#### Abstract

With the growing interest and applications in machine learning and data science, finding an efficient method to sparse analysis the high-dimensional data and optimizing a dimension reduction model to extract lower dimensional features has becoming more and more important. Orthogonal constraints (Stiefel manifold) is a commonly met constraint in these applications, and the sparsity is usually enforced through the element-wise L1 norm. Many applications can be found on optimization over Stiefel manifold within the area of physics and machine learning. In this paper, we propose a novel idea by tackling the Stiefel manifold through an nonlinear eigen-approach by first using ADMM to split the problem into smooth optimization over manifold and convex non-smooth optimization, and then transforming the former into the form of nonlinear eigenvalue problem with eigenvector dependency (NEPv) which is solved by self-consistent field (SCF) iteration, and the latter can be found to have an closed-form solution through proximal gradient. Compared with existing methods, our proposed algorithm takes the advantage of specific structure of the objective function, and has efficient convergence results under mild assumptions.

Keywords: Stiefel manifold, Nonlinear eigenvalue problem with eigenvector dependency (NEPv), self-consistent field (SCF) iteration, ADMM, proximal algorithm, orthogonal constraints

# 1 Introduction

# 1.1 Problem Description

In this paper, we are concerned with the following non-smooth composite minimization problem

$$
\min_{X} f(X) + r(X)
$$
  
s.t.  $X \in S_{n,p}$  (1.1)

<span id="page-1-0"></span>where  $\mathcal{S}_{n,p}$  stands for the Stiefel manifold  $\mathcal{S}_{n,p} = \{X \in \mathbb{R}^{n \times p} \mid X^{\top} X = I_p\},\, f: \mathbb{R}^{n \times p} \mapsto \mathbb{R}^{n \times p}$ needs to satisfy the following Assumption 1.1, and  $r : \mathbb{R}^{n \times p} \to \mathbb{R}$  represents the convex but possibly non-smooth function whose proximal operator can be easily evaluated.

Assumption 1.1.  $f(X)$  is differentiable and possibly non-convex, and  $\nabla f(X)$  is Lipschitz continuous with Lipschitz constant  $L_f$ .

In many applications,  $r(\cdot)$  is usually being taken as the  $\ell_1$ -related regularization term to enforce sparsity, and the frequently encountered ones include for example the element-wise matrix  $\ell_1$ -norm and the  $\ell_{m,1}$ -norm

$$
r(X) := \begin{cases} \mu \|X\|_1 = \sum_{ij} \mu |X_{ij}| \\ \|\Gamma X\|_{m,1} = \sum_{i=1}^n \gamma_i \|X_{i\cdot}\|_m \end{cases}
$$
(1.2)

where  $\mu > 0$ ,  $\gamma_i \geq 0$  are weighting parameters and  $\|\cdot\|_m$  denotes the  $\ell_m$  vector norm for  $X_i$ , the *i*th row of matrix X.

# 1.2 Existing Methods

Optimization on Stiefel manifold has been a hot research topic in the past few years. [\[1\]](#page-13-0) gives a very comprehensive and structured study on optimization method over smooth manifold. However, most of the existing methods  $[2][3][4][5][6]$  $[2][3][4][5][6]$  $[2][3][4][5][6]$  $[2][3][4][5][6]$  $[2][3][4][5][6]$  are designed for smooth objective function by using the derivative of objective function and thus cannot be applied to the non-smooth objective function such as problem [\(1.1\)](#page-1-0).

Due to the non-convexity, non-smoothness as well as the manifold constraint, algorithms that can be applied here is limited, and the existing ones can be basically divided into two categories. The first type focuses on using Riemannian algorithm to handle the manifold constraint  $7\vert8\vert9\vert10\vert$ . Riemannian subgradient [\(1.3\)](#page-1-1) is used in  $7\vert8\vert$  to deal with nonsmoothness,

<span id="page-1-1"></span>
$$
X_k = \text{Retr}_{X_{k-1}}(-\alpha_{k-1}\nu_{k-1})
$$
\n(1.3)

where  $\alpha_{k-1}$  is the stepsize,  $\nu_{k-1}$  denotes the Riemannian subgradient, and Retr is the retraction mapping. However, the efficiency of these proposed algorithm is not ideal as the subgradient method has relatively slow convergence rate, and the method is too general where it does not utilize the unique properties from the problem. The idea of MADMM  $[9]$ is relatively close to our algorithm where the variable splitting and ADMM is applied first to divide the original minimization into two sub-problems, but then an inner algorithm of Riemannian gradient is used to solve the smooth manifold constraint sub-problem. This splitting technique is not new and it is first proposed in  $[11]$  by Lai and Osher where it is called splitting orthogonal constraints (SOC). However, there are no convergence guarantees for both SOC based method in  $[11]$  as well as MADMM. Chen et al.  $[10]$  proposed an retraction-based proximal gradient called manifold proximal gradient method (ManPG), where the proximal method is extended from the Euclidean setting to manifold setting. In ManPG, after computing the proximal algorithm on tangent space by an inner semismooth Newton algorithm, a retraction is then adopted to map the iteration points back to the smooth manifold. Here, the computational cost for solving the proximal mapping sub-problem is high, which may not be efficient in certain problems.

