We claim that

(81) 
$$\mathbf{P}[\mathsf{Stable}_{n,\rho}(\sigma, u_0, f_0)] \le Ce^{-cn}$$

for constants c and C depending only on  $\lambda$  and  $\rho$ , not on  $\sigma$ ,  $u_0$ , and  $f_0$ . Indeed, if  $\mathsf{Stable}_{n,\rho}(\sigma, u_0, f_0)$  holds, then by Proposition 4.6 and Corollary 4.14 the infection set  $\zeta_n = \zeta_n^{(0,0)_0}$  in a coupled instance of layer percolation contains a cell in row  $\lceil \rho n \rceil$ , thus proving (81) by Proposition 7.1.

Suppose that  $Y_n \ge \rho n$ , and let  $u_*$  be the true odometer stabilizing  $\sigma$  on  $[\![0,n]\!]$ . Then  $u_*$  is stable on  $[\![0,n]\!]$  and leaves at least  $\rho n - 1$  particles on  $[\![1,n]\!]$ . Hence  $\mathsf{Stable}_{n,\rho'}(\sigma, u_0, f_0)$  occurs for  $\rho' = \rho - \frac{1}{n}$  and some  $u_0$  and  $f_0$ . Note that for  $n \ge n_0$ , where  $n_0$  is a constant depending only on  $\lambda$  and  $\rho$ , we have  $\rho' > \rho_*(\lambda)$ . Since there is at most one particle on each site initially, we have  $-(n-1) \le f_0 \le 1$ . All together, we can say that if  $Y_n \ge \rho n$ , then either the event

(82) 
$$\bigcup_{\substack{0 \le u_0 \le 4(1+\lambda)n \\ -(n-1) \le f_0 \le 1}} \operatorname{Stable}_{n,\rho'}(\sigma, u_0, f_0)$$

occurs, or  $u_*(0) > 4(1+\lambda)n$ . By (81) and a union bound, the probability of (82) is at most  $C'e^{-c'n}$  for constants c, C' depending only on  $\lambda$  and  $\rho$ .

Now consider the event that  $u_*(0) > 4(1 + \lambda)n$ . Since there are at most n + 1 particles initially on the interval, we always have  $\mathcal{L}_0(u_*) \leq n + 1$ . Thus  $u_*(0) > 4(1 + \lambda)n$  can occur only if there are at most n + 1 left instructions within  $\mathsf{Instr}_0(1), \ldots, \mathsf{Instr}_0(\lceil 4(\lambda + 1)n \rceil)$ . Thus we have bounded  $\mathbf{P}[u_*(0) > 4(1 + \lambda)n]$  by

$$\mathbf{P}\left[\operatorname{Bin}\left(\left\lceil 4(\lambda+1)n\right\rceil,\frac{1}{2(\lambda+1)}\right)\leq n+1\right],$$

which by Hoeffding's inequality is at most  $e^{-c''n}$  with c'' depending only on  $\lambda$ . Together with our bound on the probability of (82), this completes the proof.

8.3. All critical densities are equal to  $\rho_*$ . We now apply our results to give upper and lower bounds on the critical densities of each of the four models discussed in Section 1.2. For the lower bounds for the driven-dissipative and point-source models, we use layer percolation to produce stable odometers leaving a density of  $\rho_* - \epsilon$ . We then derive the lower bounds for the fixed-energy and cyclic models from the point-source model bound. For the upper bounds, we apply Theorem 8.4 to each model.

8.3.1. Driven-dissipative model. We start with the lower bound on the density under the invariant distribution of the driven-dissipative model. We note that we can work directly with this invariant distribution: as proven by Levine and Liang in [LL21], the stabilization of a region starting with an initial configuration of a single active particle at every site exactly has this invariant distribution.

**Proposition 8.5.** Let  $S_n$  be distributed as the number of sleeping particles under the invariant distribution of the driven-dissipative Markov chain on [0, n]. For any  $\rho < \rho_*(\lambda)$ ,

$$\mathbf{P}[S_n \ge \rho(n+1)] \ge 1 - Ce^{-cn}$$

for constants c, C > 0 depending only on  $\lambda$  and  $\rho$ .

*Proof.* Let  $\sigma$  be the initial configuration placing one active particle on each site in  $[\![0, n]\!]$ . By [LL21, Theorem 1], after stabilization this model has the invariant distribution of the driven-dissipative model on  $[\![0, n]\!]$ . Let  $f_0 = -\lfloor (1-\rho)(n+1)/2 \rfloor + 1$ . Choose  $u_0$  to be the smallest value so that the first  $u_0$  instructions at site 0 include  $-f_0 + 1$  left instructions, which according to Proposition 4.15 will make all odometers in  $\mathcal{O}_n(\text{Instr}, \sigma, u_0, f_0)$  stable at 0. We will now construct an odometer  $u \in \mathcal{O}_n(\text{Instr}, \sigma, u_0, f_0)$  stable at n with  $\mathcal{R}_n(u) = -f_0 + 1$ . By Lemma 2.3, the true odometer stabilizing [0, n] thus ejects at most density  $1 - \rho$  of particles and hence retains at least density  $\rho$ .

We say that an event holds with overwhelming probability (w.o.p.) if its probability is bounded for all n by  $Ce^{-cn}$ , where c and C may depend on  $\lambda$  and  $\rho$ . Let  $\mathfrak{m}$  be the minimal odometer of  $\mathcal{O}_n(\mathsf{Instr}, \sigma, u_0, f_0)$ . We claim that  $\mathcal{R}_n(\mathfrak{m})$  is concentrated around  $-\rho n^2/2$  at a quadratic scale, i.e., for any constant  $D = D(\lambda, \rho) > 0$ ,

(83) 
$$\left|\mathcal{R}_n(\mathfrak{m}) + \rho n^2/2\right| \le Dn^2 \text{ w.o.p.}$$

To prove this claim, we apply Proposition 5.8 conditionally on  $u_0$  to show that  $\mathcal{R}_n(\mathfrak{m})$  is concentrated around

(84) 
$$\frac{u_0}{2(1+\lambda)} + \sum_{i=1}^n \left(-f_0 - i\right) = \frac{u_0}{2(1+\lambda)} + \left(\left\lfloor\frac{(1-\rho)(n+1)}{2}\right\rfloor + 1\right)n - \frac{n(n+1)}{2}$$

Since  $u_0$  is a sum of  $|f_0| + 1$  independent geometric random variables, we have  $u_0/2(1+\lambda) < Dn^2/3$  w.o.p. by [Jan18, Theorem 2]. The rest of the right-hand side of (84) is within O(n) of  $-\rho n^2/2$ . By Proposition 5.8, with overwhelming probability  $\mathcal{R}_n(\mathfrak{m})$  is within  $Dn^2/3$  of (84). Hence  $\mathcal{R}_n(\mathfrak{m})$  is within  $2Dn^2/3 + O(n)$  of  $-\rho n^2/2$  w.o.p., proving (83).

Now we construct our odometer u stable at n with  $\mathcal{R}_n(u) = -f_0 + 1$ . Let

$$r = -f_0 + 1 - \mathcal{R}_n(\mathfrak{m})$$
 and  $s = 2f_0 + n - 1$ .

According to Proposition 4.6 and Corollary 4.14, it suffices to construct an infection path in  $\mathcal{I}_n(\mathsf{Instr}, \sigma, u_0, f_0)$  ending at cell  $(r, s)_n$ . For an odometer  $u \in \mathcal{O}_n(\mathsf{Instr}, \sigma, u_0, f_0)$  in correspondence with this infection path, the condition on r makes  $\mathcal{R}_n(u) = r + \mathcal{R}_n(\mathfrak{m}) = -f_0 + 1$ , and Lemma 8.1 makes u stable at n.