The methods within the second category apply the Lagrangian based approach (e.g. augmented Lagrangian multiplier method) or indicator function on the orthogonal constraint to transform the minimization  $(1.1)$  unconditional. In [\[12\]](#page-14-2), Chen et al. proposed an proximal alternating minimized augmented Lagrangian (PAMAL) method to solve some specific  $\ell_1$ -regularized optimization problem such as the compressed modes [\[13\]](#page-14-3)[\[14\]](#page-14-4) in physics or the feature selection problem  $[15][16]$  $[15][16]$  with minor modifications. The PAMAL is based on an proximal regularized three-block Gauss-Seidel method applied to the augmented Lagrangian function [1](#page-2-0).4 after denoting the orthogonal constraint using an indicator function and splitting the variable twice.

$$
\mathcal{L}(X, Y, Z, \Lambda^1, \Lambda^2; \beta) = \text{trace}(X^T H X) + \frac{1}{\mu} ||Y||_1 + \delta_{\mathcal{S}}(Z) + \langle \Lambda^1, Y - X \rangle
$$
  
+ 
$$
\frac{\beta}{2} ||Y - X||_F^2 + \langle \Lambda^2, Z - X \rangle + \frac{\beta}{2} ||Z - X||_F^2
$$
 (1.4)

<span id="page-2-0"></span>where  $X, Y, Z, \Lambda^i \in \mathbb{R}^{n \times p}$  for  $i = 1, 2, \mu, \beta > 0$  and H is the (discrete) Hamiltonian. The update of the primal variable  $X_k, Y_k, Z_k$  is up to some predefined tolerance level  $\|\Theta_k\|_{\infty} \leq \epsilon_k, \Theta_k \in \partial \mathcal{L}(X_k, Y_k, Z_k, \Lambda_k^1, \Lambda_k^2; \beta_k)$ . Apart from the relatively complicated algorithm structure, the result of PAMAL is subjected and sensitive to its parameters settings like the three proximal parameters. When  $r(\cdot)$  within [\(1.1\)](#page-1-0) is the  $\ell_{m,1}$  norm  $(m > 1)$ , [\[17\]](#page-14-7) proposes an proximal gradient method for penalty models with a compact and convex constraints (PenCPG) based on using augmented Lagrangian method on orthogonal constraint and instead of dual ascent, the authors in  $\left|17\right|$  express the Lagrange multiplier through an close-form expression of the primal variable:

$$
\min_{X \in \mathcal{M}} g(X) := f(X) + r(X) - \frac{1}{2} \langle \Lambda(X), X^T X - I_p \rangle + \frac{\beta}{4} \| X^T X - I_p \|_F^2 \tag{1.5}
$$

where  $\mathcal{M} \subseteq \mathbb{R}^{n \times p}$  denotes a compact convex set includes the Stiefel manifold. Although this method gets rid of the dual variable and utilize the fast convergence rate of proximal algorithm, the limitation is that the closed-form expression for  $\Lambda$  only exist for  $r(\cdot)$  being  $\ell_{m,1}$  norm  $(m>1)$ .

## 1.3 Motivation and Contribution

Inspired by the novel idea of nonlinear eigenvalue problem with eigenvector dependency proposed by the authors in [\[18\]](#page-14-8), algorithms based on the NEPv formulation and then SCF iteration are designed to solve the problems like θ-trace ratio [\[6\]](#page-13-5) and orthogonal canonical correlation analysis (OCCA) [\[19\]](#page-14-9) which are defined on Stiefel manifold arise. However, the partial derivative of the objective function and its corresponding gradient on manifold are required during the process of transforming the first-order optimality condition (KKT) into the NEPv structure, which means the problem considered needs to be smooth. Therefore, ADMM is considered on problem [\(1.1\)](#page-1-0) to split the difficulty of the original minimization for which the smoothness condition for the construction of NEPv can then be satisfied.