Let  $\delta = \delta(\epsilon)$  be the constant from Lemma 6.1, with  $\epsilon = \min(\rho_* - \rho, \rho)/2$ . Setting  $D = \delta/2$ and applying (83), it holds with overwhelming probability that  $\mathcal{R}_n(\mathfrak{m})$  is within  $(\delta/2)n^2$  of  $-\rho n^2/2$ . Since  $-f_0 + 1 = O(n)$ , we have r within  $\delta n^2$  of  $\rho n^2/2$  w.o.p. Since  $s \leq \rho' n$  for  $\epsilon \leq \rho < \rho' \leq \rho_* - \epsilon$ , the infection set  $\zeta_n^{(0,0)_0}$  contains  $(r,s)_n$  w.o.p. by Lemma 6.1, yielding the desired infection path ending at  $(r,s)_n$ .

To summarize, we have produced an infection path such that any corresponding extended odometer  $u \in \mathcal{O}_n(\operatorname{Instr}, \sigma, u_0, f_0)$  is stable on  $[\![0, n]\!]$  and leaves at least  $s \ge \rho(n+1)$  particles on  $[\![1, n]\!]$ . The proof follows from Lemma 2.5 once we show that  $u(v) \ge 0$  for all v. Since  $\mathcal{L}_0(u)$  and  $\mathcal{R}_0(n)$  are positive, we have u(0) > 0 and u(n) > 0. Let  $f_v = \mathcal{R}_v(u) - \mathcal{L}_{v+1}(u)$ , consistent with the definition of  $f_0$ . By Lemma 4.1 and our choice of  $\sigma$ , we have  $f_0 \le \cdots \le f_{n-1}$ . Hence  $u(v) \ge 0$  for all v by Lemma 8.3. Thus u is an odometer and not just an extended odometer, and the proof is complete.

The upper bound on the density is just a special case of Theorem 8.4:

**Proposition 8.6.** Let  $S_n$  be distributed as the number of particles under the invariant distribution of the driven-dissipative Markov chain on an interval of length n. For any  $\rho > \rho_*(\lambda)$ ,

$$\mathbf{P}[S_n \le \rho n] \ge 1 - Ce^{-cn}$$

for constants C, c depending only on  $\lambda$  and  $\rho$ .

*Proof.* Let  $\sigma$  be the initial configuration placing one active particle on each site of the interval. By [LL21, Theorem 1], after stabilization this model has the invariant distribution of the driven-dissipative model on the interval. The result then follows immediately from Theorem 8.4.

8.3.2. *Point-source model.* The lower bound on density for the point-source model is similar to that of the driven-dissipative model, though it is a bit more work to construct the odometer. Note that the lower bound on density for the point-source model is expressed as an upper bound on the spread of a fixed number of particles starting at the origin.

**Proposition 8.7.** Let  $[\![A_N, B_N]\!]$  be the smallest interval containing all sites ever visited by a particle in the point-source model on  $\mathbb{Z}$  with N particles. For any  $\epsilon > 0$ ,

$$\mathbf{P}\left[\llbracket A_N, B_N \rrbracket \subseteq \left[ \begin{bmatrix} -\frac{N}{2(\rho_* - \epsilon)}, & \frac{N}{2(\rho_* - \epsilon)} \end{bmatrix} \right] \ge 1 - Ce^{-cN}$$

for constants c, C > 0 depending only on  $\lambda$  and  $\epsilon$ .

*Proof.* Let our initial configuration  $\sigma$  consist of N active particles at site 0 and no particles elsewhere. We will choose  $n \approx N/2(\rho_* - \epsilon)$  and construct a stable odometer on [-(n + 1), n + 1].

We say that an event holds with overwhelming probability (w.o.p.) if its probability is bounded for all N by  $Ce^{-cN}$ , where c and C may depend on  $\epsilon$  and  $\lambda$ . In our construction of an odometer, we will want the first instruction on the stack at sites n + 1 and -(n + 1)to be **sleep**. Thus we define n as the largest integer such that

$$\operatorname{Instr}_{n+1}(1) = \operatorname{Instr}_{-(n+1)}(1) = \operatorname{sleep} \quad \text{and} \quad n \leq \frac{N}{2(\rho_* - \epsilon/2)}$$

Since  $\operatorname{Instr}_{v}(1) = \operatorname{sleep}$  with probability  $\lambda/(1+\lambda)$ , independently for each v,

(85) 
$$n \ge \frac{(1 - \epsilon/4)N}{2(\rho_* - \epsilon/2)} \ge \frac{N}{2(\rho_* - \epsilon/4)}$$
 w.o.p.

Note that we have revealed information only about the instructions at site v for |v| > n; we have not imparted any conditioning on  $\mathsf{Instr}_{-n}, \ldots, \mathsf{Instr}_{n}$ .

Now we use layer percolation to construct our odometer u. We will make it so that  $\mathcal{L}_{-n}(u) = \mathcal{R}_n(u) = 1$ , and then we set u(-n-1) = u(n+1) = 1 so that single particles are sent to -n-1 and to n+1 and then sleep there. We construct u so that the remaining N-2 particles sleep on  $[\![-n,n]\!]$ . Since our notation is set up to construct odometers on an interval from 0 to a positive number, we let  $\mathsf{Instr}'_v = \mathsf{Instr}_{v-n}$  and  $\sigma'(v) = \sigma(v-n)$  and construct an odometer in  $\mathcal{O}_{2n}(\mathsf{Instr}', \sigma', u_0, f_0)$ . From now on,  $\mathcal{L}_{\cdot}(\cdot)$  and  $\mathcal{R}_{\cdot}(\cdot)$  will use  $\mathsf{Instr}'_v$  rather than  $\mathsf{Instr}$ .

Let  $f_0 = -1$  and choose  $u_0$  to be the index of the first left instruction after index 0 in  $\operatorname{Instr}'_0$ . Let  $\rho = (N-2)/2n$ , observing that  $\rho \leq \rho_* - \epsilon/4$  w.o.p. by (85) and let  $\delta = \delta(\epsilon/4)$  be the constant from Lemma 6.1. Let  $\mathfrak{m}$  be the minimal odometer of  $\mathcal{O}_{2n}(\operatorname{Instr}', \sigma', u_0, f_0)$ . According to Proposition 5.8, the value of  $\mathcal{R}_{2n}(\mathfrak{m})$  is concentrated around

$$\frac{u_0}{2(1+\lambda)} + \sum_{i=1}^{2n} \left( -f_0 - N\mathbf{1}\{i \ge n\} \right) = \frac{u_0}{2(1+\lambda)} - 2\rho n^2$$

Since  $u_0 \sim \text{Geo}(1/2(1+\lambda))$ , we have  $u_0 \leq n$  w.o.p. By Proposition 5.8, the value of  $\mathcal{R}_{2n}(\mathfrak{m})$  is within  $(\delta/2)(2n)^2$  of  $-2\rho n^2$  w.o.p.

By Corollary 4.14, the set  $\mathcal{I}_{2n}(\mathsf{Instr}', \sigma', u_0, f_0)$  is distributed as the set of length 0 infection paths in layer percolation. Let s = N - 2 and let

(86) 
$$r = f_0 + \sum_{v=1}^{2n} |\sigma'(v)| - \mathcal{R}_{2n}(\mathfrak{m}) - s = 1 - \mathcal{R}_{2n}(\mathfrak{m}).$$

Now r is within  $\delta(2n)^2$  of  $2\rho n^2$ , and by Lemma 6.1 the infection set  $\zeta_{2n}^{(0,0)_0}$  contains  $(r,s)_{2n}$  w.o.p. Thus there is an infection path in  $\mathcal{I}_{2n}(\mathsf{Instr}', \sigma', u_0, f_0)$  ending at  $(r,s)_{2n}$  w.o.p. By Proposition 4.6, this infection path has a corresponding extended odometer  $u' \in \mathcal{O}_{2n}(\mathsf{Instr}', \sigma', u_0, f_0)$  stable on [1, 2n-1] with  $\mathcal{R}_{2n}(u) = r + \mathcal{R}_{2n}(\mathfrak{m}) = 1$ . By Lemma 8.1 and (86), the odometer u' is stable at 2n. And it is stable at 0 by Proposition 4.15.