Many of the optimization problems in machine learning defined over Stiefel manifold (e.g. principal component analysis (PCA), orthogonal linear discriminant analysis (OLDA), canonical correlations analysis (CCA) etc.) are aim at (linear) dimensionality reduction, which is the cornerstone when studying the high dimensional data, and the related function can be expressed through the matrix trace function. The  $p$  in problem  $(1.1)$  is usually referred to as the number of selected features and is a very small number compared to  $n \ (p \ll n)$ , the original dimensionality from data points. The NEPv approach from our NEPvADMM can be designed to better take advantage of these circumstances as well as the structure of each specific objective function to further lower the computational cost than the Riemannian gradient descent method from MADMM.

#### 1.4 Notation and Organization

In this paper,  $\mathbb{R}^{n \times p}$  is the set of  $n \times p$  real matrices,  $\mathbb{S}^{n \times n}$  denotes all  $n \times n$  real symmetric matrices.  $I_n$  is the identity matrix and  $X^T$  is the transpose of a matrix. The Euclidean inner product of  $X, Y \in \mathbb{R}^{n \times p}$  is defined through the trace function  $\langle X, Y \rangle = \text{tr}(X^T Y)$ , where  $tr(H) = \sum_i H_{ii}$  for  $H \in \mathbb{R}^{n \times n}$ . Here we will use  $\lambda_i(A)$  to denote the *i*-th largest eigenvalue of matrix  $A \in \mathbb{R}^{n \times n}$  and  $\sigma_i(A)$  being its *i*-th largest singular value.

$$
||A||_F = (\sum_{i,j} A_{i,j}^2)^{\frac{1}{2}} = (\sum_j \sigma_j^2)^{\frac{1}{2}},
$$
  

$$
||A||_2 = \max_j \sigma_j,
$$
  

$$
||A||_{\text{trace}} = \sum_j \sigma_j,
$$

denote the Frobenius norm, matrix spectral norm, and matrix trace norm respectively. Finally,  $A \in \mathbb{S}^{n \times n} \succeq (\succ)0$  means the matrix is positive semi-definite (positive definite).

The rest of the paper is organized as follows. In Section 2, we will explain the methodology of the NEPv ADMM method in detail and provide its algorithm. And in Section 3, real-life applications will be introduced and relative numerical experiments are implemented. Finally, we draw the conclusion in Section 4.

# 2 NEPv ADMM

The objective function [1.1](#page-1-0) is a combination of a smooth (possibly non-convex) function and a convex non-smooth function, it is natural to think of using alternating direction method of multipliers (ADMM) to split the difficulty of the original problem and handle each subproblem separately, where one is smooth optimization on manifold and the other is simply convex optimization.

<span id="page-4-0"></span>First, we split the variables and transform the original problem [1.1](#page-1-0) into an equivalent one

$$
\min_{X,Y} -\phi(X) + r(Y)
$$
  
s.t.  $X \in \mathcal{S}_{n,p}, Y \in \mathbb{R}^{n \times p}, X = Y$  (2.1)

where  $\phi(X) = -f(X)$ .

The augmented Lagrangian function is of [2.1](#page-4-0) is then

$$
\mathcal{L}_{\beta}(X,Y;\Lambda) = -\phi(X) + r(Y) + \langle \Lambda, X - Y \rangle + \frac{\beta}{2} \|X - Y\|_{F}^{2},\tag{2.2}
$$

Applying ADMM on the augmented Lagrangian function and update each variable iteratively

$$
X_{k+1} := \underset{Y}{\arg \max} -\mathcal{L}_{\beta}(X, Y_k; \Lambda_k)
$$
  
\n
$$
Y_{k+1} := \underset{Y}{\arg \min} \mathcal{L}_{\beta}(X_{k+1}, Y; \Lambda_k)
$$
  
\n
$$
\Lambda_{k+1} := \Lambda_k + \beta(X_{k+1} - Y_{k+1}).
$$
\n(2.3)

<span id="page-4-1"></span>From [2.3,](#page-4-1) due to the existence of the Stiefel manifold constraints, the X sub-problem is an optimization on smooth manifold. Instead of using the commonly applied methods such as Riemannian gradient descent, we apply a more customized nonlinear eigenvalue problem with eigenvector dependency (NEPv) approach to tackle it which is more efficient as  $f(X)$  within [1.1](#page-1-0) is usually about dimensionality reduction. The general idea of the NEPv approach is to get the first order optimality condition by taking the gradient of the objection function first, and then transform the equality into the form of nonlinear eigenvalue problem with eigenvector dependency and followed by using the self-consistent field (SCF) iteration.

Denoting  $g_k(X) = -\mathcal{L}_\beta(X, Y_k; \Lambda_k)$  for simplicity, the gradient of  $g_k(X)$  on Stiefel manifold is

$$
\operatorname{grad} g_k(X) = \frac{\partial g_k(X)}{\partial X} - X \operatorname{sym}(X^T \frac{\partial g_k(X)}{\partial X})
$$
\n(2.4)

where  $\text{sym}(A) = \frac{A + A^{T}}{2}$ .

Therefore, the KKT condition of the X sub-problem can be transformed into

<span id="page-5-0"></span>
$$
\frac{\partial g_k(X)}{\partial X} = X\hat{\Omega}
$$
 (2.5)

where  $X \in \mathbb{O}^{n \times p}$  and  $\hat{\Omega}^T = \hat{\Omega} \in \mathbb{R}^{p \times p}$ .

The partial derivative  $\frac{\partial g_k(X)}{\partial X}$  is computed by treating each entries within X independent from each other:

$$
\frac{\partial g_k(X)}{\partial X} = \frac{\partial \phi(X)}{\partial X} - \Lambda_k - \beta(X - Y_k)
$$
\n(2.6)

Here we do not have the specific form of  $\phi(X)$ , thus we take the general method to transform the left hand side of [2.5](#page-5-0) into the form of NEPv  $H(X)X$  where  $H(X) \in \mathbb{R}^{\times \times \times}$  is a symmetric matrix

$$
H(X) = \frac{\partial (g_k(X) + \beta X)}{\partial X} X^T + X \left( \frac{\partial (g_k(X) + \beta X)}{\partial X} \right)^T - \beta I_n
$$
  
= 
$$
\frac{\partial \phi(X)}{\partial X} X^T + X \left( \frac{\partial \phi(X)}{\partial X} \right)^T + D_k X^T + X D_k^T - \beta I_n
$$
 (2.7)

<span id="page-5-2"></span>where  $D_k = \beta Y_k - \Lambda_k$ .

But special and simpler formulations are often available if the specific form of  $\phi(X)$  is known. For example, in sparse PCA,  $\phi(X) = \frac{1}{2}$ trace( $X^T A X$ ) where  $A \succeq 0$ , we can take  $H(X) = A - \beta I_n + D_k X^T + X D_k.$ 

The NEPv of the X sub-problem takes the form

<span id="page-5-1"></span>
$$
H(X)X = X\Omega, X \in \mathcal{S}_{n,p}, \Omega^T = \Omega \in \mathbb{R}^{p \times p}
$$
\n(2.8)

**Theorem 1.**  $X \in S_{n,p}$  satisfies the first order optimality condition of  $\max_{X \in S_{n,p}} g_k(X)$  if and only if it is a solution of NEPv [\(2.8\)](#page-5-1) and  $X^T(D_k + \frac{\partial \phi(X)}{\partial X})$  is symmetric.

To make sure the monotonic increase of each iteration step with the X sub-problem, we assume the NEPv Ansatz holds, meaning for  $\tilde{X} \in \mathcal{S}_{n,p}$ ,  $X \in \mathbb{X} \subseteq \mathcal{S}_{n,p}$ , if

$$
\text{trace}(\hat{X}^T H(X)\hat{X}) \ge \text{trace}(X^T H(X)X) + \eta \quad \text{for some } \eta \in \mathbb{R}
$$
 (2.9)

Then there exist  $Q \in \mathcal{S}_{p,p}$  with  $\tilde{X} = \hat{X}Q \in \mathbb{X}$  such that  $g_k(\tilde{X}) \ge g_k(X) + \omega \eta$ .

Next, the SCF iteration described in Algorithm 1 can be used

Since the exact optimizer of X sub-problem is hard to solve, we proposed to replace it by only one SCF iteration in the X sub-problem.

The Y sub-problem is a convex optimization, and it has a closed-form solution through proximal gradient method.

# Algorithm 1 Self-Consistent Field Iteration

**Require:**  $X_0 \in \mathbb{X}$ , set  $k = 0$ while certain stopping criterion is not reached do Construct  $H_k = H(X_k);$ Compute orthonormal eigenbasis matrix  $\hat{X}_{k+1}$  associated with the p largest eigenvalues of  $H_k$ ; Compute  $Q_{k+1} \in \mathbb{X}$  and set  $X_{k+1} = \hat{X}_{k+1} Q_{k+1} \in \mathbb{X}$ ; Set  $k \coloneqq k + 1$ . end while Return the last  $X_k$  as a maximizer of  $g_k(X)$ .