To see that u' takes nonnegative values, observe that since  $\mathcal{L}_0(u') > 0$  and  $\mathcal{R}_{2n}(u') > 0$ , we have u'(0) > 0 and u'(2n) > 0. Let  $f_v = \mathcal{R}_v(u') - \mathcal{L}_{v+1}(u')$ . By Lemma 4.1, we have  $f_v \leq -1$  for  $v \leq -1$  and  $f_v \geq 1$  for  $v \geq 0$ . Hence  $u'(v) \geq 0$  for all  $v \in [0, 2n]$  by Lemma 8.3.

By Lemma 2.3, with overwhelming probability the stabilization of  $[\![0, 2n]\!]$  using instructions  $\mathsf{Instr}'$  sends at most one particle to site -1 and at most one particle to site 2n + 1. Shifting back to  $[\![-n, n]\!]$ , we have shown that with overwhelming probability the stabilization of  $[\![-n, n]\!]$  sends at most one particle to site -n - 1 and at most one particle to site n + 1. Since  $\mathsf{Instr}_{-n-1}(1) = \mathsf{Instr}_{n+1}(1) = \mathsf{sleep}$ , no particle moves to the left of -n - 1 or to the right of n + 1, showing that  $A_n \ge -n - 1$  and  $B_N \le n + 1$  w.o.p., thus completing the proof since  $n \le \frac{N}{2(\rho_* - \epsilon/2)}$ .

And now we give the upper bound on density:

**Proposition 8.8.** Let  $[\![\tilde{A}_N, \tilde{B}_N]\!]$  be the smallest interval containing all sleeping particles after stabilization in the point-source model on  $\mathbb{Z}$  with N particles. For any  $\epsilon > 0$ ,

$$\mathbf{P}\left[ \llbracket \tilde{A}_N, \tilde{B}_N \rrbracket \supseteq \left[ \left[ -\frac{N}{2(\rho_* + \epsilon)}, \frac{N}{2(\rho_* + \epsilon)} \right] \right] \ge 1 - Ce^{-cN}$$

for constants c, C > 0 depending only on  $\lambda$  and  $\epsilon$ .

*Proof.* Let  $\sigma$  denote the configuration placing N particles at 0 and none elsewhere. Let  $u_*$  be the true odometer on  $\mathbb{Z}$  obtained by stabilizing  $\sigma$ . If  $|\tilde{A}_N| \leq N/2(\rho_* + \epsilon)$ , then one of the following events occurs:

- (i)  $\tilde{B}_N > N/2(\rho_* \epsilon/2);$
- (ii)  $|\tilde{A}_N| \leq N/2(\rho_* + \epsilon)$  and  $\tilde{B}_N \leq N/2(\rho_* \epsilon/2)$ .

The probability of (i) vanishes exponentially by Proposition 8.7. If (ii) occurs, then the density after stabilization is  $N/(\tilde{A}_N + \tilde{B}_N + 1) \ge \rho_* + \delta$  for some constant  $\delta > 0$  depending on  $\lambda$  and  $\epsilon$ . By Theorem 8.4, the probability of this event decays exponentially in N with the rate depending only on  $\lambda$  and  $\epsilon$ . This confirms that the probability that  $|\tilde{A}_N| \le N/2(\rho_* + \epsilon)$  decays exponentially. By symmetry, the same holds for the probability that  $\tilde{B}_N \le N/2(\rho_* + \epsilon)$ , completing the proof.

**Corollary 8.9** (Conjecture 1 from [LS23] for d = 1). Let  $[\![A_N, B_N]\!]$  be the smallest interval containing all sites visited until stabilization in the point-source model on  $\mathbb{Z}$  with N particles. For any  $\epsilon > 0$ ,

$$\mathbf{P}\left[\left[\left[-\frac{N}{2(\rho_*+\epsilon)}, \frac{N}{2(\rho_*+\epsilon)}\right]\right] \subseteq \left[\left[A_N, B_N\right]\right] \subseteq \left[\left[-\frac{N}{2(\rho_*-\epsilon)}, \frac{N}{2(\rho_*-\epsilon)}\right]\right]\right] \ge 1 - Ce^{-cN}$$

for constants c, C > 0 depending only on  $\lambda$  and  $\epsilon$ .

*Proof.* The smallest interval containing all sleeping particles after fixation is contained in the smallest interval containing all sites visited. Thus the conjecture follows directly from Proposition 8.7 and Proposition 8.8.

8.3.3. Fixed-energy model on  $\mathbb{Z}$ . It suffices to consider activated random walk on  $\mathbb{Z}$  with an i.i.d. Bernoulli( $\rho$ )-distributed number of particles initially at each site. By the main result of [RSZ19], if this Bernoulli configuration fixates or remains active almost surely for a given  $\rho$ , then the same behavior occurs for any stationary configuration with mean  $\rho$ .

**Proposition 8.10.** If  $\rho > \rho_*$ , then the fixed-energy model almost surely remains active.

*Proof.* Consider the stabilization of the i.i.d. Bernoulli( $\rho$ ) initial configuration on  $[\![-n, n]\!]$ , and let  $M_n$  be the number of particles starting in  $[\![-n, n]\!]$  that terminate at the sinks -n-1 and n+1. [Rol20, Theorem 2.11] states that if

(87) 
$$\limsup_{n \to \infty} \frac{\mathbf{E}M_n}{2n+1} > 0,$$

then the fixed-energy system on  $\mathbb{Z}$  stays active a.s.

Let  $|\sigma_n|$  be the total number of particles starting in  $[\![-n,n]\!]$  and  $S_n$  be the number of particles sleeping in  $[\![-n,n]\!]$  once the system stabilizes. Since mass is conserved,  $M_n = |\sigma_n| - S_n$ . Fix  $0 < \delta < \rho - \rho_*$ . We will show that  $|\sigma_n| - S_n$  is larger than  $\delta n$  with exponentially high probability, establishing (87) and, thus, the desired result.

Observe that  $|\sigma_n| \sim \text{Bin}(2n+1,\rho)$ . Let  $\text{ManyParticles}_n$  be the event that  $|\sigma_n| \ge (\rho_* + \delta)(2n+1)$ . A standard concentration estimate ensures that

$$\mathbf{P}(\mathsf{ManyParticles}_n) \geq 1 - Ae^{-an}$$

for positive constants A and a that depend only on  $\delta$ . Define  $\mathsf{FewSleepers}_n$  to be the event that  $S_n \leq \rho_* + \delta/2$ . It follows from Theorem 8.4 that

 $\mathbf{P}(\mathsf{FewSleepers}_n \mid \mathsf{ManyParticles}_n) \geq 1 - Be^{-bn}$ 

for positive constants B and b that depend only on  $\delta$  and  $\lambda$ . Since  $M_n = |\sigma_n| - S_n$ , on the event  $\mathsf{ManyParticles}_n \cap \mathsf{FewSleepers}_n$  we have  $M_n \ge \delta n$ . Thus,  $\mathbf{P}(M_n \ge \delta n) \ge 1 - Ce^{-cn}$  for positive constants C and c that depend only on  $\delta$ . This implies that

$$\limsup_{n \to \infty} \frac{\mathbf{E}M_n}{2n+1} \ge \delta/2.$$

**Proposition 8.11.** If  $\rho < \rho_*$ , then the fixed-energy model almost surely fixates.

*Proof.* Fix an odd positive integer k. Partition  $\mathbb{Z}$  into successive intervals ...,  $I_{-1}$ ,  $I_0$ ,  $I_1$ , ... where  $|I_n| = k(2|n| + 1)$ , and let  $x_n$  be the integer at the center of  $I_n$ . Declare the points  $x_n$  to be sources. The idea will be to first let all particles move as random walks with no interaction until they reach a source; this only increases the odometer since we are awakening particles whenever they sleep. We then allow ARW to run as usual. By applying Proposition 8.7, we will show that for sufficiently large k, it holds with positive probability that the particles at each source fall asleep without interacting with particles from any other source. Thus the fixed-energy model fixates with positive probability, and by the zero-one law [Rol20, Theorem 2.7] it fixates a.s.