**Lemma 1.** The Y sub-problem has closed-form solution  $Y_{k+1} = \text{Prox}_{\frac{r(\cdot)}{\beta}}(X_{k+1} + \frac{\Lambda_k}{\beta}),$  and we have  $\Lambda_{k+1} \in \partial r(Y_{k+1})$ . For  $r(\cdot)$  being the element-wise  $\mathcal{L}_1$ -norm, the proximal operator can be solved by soft-thresholding function.

Proof. The Y sub-problem:

$$
Y_{k+1} := \underset{Y \in \mathbb{R}^{n \times p}}{\arg \min} r(Y) + \langle \Lambda_k, X_{k+1} - Y \rangle + \frac{\beta}{2} \| X_{k+1} - Y \|^2_F \tag{2.10}
$$

<span id="page-6-0"></span>It has optimality condition:

$$
0 \in \partial r(Y_{k+1}) - \Lambda_k + \beta(Y_{k+1} - X_{k+1})
$$
  
\n
$$
0 \in \partial \frac{1}{\beta} r(Y_{k+1}) + Y_{k+1} - (X_{k+1} + \frac{1}{\beta} \Lambda_k)
$$
\n(2.11)

which can be expressed through a one-step proximal gradient:  $Y_{k+1} = \text{Prox}_{\frac{r(\cdot)}{\beta}}(X_{k+1} +$  $\frac{\Lambda_k}{\beta}).$ 

Rearranging the terms of the first equation within [\(2.11\)](#page-6-0):

$$
\Lambda_k + \beta(X_{k+1} - Y_{k+1}) \in \partial r(Y_{k+1})
$$
  

$$
\Lambda_{k+1} \in \partial r(Y_{k+1})
$$
\n(2.12)

 $\Box$ 

Our NEPv based ADMM can then be summarized by the following Algorithm 2, where we can see the purcedure is straightforward and no inner loops are included.

For standard two-block ADMM algorithm which has already been proven to converge to the first-order optimality point, the two functions  $f(X)$  and  $r(X)$  from the composite objective function both need to be proper, closed convex functions, as well as each of the two sub-problems are optimized exactly. In our ADMM structure from Algorithm 2, the X sub-problem is non-convex and is an inexact optimization. Although several works have expanded the convergence condition of ADMM to some mild assumption on the objective function, none of them cover the type of the problem considered here.

# Algorithm 2 NEPv based ADMM Algorithm

Require:  $X_0 \in \mathbb{X} \subseteq \mathcal{S}_{n,p}$ ,  $Y_0$ ,  $\beta$ , set  $k = 0$ while certain stopping criterion is not reached do Construct  $H_k = H(X_k);$ Compute orthonormal eigenbasis matrix  $\hat{X}_{k+1}$  associated with the p largest eigenvalues of  $H_k$ ; Compute  $Q_{k+1} \in \mathbb{X}$  and update  $X_{k+1} = \hat{X}_{k+1} Q_{k+1} \in \mathbb{X}$ ; Update  $Y_{k+1} := \text{Prox}_{\frac{r(\cdot)}{\beta}} (X_{k+1} + \frac{\Lambda_k}{\beta});$ Update  $\Lambda_{k+1} := \Lambda_k + \beta(X_{k+1} - Y_{k+1});$ Set  $k \coloneqq k+1$ . end while

# 3 Numerical Experiments

# 3.1 Applications

Many applications can be found suited to the problem formulation [\(1.1\)](#page-1-0) within the area of machine learning, data science, and physics. We list some of them in the following.

Example 4.1 (sparse principle component analysis (sPCA)) Principal component analysis is one of the most widely used unsupervised learning method in machine learning for dimension reduction. It was first proposed by Pearson in 1901 [\[20\]](#page-14-10) as a method to minimize the projection residuals, but nowadays it is often treated as finding a projection that can maximize the variance, and the two perspectives are equivalent. However, in traditional PCA, it is difficult to interpret the corresponding principal components as the each of them is a dense linear combination of all the original features  $[21]$ . Nowadays, massive amounts of data needs to be processed and these data are of high-dimensional (usually the number of features is larger than the number of data observations) in general, and the lack of feature selection has restricted the performance of traditional PCA in many applications such as the sparse coding of image processing [\[22\]](#page-15-1)[\[23\]](#page-15-2) as well as the natural language processing [\[24\]](#page-15-3).