To carry out this plan, fix  $n \in \mathbb{Z}$  and arbitrarily topple sites in  $[x_n+1, x_{n+1}-1]$  containing particles, regardless of whether the particles are sleeping, until all particles settle on  $x_n$  or  $x_{n+1}$ . Do the same for  $[x_{n-1}+1, x_n-1]$  so that all particles starting in  $[x_{n-1}, x_{n+1}]$  are placed onto sites  $x_{n-1}, x_n$ , and  $x_{n+1}$ , and let  $Z_n$  be the number of particles settling on  $x_n$ . Then stabilize interval  $I_n$ , and define Contained<sub>n</sub> as the event that all the particles on  $x_n$  stabilize without leaving  $I_n$ .

We claim that that for large enough k, it holds with positive probability that Contained<sub>n</sub> occurs for all  $n \in \mathbb{Z}$ . To prove this, we give an exponentially decaying failure bound on Contained<sub>n</sub>. First consider  $Z_n$ , the number of particles initially settling on  $x_n$ . By symmetry, the sites in  $[x_{n-1} + 1, x_n - 1]$  contribute equally to  $Z_{n-1}$  and  $Z_n$  in expectation; likewise, the sites in  $[x_n + 1, x_{n+1} - 1]$  contribute equally to  $Z_n$  and  $Z_{n+1}$  in expectation. Adding in the contribution to  $Z_n$  from site  $x_n$  itself, we have for any  $n \ge 1$ 

$$\mathbf{E}Z_n = \frac{1}{2}\rho \big| [\![x_{n-1}+1, x_n-1]\!] \big| + \frac{1}{2}\rho \big| [\![x_n+1, x_{n+1}-1]\!] \big| + \rho = \frac{1}{2}\rho(x_{n+1}-x_{n-1}) = \rho |I_n|.$$

Fix any  $\rho'$  such that  $\rho < \rho' < \rho_*$ . Since  $Z_n$  can be realized as a sum of independent Bernoulli random variables, a Chernoff bound gives

(88) 
$$\mathbf{P}[Z_n \le \rho' | I_n |] \ge 1 - e^{-ank}$$

for constant a not depending on n or k. By Proposition 8.7, conditional on  $Z_n \leq \rho' |I_n|$ , the particles on  $x_n$  will stabilize within

$$\left[\!\left[x_n - \frac{Z_n}{2\rho'}, \ x_n + \frac{Z_n}{2\rho'}\!\right]\!\right] \subseteq \left[\!\left[x_n - \frac{|I_n|}{2}, \ x_n + \frac{|I_n|}{2}\!\right]\!\right] = I_n$$

with probability at least  $1 - Be^{-bnk}$  for positive constants B and b that do not depend on n or k. Together with (88), this shows that for some constants c and C independent of n and k, we have  $\mathbf{P}[\mathsf{Contained}_n] \ge 1 - Ce^{-cnk}$  for all  $n \ge 1$ . By symmetry  $\mathbf{P}[\mathsf{Contained}_{-n}]$  obeys the same bound. Thus by taking k sufficiently large, we can make the probability of  $\bigcap_{n\neq 0}\mathsf{Contained}_n$  arbitrarily close to 1. Since  $\mathbf{P}[\mathsf{Contained}_0] > 0$ , this proves that for some k, we have  $\mathbf{P}[\bigcap_{n\in\mathbb{Z}}\mathsf{Contained}_n] > 0$ .

To prove that the system fixates, we argue along similar lines as [Rol20, Section 4] that on the event  $\bigcap_{n \in \mathbb{Z}} \text{Contained}_n$ , for each n we have a finite sequence of acceptable topplings (i.e., sites with sleeping or active particles may be toppled) stabilizing  $[\![x_{-n}, x_n]\!]$ . The odometer for this sequence of topplings provides an upper bound on the true odometer stabilizing  $[\![x_{-n}, x_n]\!]$  by [Rol20, Lemma 2.1] (or by our own least-action principle, once it is noted that the odometer of a sequence of acceptable topplings stabilizing a set is always stable on that set). And since our upper bound on the odometer at 0 remains bounded as  $n \to \infty$ , we have fixation a.s. by [Rol20, Theorem 2.7].

# 8.3.4. The cycle.

**Proposition 8.12.** Fix  $\rho \in (0,1)$  and place  $\lfloor \rho n \rfloor$  active particles uniformly throughout the sites of the cycle with n vertices. Let  $\tau_n$  be the total number of instructions used by all particles once the system has stabilized.

- (i) If  $\rho < \rho_*$ , then  $\mathbf{P}(\tau_n > Cn \log^2 n) \le n^{-b}$  and  $\mathbf{P}(\tau_n > C'n^4) \le Be^{-b'n}$  for positive constants C, C', B, b, b' that do not depend on n.
- (ii) If  $\rho > \rho_*$ , then  $\mathbf{P}(\tau_n < e^{cn}) \leq e^{-cn}$  for a positive constant c that does not depend on n.

*Proof.* The proofs of (i) and (ii) are similar to the arguments in [BGHR19]. We give a brief sketch and refer the reader to [BGHR19] for more details.

To prove (i), a source scheme like in the proof of Proposition 8.10 is used. Sources are spaced uniformly at distance  $c_0 \log n$  apart. Particles perform random walk until reaching a source, upon which they switch to activated random walk dynamics. It takes  $O(n \log^2 n)$  steps to freeze all of the particles. With Proposition 8.7, we can deduce that the particles

coming from each source are likely to stabilize in  $O(n \log^2 n)$  steps without interacting with particles at other sources. Following the proof of [BGHR19, Theorem 1], this happens for all of the sources with probability at least  $1 - n^{-b}$  for some b > 0. To obtain the exponential bound the argument can be repeated with a single source at 0. It is exponentially likely that all particles will reach the source within  $n^4$  steps and, by Proposition 8.7, that the particles will then stabilize in no more than  $n^4$  additional steps without reaching  $\lfloor n/2 \rfloor$ .

To prove (ii), the idea is to stabilize the process on the cycle while freezing points at 0 then to recycle the approximately  $(\rho - \rho_* - \epsilon)n$  particles that are overwhelmingly likely to freeze there by Theorem 8.4. These particles are used to reactivate many particles of which many are then frozen at site n/2 again by Theorem 8.4. The proof of [BGHR19, Theorem 2] shows that this process is overwhelmingly likely to continue for exponentially many steps. Adapting their approach gives (ii).