To address these issues by improving the interpretability as well as reducing the storage required [\[25\]](#page-15-4), sparse PCA was proposed using the idea that most of the variation in the data can be explained using only a small number of significant original features and thus the principal components are formed by sparse combinations instead. There are different ways to enforce sparsity, here we consider adding the  $\ell_1$ -regularization term to the original PCA objective function as it is generally easy to solve and can be useful in many applications [\[26\]](#page-15-5). The problem formulation is as follows  $(3.1)$  $(3.1)$ .

$$
\min_{X} -\frac{1}{2}tr(X^{\top}AA^{\top}X) + \mu \|X\|_1
$$
\n
$$
\text{s.t.} \quad X \in \mathcal{S}_{n,p} \tag{3.1}
$$

<span id="page-8-0"></span>where A is  $\mathbb{R}^{n \times m}$  data matrix and  $AA^T \succeq 0$ . *n* denote the dimension of a single data, meaning the types of features, m is the amount of data observations, and  $\mu > 0$  here is a weighting parameter for the problem and  $(3.1)$  reduces back to PCA if  $\mu = 0$  (the leading p eigenvalues of  $AA<sup>T</sup>$ ).

Example 4.2 (orthogonal dictionary learning (ODL)) Given the data matrix  $A \in \mathbb{R} \times \mathbb{R}$  with the column vectors represent the data points  $a_i, i = 1, ..., p$  and  $p \gg n$ , the purpose of ODL is to find an orthogonal matrix  $X \in \mathbb{R}^{n \times n}$  so that A can be compactly represented [\[27\]](#page-15-6)[\[28\]](#page-15-7)[\[29\]](#page-15-8). The problem has the following generalized mathematical format:

$$
\min_{X} \|A^T X\|_1
$$
  
s.t.  $X \in \mathcal{S}_{n,n}$  (3.2)

<span id="page-8-1"></span>The  $A<sup>T</sup>X$  from the objective function of [\(3.2\)](#page-8-1) can be seen as the correlation matrix, which we want it to be sparse by controlling the orthogonal basis matrix  $X$ , and the element-wise  $\ell_1$  norm here is used to enforce the sparsity. Based on [\(3.2\)](#page-8-1), [\[30\]](#page-15-9) introduces an application called robust subspace recovery (RSR), and the corresponding dual principal component pursuit (DPCP) approach for solving RSR can be found in  $[31][32][33]$  $[31][32][33]$  $[31][32][33]$ , where they transform the problem into:

$$
\min_{X} \|A^T X\|_1
$$
  
s.t.  $X \in \mathcal{S}_{n,p}$  (3.3)

where  $p = n - d$  and d is the dimensionality of the subspace spanned by the inlier point from the data matrix A.

**Example 4.3 (compressed modes in physics)** For the independent-particle Schrödinger equation about a finite system of electrons, the compressed modes problem is to compute a spatially localized solutions to its eigenvalue problem, where the sparsity is enforced through adding the  $\ell_1$  regularization term after the wave function. According to [\[34\]](#page-16-0), the problem has the following formulation:

$$
\min_{X \in \mathbb{R}^{n \times p}} \text{trace}(X^T H X) + \frac{1}{\mu} \|X\|_1
$$
\n
$$
\text{s.t. } X^T X = I_p \tag{3.4}
$$

where  $H \in \mathbb{R}^{n \times n}$  represents the (discrete) Hamiltonian, parameter  $\mu > 0$  is predefined for balancing the weight of sparsity.

Example 4.4 (sparse spectral clustering) Spectral clustering (SC) is one of the most commonly used data clustering technique, and it requires to find out a lower dimensional embedding X of the original data through calculating the eigenvalues of the normalized Laplacian matrix first, then the final results can be derived through applying the K-means algorithm on  $X^T$ . The sparse SC is an extension of SC by implementing the idea of sparse regularization into SC, and according to the authors from [\[35\]](#page-16-1), the mathematical expression of the problem can be formulated as following:

$$
\min_{Y \in \mathbb{R}^{n \times n}, X \in \mathbb{R}^{n \times p}} \langle L, XX^T \rangle + g(Y)
$$
\n
$$
\text{s.t. } Y = XX^T, X^T X = I.
$$
\n(3.5)

where L denotes the normalized Laplacian matrix and  $g : \mathbb{R}^{n \times n} \to \mathbb{R}$  is the sparse regularizer which may be selected differently depending on problem settings.