8.3.5. Proof of Theorem 1.1. Let  $S_n$  be the number of sleeping particles in a sample from the invariant distribution of the driven-dissipative chain on [0, n]. Proposition 8.5 proves that

$$\liminf_{n \to \infty} \frac{\mathbf{E}[S_n]}{n+1} \ge \rho_*$$

and Proposition 8.6 proves that

$$\limsup_{n \to \infty} \frac{\mathbf{E}[S_n]}{n+1} \le \rho_*,$$

demonstrating that  $\rho_{DD} = \rho_*$ . Similarly, Propositions 8.7 and 8.8 prove  $\rho_{PS} = \rho_*$ , and Propositions 8.10 and 8.11 prove  $\rho_{FE} = \rho_*$ , and Proposition 8.12 proves  $\rho_{CY} = \rho_*$ .

8.4. Bounds on critical densities away from 0 and 1. As we mentioned in the introduction, with it now established that

$$\rho_* = \rho_{\rm DD} = \rho_{\rm PS} = \rho_{\rm FE} = \rho_{\rm CY},$$

we can approach the classical problem of bounding these critical densities away from 0 and 1 using layer percolation. We give simple arguments that the critical density for onedimensional ARW is bounded away from 0 for all  $\lambda$  and away from 1 for small enough  $\lambda$ . We have not tried to optimize our proofs. Rather, we wish to demonstrate that these two bounds, which were major accomplishments when first carried out in [RS12] and [BGH18], are easy consequences of our theory. We start with a slight improvement of Rolla and Sidoravicius's celebrated lower bound  $\rho_{\text{FE}} \geq \frac{\lambda}{1+\lambda}$  [RS12]:

**Proposition 8.13.** For any  $\lambda > 0$ , we have  $\rho_* \geq \frac{1}{1/2+\lambda}$ .

Proof. Let  $X_n$  denote the greatest row present in the infection set  $\zeta_n^{(0,0)_0}$ . Any given cell in layer percolation infects 1 + Geo(1/2) cells in its row in the next step; in the row above it, it infects this quantity of cells thinned by  $\lambda/(1+\lambda)$ , which is at least 1 with probability  $\frac{\lambda}{1/2+\lambda}$ . Thus, conditional on layer percolation up to step n, we have  $X_{n+1} = X_n + 1$  with at least probability  $\frac{\lambda}{1/2+\lambda}$ , yielding  $\rho_* \geq \frac{\lambda}{1/2+\lambda}$ .

Next, we reproduce the result of [BGH18] that  $\rho_{FE}$  is strictly below 1 for small enough  $\lambda$ . **Proposition 8.14.** If  $\lambda < 1$ , then  $\rho_* < 1$ . *Proof.* A given cell infects on average 2 cells in its row in the next step and on average  $2\lambda_0$  cells in the row above, where  $\lambda_0 = \lambda/(1+\lambda)$ . Hence, if  $Z_n(s)$  is the number of cells in the infection set  $\zeta_n^{(0,0)_0}$  in row s, we have

$$\mathbf{E}[Z_{n+1}(s) \mid Z_n(\cdot)] \le 2Z_n(s) + 2\lambda_0 Z_n(s-1).$$

Setting  $\mu_n(s) = \mathbf{E}Z_n(s)$ , we thus have  $\mu_{n+1}(s) \leq 2\mu_n(s) + 2\lambda_0\mu_n(s-1)$ . We can view this inequality as stating that each component of the vector  $\mu_{n+1}(\cdot)$  is bounded by the corresponding component of  $A\mu_n(\cdot)$ , where A is the infinite matrix

$$A = \begin{bmatrix} 2 & 0 & 0 & 0 & \cdots \\ 2\lambda_0 & 2 & 0 & 0 & \cdots \\ 0 & 2\lambda_0 & 2 & 0 & \cdots \\ 0 & 0 & 2\lambda_0 & 2 & \cdots \\ \vdots & \vdots & \vdots & \vdots & \ddots \end{bmatrix}.$$

We can iterate the inequality to bound each component of  $\mu_n(\cdot)$  by that of  $A^n \mu_0(\cdot)$ , with  $\mu_0(s) = \mathbf{1}\{s = 0\}$ . Hence  $\mu_n(\cdot)$  is bounded by the first column of  $A^n$ , which after a calculation yields

$$\mu_n(s) \le 2^n \lambda_0^s \binom{n}{s}.$$

Now let  $s = \rho n$  for  $0 < \rho < n$  and apply the standard bound  $\binom{n}{s} = \binom{n}{n-s} \leq (en/(n-s))^{n-s}$  to get

(89) 
$$\mathbf{P}[Z_n(\rho n) \ge 1] \le \mathbf{E}Z_n(\rho n) \le \left(2\lambda_0^{\rho} \left(\frac{e}{1-\rho}\right)^{1-\rho}\right)^n.$$

The expression  $2\lambda_0^{\rho}((e/(1-\rho))^{1-\rho}$  converges to  $2\lambda_0$  as  $\rho \to 1$ , which is strictly less than 1 by our assumption  $\lambda < 1$ . Thus there exists  $\rho < 1$  so that the right-hand side of (89) decays exponentially. For such  $\rho$ , the infection set at step n is exponentially unlikely to contain cells in rows at or above  $\rho n$ , which by Proposition 5.18 proves that  $\rho_* \leq \rho$ .

As we mentioned, we have not tried to optimize these results. We suspect that by similar technique, we could achieve the optimal lower bound  $\rho_* \geq C\sqrt{\lambda}$  as  $\lambda \to 0$  proven in [ARS22], and that we could show  $\rho_* < 1$  for all  $\lambda > 0$  as proven in [HRR23].

### APPENDIX A. GALTON–WATSON PROCESSES WITH MIGRATION

In this appendix, we prove the following concentration result for critical geometric branching processes with migration (see Definition 5.3).

**Proposition A.1.** Let  $(X_j)_{j\geq 0}$  be a critical geometric branching process with migration  $(e_j)_{j\geq 1}$ . Let  $X_0 = x_0$  and let  $|e_j| \leq e_{\max}$  for all j, for some  $e_{\max} \geq 1$ . Then for any  $t \geq 0$ ,

(90) 
$$\max\left(\mathbf{P}[X_j - \mu_j \ge t], \ \mathbf{P}[X_j - \mu_j \le -t]\right) \le C \exp\left(-\frac{ct^2}{j(je_{\max} + |x_0| + t)}\right),$$

for some absolute constants c, C > 0 and

$$\mu_j = \mathbf{E}X_j = x_0 + \sum_{i=1}^j e_j.$$

In a typical application, we have  $j, e_{\max} = O(n), |x_0| = O(n^2)$ , and  $t = sn^2$  for s bounded away from 0. The right-hand side of (90) is then bounded by  $Ce^{-csn}$  for some constants c and C, and in particular for any fixed s we obtain an exponential bound in n.

A benefit of considering branching processes with geometric offspring distribution is that the distribution of the jth generation can be explicitly calculated. The following facts are well known and can be proven by simple inductive arguments.

**Proposition A.2.** Consider a critical geometric branching process  $(X_j)_{j\geq 0}$  with  $X_0 = 1$  and constant migration m after each step.

- (a) If m = 0, then  $\mathbf{P}[X_j > 0] = 1/(j+1)$  and the conditional distribution of  $X_j$  given  $X_j > 0$  is 1 + Geo(1/(j+1)).
- (b) If m = 1, then  $X_j$  has distribution 1 + Geo(1/(j+1)).

In the next result, we consider a signed Galton–Watson process  $(V_j)_{j\geq 0}$  with migration  $(e_j)_{j\geq 1}$  satisfying  $|e_j| \leq e_{\max}$ . We then consider two (nonnegative) Galton–Watson processes  $(Y_j)_{j\geq 0}$  and  $(Z_j)_{j\geq 0}$ , both of which have constant immigration  $e_{\max}$  at each step. The idea is that  $(Y_j - Z_j)_{j\geq 0}$  has similar dynamics as  $(V_j)_{j\geq 0}$  but should be less concentrated because of the extra immigration. We make this precise by showing that after centering both processes around their means, the first is dominated by the second in the convex stochastic order, signifying that it is stochastically less variable than the second (see [SS07, Section 3.A]). Thus we can bound  $V_j$  in terms of  $Y_j - Z_j$ , whose distribution can be explicitly calculated when the child distributions are geometric.

**Lemma A.3.** Let  $(V_j)_{j\geq 0}$  be a signed Galton–Watson process with migration  $(e_j)_{j\geq 0}$  whose child distribution has mean 1. Suppose that  $V_0 = v_0$  for some integer  $v_0$  and that  $|e_j| \leq e_{\max}$  for all j. Let  $(Y_j)_{j\geq 0}$  and  $(Z_j)_{j\geq 0}$  be independent Galton–Watson processes with constant immigration  $e_{\max}$  and the same child distribution as  $(V_j)$ . Let  $Y_0 = v_0$  and  $Z_0 = 0$  if  $v_0 \geq 0$ , and let  $Y_0 = 0$  and  $Z_0 = |v_0|$  if  $v_0 < 0$ . For any convex function  $\varphi \colon \mathbb{R} \to \mathbb{R}$ ,

(91) 
$$\mathbf{E}\varphi(V_j - \mathbf{E}V_j) \le \mathbf{E}\varphi(Y_j - Z_j - \mathbf{E}[Y_j - Z_j])$$

*Proof.* We define a more complicated branching process and embed  $(V_j)$ ,  $(Y_j)$ , and  $(Z_j)$  in it. Each population member has a sign (positive or negative) and a visibility (visible or invisible). Generation 0 consists of  $|v_0|$  visible members, which are all positive if  $v_0 \ge 0$  and negative if  $v_0 < 0$ . From generation j - 1, we produce generation j by the following steps:

- 1. Each member of generation j-1 gives birth to an independent quantity of children, sampled from the offspring distribution. Each child has the same sign as its parent and provisionally has the same visibility.
- 2. Add  $e_{\text{max}}$  new positive invisible population members and  $e_{\text{max}}$  new negative invisible population members.
- 3. (a) If  $e_j \ge 0$ , switch  $e_j$  negative visible members to invisible; if there are fewer than  $e_j$  negative visible members, switch all of them to invisible and then switch positive invisible members to visible so that a total of  $e_j$  members switch visibility.
  - (b) If  $e_j < 0$ , switch  $|e_j|$  positive visible members to invisible; if there are fewer than  $|e_j|$  positive visible members, switch all of them to invisible and then

switch negative invisible members to visible so that a total of  $|e_j|$  members switch visibility.

Observe that it is always possible to switch the visibility of  $|e_j|$  population members because  $|e_j| \leq e_{\max}$  and we add  $e_{\max}$  positive and negative invisible elements at each step. Also observe that in each generation, all visible members have the same sign. This is true by definition at generation 0, and then it holds at successive generations by induction: each successive generation has all its provisionally visible elements with the same sign, and then new elements of a given sign are turned visible only when there are no visible elements of the opposite sign.

We define  $V_j^+$  and  $V_j^-$  as the number of visible positive and negative members, respectively, at generation j. Let  $V_j = V_j^+ - V_j^-$ . Let  $I_j^+$  and  $I_j^-$  be the number of invisible positive and negative members, respectively, at generation j, and let  $I_j = I_j^+ - I_j^-$ . Finally let  $Y_j = V_j^+ + I_j^+$  and  $Z_j = V_j^- + I_j^-$ . We claim that

- (i)  $(V_j)_{j\geq 0}$  is a signed Galton–Watson process with migration  $e_j$ , consistent with its definition in the statement of the proposition;
- (ii)  $(Y_j)_{j\geq 0}$  and  $(Z_j)_{j\geq 0}$  are independent Galton–Watson processes with immigration  $e_{\max}$ , and  $V_j + I_j = Y_j - Z_j$ ;
- (iii)  $\mathbf{E}[V_j + I_j | V_j] = V_j \sum_{i=1}^j e_i$  a.s. for all  $j \ge 0$ .

Claim (i) is evident by considering the dynamics of the visible population members only. The part of claim (ii) about  $(Y_j)$  and  $(Z_j)$  is proven similarly: The processes  $(Y_j)$  and  $(Z_j)$  give the counts of positive and negative members, respectively, with visibility ignored. For each of these processes, the changes in visibility are irrelevant, and we simply see two independent Galton–Watson processes with  $e_{\max}$  new members added at each step. And the statement  $V_j + I_j = Y_j - Z_j$  holds by definition.

To prove claim (iii), we will show that

(92) 
$$\mathbf{E}[I_j \mid V_j^+, V_j^-] = -\sum_{i=1}^j e_i \text{ a.s}$$

Claim (iii) follows by adding  $V_j$  to both sides of the equation and taking conditional expectations with respect to  $V_j$ . When j = 0, equation (92) is trivial. Now we proceed inductively, assuming (92). Let  $(L_i^{\text{vis}+})_{i\geq 1}$ ,  $(L_i^{\text{vis}-})_{i\geq 1}$ ,  $(L_i^{\text{inv}+})_{i\geq 1}$ , and  $(L_i^{\text{inv}-})_{i\geq 1}$  be the offspring counts of each visible positive, visible negative, invisible positive, and invisible negative population member, respectively, in generation j. These random variables have mean 1 and are independent of each other and of the process up to generation j. From step j to step j + 1, the invisible members give birth to new provisionally invisible members of the same signs as their parents, a quantity of  $e_{\max}$  positive and negative invisible elements are added, and  $|e_{j+1}|$  elements have their visibility switched. Hence,

$$I_{j+1} = \sum_{i=1}^{I_j^+} L_i^{\text{inv}+} - \sum_{i=1}^{I_j^-} L_i^{\text{inv}-} - e_{j+1}.$$

Now, we consider  $I_{j+1}$  conditional on the full information at generation j together with the offspring counts of the visible elements at generation j. This information is independent of  $(L_i^{\text{inv}+})_{i\geq 1}$  and  $(L_i^{\text{inv}-})_{i\geq 1}$ , yielding

$$\mathbf{E} \begin{bmatrix} I_{j+1} \mid V_j^+, V_j^-, I_j^+, I_j^-, (L_i^{\text{vis}+})_{i \ge 1}, (L_i^{\text{vis}-})_{i \ge 1} \end{bmatrix}$$
$$= I_j^+ - I_j^- - e_{j+1} = I_j - e_{j+1} \text{ a.s.}$$

Taking a conditional expectation of both sides of this equation given the above information except for  $I_i^+$  and  $I_j^-$  gives

$$\mathbf{E} \begin{bmatrix} I_{j+1} \mid V_j^+, V_j^-, (L_i^{\text{vis}+})_{i \ge 1}, (L_i^{\text{vis}-})_{i \ge 1} \end{bmatrix}$$
  
=  $\mathbf{E} \begin{bmatrix} I_j \mid V_j^+, V_j^-, (L_i^{\text{vis}+})_{i \ge 1}, (L_i^{\text{vis}-})_{i \ge 1} \end{bmatrix} - e_{j+1} \text{ a.s.}$   
=  $\mathbf{E} \begin{bmatrix} I_j \mid V_j^+, V_j^- \end{bmatrix} - e_{j+1} = -\sum_{i=1}^{j+1} e_i \text{ a.s.}$ 

The second to last equality is by Doob's conditional independence property [Kal02, Proposition 6.6], and the last is by the inductive hypothesis (92). Since  $V_{j+1}^+$  and  $V_{j+1}^-$  are measurable with respect to  $\sigma(V_j^+, V_j^-, (L_i^{\text{vis}+})_{i\geq 1}, (L_i^{\text{vis}-})_{i\geq 1})$ , we can now take expectations with respect to  $V_{j+1}^+$  and  $V_{j+1}^-$  to obtain (92) with j replaced by j + 1, thus completing the proof of claim (iii).