Example 4.5 (unsupervised feature selection) Feature selection (FS) is about getting rid of the noisy features and selecting a feature subset with much smaller dimensionality from some high-dimensional feature set, so that the researcher may have a better data representation. In contrast to supervised FS such as trace ratio and Fisher score, unsupervised FS is much more difficult to handle because of its lack of label information. By adopting the assumption that a linear classifier can be used to predict the class label of input data, [\[16\]](#page-14-6) incorporates the  $\ell_{2,1}$  norm and discriminative analysis to model the unsupervised FS as a manifold optimization problem in the form of problem [\(1.1\)](#page-1-0):

$$
\min_{W} \text{ trace}(W^T M W) + \gamma \|W\|_{2,1}
$$
\n
$$
\text{s.t. } W \in \mathcal{S}_{n,p} \tag{3.6}
$$

where  $M \in \mathbb{S}^{n \times n}$  is calculated from the input data.

# 3.2 Numerical Experiments on sparse PCA

In this section, the efficiency of our NEPvADMM will be illustrated and presented through conducting numerical experiments on the problem of sparse PCA. Firstly, the test problem and the basic setting such as the stopping criterion and default parameter values will be explained. Next, we will compare the numerical performances between our algorithm with the existing ones and draw some conclusions. All the algorithms are performed in MATLAB R2022b, and the experiments are conducted on a laptop with Intel Core i5-1035G1 CPU @ 1.00GHz and 8G of RAM.

### 3.2.1 Experimental Settings

To implement the NEPvADMM, the variables within the original sparse PCA [\(3.1\)](#page-8-0) are splitted and transformed to

$$
\min_{X,Y} \quad -\frac{1}{2} \text{trace}(X^T M X) + \mu \|Y\|_1
$$
\n
$$
\text{s.t. } X = Y, X \in \mathcal{S}_{n,p} \tag{3.7}
$$

<span id="page-10-0"></span>where  $M = A^T A \in \mathbb{R}^{n \times n}$ . The augmented Lagrangian function of [\(3.7\)](#page-10-0) is

<span id="page-10-1"></span>
$$
\mathcal{L}_{\beta}(X,Y;\Lambda) = -\frac{1}{2}\text{trace}(X^T M X) + \mu \|Y\|_1 + \langle \Lambda, X - Y \rangle + \frac{\beta}{2} \|X - Y\|_F^2, \tag{3.8}
$$

After applying the ADMM  $(2.3)$  to  $(3.8)$ , we need to check the assumption that the function value  $(3.9)$  from X-subproblem is monotonic increasing under the SCF iteration

<span id="page-10-2"></span>
$$
g_k(X) = \frac{1}{2} \operatorname{trace}(X^T M X) - \langle \Lambda_k, X - Y_k \rangle - \frac{\beta}{2} \| X - Y_k \|_F^2 \tag{3.9}
$$

The following Lemma tells us whether the NEPv ansatz holds for sparse PCA:

**Lemma 2.** Given  $X \in S_{n,p}$ , the NEPv ansatz holds for the objective function [\(3.9\)](#page-10-2) of X-subproblem from sparse PCA.

Proof. First, we need to transform the gradient of [\(3.9\)](#page-10-2) into the form of NEPv to contract the matrix  $H(X)$ . In Section 2, for the sparse PCA, a simpler form of  $H(X)$  can be derived instead of directly applying [\(2.7\)](#page-5-2)

<span id="page-10-3"></span>
$$
H(X) = M - \beta I_n + D_k X^T + X D_k \tag{3.10}
$$

where  $D_k = \beta Y_k - \Lambda_k$ . Next, for  $X, \hat{X} \in \mathcal{S}_{n,p}$ , if

<span id="page-10-4"></span>
$$
trace(\hat{X}^T H(X)\hat{X}) \geq trace(X^T H(X)X),
$$
\n(3.11)

Inserting [\(3.10\)](#page-10-3) into [\(3.11\)](#page-10-4), through simple derivation, the left-hand side of [\(3.11\)](#page-10-4) is

<span id="page-10-5"></span>
$$
\begin{aligned} \text{trace}(\hat{X}^T H(X)\hat{X}) &= \text{trace}(\hat{X}^T M \hat{X}) - \beta \text{trace}(\hat{X}^T \hat{X}) + 2 \text{trace}(\hat{X}^T D_k X^T \hat{X}) \\ &\leq \text{trace}(\hat{X}^T M \hat{X}) - \beta \text{trace}(\hat{X}^T \hat{X}) + \|\hat{X}^T D_k\|_{\text{trace}} \end{aligned} \tag{3.12}
$$
\n
$$
= \text{trace}(\tilde{X}^T M \tilde{X}) - \beta \text{trace}(\tilde{X}^T \tilde{X}) + \text{trace}(\tilde{X}^T D_k)
$$

where the inequality within [\(3.12\)](#page-10-5) is done by von Neumann's trace inequality and  $\tilde{X} =$  $\hat{X}(UV^T)$  in the last equality is defined through singular value decomposition (SVD)  $\hat{X}^TD_k=$  $U\Sigma V^T$ . Similarly, the right-hand side of [\(3.11\)](#page-10-4) has the form of