It follows from claim (iii) that

$$V_j - \mathbf{E}V_j = V_j - v_0 - \sum_{i=1}^j e_j = \mathbf{E}[V_j + I_j \mid V_j] - v_0$$

Finally, by (ii) we have  $V_j + I_j = Y_j - Z_j$  and  $\mathbf{E}[Y_j - Z_j] = v_0$ , yielding

$$V_j - \mathbf{E}V_j = \mathbf{E}\Big[Y_j - Z_j - \mathbf{E}[Y_j - Z_j] \mid V_j\Big].$$

Now (91) follows by Jensen's inequality.

Lemma A.4. Let

$$X = \sum_{i=1}^{N} (1 + \operatorname{Geo}(p_i))$$

and let  $p_* = \min_i p_i$ . If  $\mathbf{E}X \leq \nu$ , then for all  $t \geq 0$ 

(93) 
$$\mathbf{P}[X-\nu \ge t] \le \exp\left(-\frac{p_*t^2}{2(\nu+t)}\right)$$

If  $\mathbf{E}X \ge \nu$ , then for all  $t \ge 0$ 

(94) 
$$\mathbf{P}[X-\nu \le -t] \le \exp\left(-\frac{p_*t^2}{2(\nu+t)}\right)$$

*Proof.* Let  $\mu = \mathbf{E}X$  and fix  $\nu, s \in \mathbb{R}$ . Define

$$h(x) = x \left( \frac{s - x + \nu}{x} - \log\left(\frac{s + \nu}{x}\right) \right).$$

Observe that  $h'(x) = -\log((s+\nu)/x)$ , and hence h is decreasing on  $(0, s+\nu]$  and increasing on  $[s+\nu,\infty)$ .

Suppose  $\mu \leq \nu$  and  $s \geq 0$ . By [Jan18, Theorem 2.1],

(95) 
$$\mathbf{P}[X - \nu \ge s] \le e^{-p_* h(\mu)} \le e^{-p_* h(\nu)},$$

with the final inequality holding because h is decreasing on the interval from  $\mu$  to  $\nu$ . Similarly,  $\mu \geq \nu$  and  $-\mu \leq s \leq 0$ . By [Jan18, Theorem 3.1],

(96) 
$$\mathbf{P}[X - \nu \le s] \le e^{-p_* h(\mu)} \le e^{-p_* h(\nu)},$$
with the final inequality holding because h is increasing on the interval from  $\nu$  to  $\mu$ . Now we bound the right-hand sides of (95) and (96). Assuming that  $s \ge -\nu$ .

w we bound the right-hand sides of (95) and (90). Assuming that 
$$s \ge -\nu$$
,

$$e^{-p_*h(\nu)} = \exp\left(-p_*\nu\left(\frac{s}{\nu} - \log\left(1 + \frac{s}{\nu}\right)\right) \le \exp\left(-\frac{p_*s^2}{2(\nu+|s|)}\right),$$

using the inequality  $x - \log(1+x) \ge x^2/2(1+|x|)$  for all  $x \ge -1$ . (To prove this inequality, observe that the derivative of  $x - \log(1+x) - x^2/2(1+|x|)$  is negative for -1 < x < 0 and positive for x > 0.) Applying (95) combined with this bound when  $\mu \le \nu$  and  $s \ge 0$  proves (93), setting t = s. And applying (96) combined with this bound when  $\mu \ge \nu$  and  $-\nu \le s \le 0$  proves (94), setting t = -s, at least for the case  $t \le \nu$ . And in fact (94) holds even when  $t > \nu$  since the left-hand side of (94) is equal to zero in that case.

Proof of Proposition A.1. Let  $(Y_j)$  and  $(Z_j)$  be independent Galton–Watson processes with child distribution Geo(1/2) and immigration  $e_{\max}$  and let  $Y_0 = |x_0|$  and  $Z_0 = 0$ . First, we work out the distributions of  $Y_j$  and  $Z_j$ . By Proposition A.2,

$$Z_j \stackrel{d}{=} \sum_{1}^{c_{\max}} \left( 1 + \operatorname{Geo}\left(\frac{1}{j}\right) \right),$$

with the summands taken as independent random variables with the given distributions. Thinking of  $Y_j$  as being distributed as  $Z_j$  plus  $|x_0|$  many independent Galton–Watson processes starting from 1 with no immigration,

(97) 
$$Y_j \stackrel{d}{=} \sum_{1}^{e_{\max}} \left(1 + \operatorname{Geo}\left(\frac{1}{j}\right)\right) + \sum_{1}^{|x_0|} \operatorname{Bernoulli}\left(\frac{1}{j+1}\right) \left(1 + \operatorname{Geo}\left(\frac{1}{j+1}\right)\right).$$

Now, we want to prove concentration bounds for  $Y_j$  and  $Z_j$  that we can then transfer to  $X_j$  via Lemma A.3. We start with  $Z_j$ . Since  $\mathbf{E}Z_j = je_{\max}$ , by Lemma A.4 for all  $t \ge 0$ ,

(98) 
$$\max\left(\mathbf{P}[Z_j \ge \mathbf{E}Z_j + t], \, \mathbf{P}[Z_j \le \mathbf{E}Z_j - t]\right) \le \exp\left(-\frac{t^2}{2j(je_{\max} + t)}\right)$$

For  $Y_j$ , we prove bounds on on the second sum in (97) by separately controlling the Bernoulli and geometric random variables. Let  $S \sim Bin(|x_0|, \frac{1}{j+1})$  so that we can express the second sum as

$$Y'_j := \sum_{1}^{S} \left( 1 + \operatorname{Geo}\left(\frac{1}{j+1}\right) \right).$$

We will then bound the four terms on the right-hand sides of

(99) 
$$\mathbf{P}[Y'_{j} \ge \mathbf{E}Y'_{j} + 2t] \le \mathbf{P}\left[Y'_{j} \ge \mathbf{E}Y'_{j} + 2t \text{ and } S \le \frac{|x_{0}| + t}{j+1}\right] + \mathbf{P}\left[S > \frac{|x_{0}| + t}{j+1}\right]$$

and

(100) 
$$\mathbf{P}[Y'_{j} \le \mathbf{E}Y'_{j} - 2t] \le \mathbf{P}\left[Y'_{j} \le \mathbf{E}Y'_{j} - 2t \text{ and } S \ge \frac{|x_{0}| - t}{j+1}\right] + \mathbf{P}\left[S < \frac{|x_{0}| - t}{j+1}\right]$$

for  $t \ge 0$ . By Bernstein's inequality,

(101) 
$$\max\left(\mathbf{P}\left[S > \frac{|x_0| + t}{j+1}\right], \ \mathbf{P}\left[S < \frac{|x_0| - t}{j+1}\right]\right) \le \exp\left(-\frac{t^2}{2(j+1)(|x_0| + t/3)}\right).$$