<span id="page-10-6"></span>
$$
trace(X^T H(X)X) = trace(X^T M X) - \beta trace(X^T X) + 2trace(X^T D_k)
$$
 (3.13)

Setting		<b>NEPvADMM</b>		<b>RSG</b>		MADMM	
$\mu$	(n,p)	Obj.	Spa.	Obj.	Spa.	Obj.	Spa.
0.5	(300,5)	1.1580	0.9967	3.0364	$\theta$	1.1786	0.9967
0.5	(300, 50)	12.5907	0.9967	30.7831	$\theta$	12.5042	0.9960
0.5	(500, 5)	1.2330	0.9980	4.3290	$\theta$	1.2330	0.9980
0.5	(500, 50)	12.6830	0.9980	43.6577	$\theta$	12.6816	0.9980
1	(300,5)	3.7739	0.9967	10.7888	$\theta$	3.7739	0.9967
1	(300, 50)	36.9932	0.9967	110.0859	$\overline{0}$	37.1584	0.9967
1	(500, 5)	3.7146	0.9980	11.5442	$\theta$	3.7146	0.9980
1	(500, 50)	38.0765	0.9980	157.2606	$\theta$	38.1054	0.9980

Table 1: Results comparison between NEPvADMM, Riemannian subgradient method and MADMM from the aspects of objection value and sparsity

Adding the term  $trace(Y_k^T \Lambda_k) - \beta trace(Y_k^T Y_k)$  on both side of [\(3.12\)](#page-10-5) and [\(3.13\)](#page-10-6), the inequality [\(3.11\)](#page-10-4) can be transformed into the form of [\(3.9\)](#page-10-2)

$$
g_k(\tilde{X}) \ge g_k(X) \tag{3.14}
$$

which shows that the ansatz is satisfied.

The data matrix  $A \in \mathbb{R}^{n \times p} := \text{randn}(n, p)$  is randomly generated, where *n* is chosen from  $\{500, 1000\}$ , p from  $\{5, 10\}$ . We set  $\beta = 20$  and  $\mu$  from  $\{0.5, 1\}$ . The stopping criterion is defined as

$$
\frac{|F(Y_{k+1}) - F(Y_k)|}{|F(Y_k)|} < 10^{-8}
$$

where  $F(\cdot) := f(\cdot) + r(\cdot)$ .

#### 3.2.2 Numerical Results

We compare the performance of our NEPvADMM with the Riemannian subgradient descent method and the MADMM approach. The following Table 1 presents the results from three aspects: the objection value and the sparisty, where the sparsity formula is calculated by the percentage of the zero element within the matrix. From the table, we can see that the Riemannian subgradient method is unable to iteration a sparse result while the NEPvADMM and MADMM can, and the sparisty are very high both the latter two methods. Besides, the objective value generated by our approach and MADMM are very close, however, the ones derived by RSG is high compared to the others.

To have a better presentation of the efficiency of these three methods, Figure 1 shows how the objective value changes along with iteration counts as well as the CPU times. From

 $\Box$ 

Figure 1: Comparison of the iteration counts required and the CPU time (in seconds) consumed among the NEPvADMM, Riemannian gradient method, and the MADMM approach for  $\mu = 1$ 

Figure 1, the objective value of NEPvADMM and MADMM are similar while the RSG (blue line) performs badly, and it is clear that our approach requires much lower iteration counts as well as CPU time to converge in both four cases.

# 4 Conclusion

In this paper, we introduced an innovative method to address the non-smooth composite optimization on Stiefel manifold by employing a nonlinear eigen-approach (NEPv) together with alternating direction method of multipliers, which fully utilize the unique properties from the problem such as dimension reduction as well as sparsity, has great advantages compared to the limited existing algorithms, and can be applied to many applications from machine learning and data science. The steps from our algorithm in straightforward and easy to implement. It can be customized to specific problems to further improve the efficiency, and requires much smaller iteration counts to converge compared to other existing approaches. We have strong belief in our method for solving the non-smooth problems with orthogonal constraint. In future work, we will not only conducted detailed mathematical analysis on the convergence property of the algorithm, but also study and generalize the conditions for objective functions where the NEPv ansatz is guaranteed to hold.