To bound the other two terms, we apply Lemma A.4 conditionally given S. Let  $\nu = \mathbf{E}Y'_j + t = |x_0| + t$ , so that the event  $\{Y'_j \ge \mathbf{E}Y'_j + 2t\}$  can be viewed as  $\{Y'_j \ge \nu + t\}$ . On the event  $S \le (|x_0| + t)/(j + 1)$ , we have  $\mathbf{E}[Y'_j | S] = S(j + 1) \le \nu$  a.s. Applying Lemma A.4,

$$\begin{aligned} \mathbf{P}[Y'_{j} \geq \mathbf{E}Y'_{j} + 2t \mid S] \mathbf{1} \bigg\{ S \leq \frac{|x_{0}| + t}{j + 1} \bigg\} &= \mathbf{P} \Big[ Y'_{j} \geq \nu + t \mid S \Big] \mathbf{1} \bigg\{ S \leq \frac{|x_{0}| + t}{j + 1} \bigg\} \\ &\leq \exp \left( -\frac{t^{2}}{2(j + 1)(|x_{0}| + 2t)} \right) \text{ a.s.} \end{aligned}$$

Hence

(102) 
$$P\left[Y'_{j} \ge \mathbf{E}Y'_{j} + 2t \text{ and } S \le \frac{|x_{0}| + t}{j+1}\right] \le \exp\left(-\frac{t^{2}}{2(j+1)(|x_{0}| + 2t)}\right).$$

Similarly, for  $\nu' = \mathbf{E}Y'_j - t$ , we have  $\mathbf{E}[Y'_j | S] \ge \nu'$  a.s. on the event  $S \ge (|x_0| - t)/(j + 1)$ , and by Lemma A.4 we obtain

$$\begin{aligned} \mathbf{P}[Y'_{j} - \mathbf{E}Y'_{j} &\leq -2t \mid S] \mathbf{1} \left\{ S \geq \frac{|x_{0}| - t}{j+1} \right\} &= \mathbf{P} \Big[ Y'_{j} - \nu' \leq -t \mid S \Big] \mathbf{1} \left\{ S \leq \frac{|x_{0}| - t}{j+1} \right\} \\ &\leq \exp \left( -\frac{t^{2}}{2(j+1)(\nu'+t)} \right) \text{ a.s.,} \end{aligned}$$

yielding

(103) 
$$P\left[Y'_{j} \le \mathbf{E}Y'_{j} - 2t \text{ and } S \ge \frac{|x_{0}| - t}{j+1}\right] \le \exp\left(-\frac{t^{2}}{2(j+1)|x_{0}|}\right).$$

Combining (101), (102), and (103), the right-hand sides of (99) and (100) are both bounded by

$$2\exp\left(-\frac{t^2}{2(j+1)(|x_0|+2t)}\right).$$

Expressing  $Y_j - Z_j$  as  $Y'_j + Z'_j - Z_j$  with  $Z'_j$  an independent copy of  $Z_j$  and applying our bound on (99) and (100) together with (98), we obtain

(104)  
$$\max\left(\mathbf{P}\left[Y_j - Z_j - \mathbf{E}[Y_j - Z_j] \ge t\right], \ \mathbf{P}\left[Y_j - Z_j - \mathbf{E}[Y_j - Z_j] \le -t\right]\right)$$
$$\le C_0 \exp\left(-\frac{c_0 t^2}{j(j e_{\max} + |x_0| + t)}\right)$$

for some constants  $c_0, C_0 > 0$ .

Now, we transfer these estimates to  $X_k$  using Lemma A.3. Fix some  $s \ge 2$  and define

$$\varphi(x) = \left(\frac{x}{\sqrt{j(je_{\max} + |x_0|)}} - s + 1\right) \mathbf{1} \left\{\frac{x}{\sqrt{j(je_{\max} + |x_0|)}} - s + 1 \ge 0\right\},$$

which is convex. Since  $\varphi(x) \ge 1$  for  $x \ge s\sqrt{j(je_{\max} + |x_0|)}$ ,

(105) 
$$\mathbf{P}\Big[X_j - \mathbf{E}X_j \ge s\sqrt{j(je_{\max} + |x_0|)}\Big] \le \mathbf{E}\varphi\big(X_j - \mathbf{E}X_j\big) \le \mathbf{E}\varphi\big(Y_j - Z_j - \mathbf{E}[Y_j - Z_j]\big),$$

applying Lemma A.3 in the second line. (If  $x_0 < 0$ , then  $Y_j - Z_j$  should be replaced by  $Z_j - Y_j$ . For notational simplicity we continue to write  $Y_j - Z_j$ , since our tail bound (104) on  $Y_j - Z_j$  is symmetric anyhow.) Continuing the calculation,

using (104). Let

$$h(v) = \frac{c_0 v^2}{1 + \frac{v}{\sqrt{e_{\max} + |x_0|/j}}}$$

The function h(v) is convex and hence for  $v \ge v_0 \ge 1$ 

(107) 
$$h(v) - h(v_0) \ge h'(v_0)(v - v_0) \ge h'(1)(v - v_0).$$

We compute

$$h'(1) = \frac{2c_0}{1 + \frac{1}{\sqrt{e_{\max} + |x_0|/j}}} - \frac{c_0}{\sqrt{e_{\max} + |x_0|/j} + 2 + \frac{1}{\sqrt{e_{\max} + |x_0|/j}}}$$
$$\geq \frac{2c_0}{1 + \frac{1}{\sqrt{e_{\max} + |x_0|/j}}} - \frac{c_0}{\sqrt{e_{\max} + |x_0|/j} + 2}.$$

This expression is increasing in  $e_{\max}$  and  $|x_0|$ , and hence it is bounded below by its value when  $e_{\max} = 1$  and  $x_0 = 0$ , yielding  $h'(1) \ge \frac{2}{3}c_0$ .

Combining this bound with (105)–(107) and recalling that we have assumed  $s \ge 2$  which makes  $v \ge 1$  in the integral,

$$\begin{aligned} \mathbf{P}\Big[X_j - \mathbf{E}X_j &\geq s\sqrt{j(je_{\max} + |x_0|)}\Big] &\leq \int_{s-1}^{\infty} C_0 e^{-h(s-1)} \exp\Big(-\big(h(v) - h(s-1)\big)\Big) \, dv \\ &\leq C_0 e^{-h(s-1)} \int_{s-1}^{\infty} e^{-\frac{2}{3}c_0(v-s+1)} \, dv \\ &\leq C_1 \exp\left(-\frac{c_1 s^2}{1 + \frac{s}{\sqrt{e_{\max} + |x_0|/j}}}\right) \end{aligned}$$

for absolute constants  $c_1, C_1 > 0$ . Finally, substituting  $t = s\sqrt{j(je_{\max} + |x_0|)}$  gives

$$\mathbf{P}[X_j - \mathbf{E}X_j \ge t] \le C_1 \exp\left(-\frac{c_1 t^2}{j(je_{\max} + |x_0| + t)}\right),$$

thus proving the upper bound in (90) so long as  $t \ge 2\sqrt{j(je_{\max} + |x_0|)}$ . The lower bound under the same assumption on t is derived from (104) in the exact same way, using the convex function

$$x \mapsto \left| \frac{x}{\sqrt{j(je_{\max} + x_0)}} - s - 1 \right| \mathbf{1} \left\{ \frac{x}{\sqrt{j(je_{\max} + x_0)}} - s - 1 \le 0 \right\},$$

for fixed  $s \leq -2$ . To remove the condition  $t \geq 2\sqrt{j(je_{\max} + |x_0|)}$ , observe the the right-hand side of (90) is decreasing in t and when  $t = 2\sqrt{j(je_{\max} + |x_0|)}$  is equal to

$$C \exp\left(-\frac{4c(je_{\max} + |x_0|)}{je_{\max} + |x_0| + 2\sqrt{j(j + e_{\max} + |x_0|)}}\right) \ge Ce^{-4c},$$

and by increasing C to ensure that  $Ce^{-4c} \ge 1$ , we obtain (90) trivially for the case that  $0 \le t \le 2\sqrt{j(je_{\max} + |x_0|)}$ .
