Abstract

Materials with broadband tunable optical properties are looked for in smart windows applications. Doped metal oxides presenting dual-band visible (VIS) – near-infrared (NIR) electrochromic properties can be used for solving such a challenge, and their accurate optical characterization is therefore of prime importance. Kubelka-Munk model is a state-of-the-art way to optically quantify the absorption properties of materials and is occasionally applied to plasmonic materials, even if great care should be taken to meet the formalism hypotheses. In the present work, Kubelka-Munk theory is discussed in the context of particles of indium-tin oxide and molybdenum-tungsten oxide formulations that are used as single-NIR and both-VIS/NIR active advanced electrochromic materials, respectively. An analytical model is derived for particles of much smaller dimensions than the incident wavelength and is experimentally verified. A dilution method is applied to verify the plasmonic characteristics of the particles. This study is key for efficient characterization of optical properties of metal oxides, and plasmonic materials in general, from diffuse reflectance measurements.

1. Introduction

Plasmonic materials have gained interest due to their enhanced light-matter interactions, impacting fields such as sensing, imaging, targeted drug delivery or photothermal therapy¹. Among the variety of compositions of plasmonic particles, doped metal oxides have shown interesting properties for Surface-Enhanced Raman Scattering (SERS) spectroscopy, visible light enhanced catalytic reactions and electrochromic materials for smart windows applications. Smart windows based on plasmonic electrochromic compounds offer the possibility to fine tune the visible (VIS) and near-infrared (NIR) parts of the solar spectrum independently, which is not possible with conventional, non-plasmonic electrochromic materials². Such dual-band

operation is looked for increasing the energy savings in buildings, allowing one to manage selectively the luminosity and the heat via different modes of solar light modulation amongst bright (VIS- and NIR-transparent), cool (VIS-transparent, NIR-opaque), warm (VIS-opaque, NIR-transparent), or dark (VIS- and NIR-opaque) optical states³.

Selected formulations of doped metal oxides such as indium-tin oxide ITO⁴ or substoichiometric tungsten oxide $WO_{3-x}^{5,6}$ are particularly relevant in this context, respectively responding in the 1500-2000 nm and 800-1200 nm wavelength ranges. Their optical properties (absorption/transmission) need however to be finely characterized. A common experimental way to determine the absorbance spectrum of plasmonic particles is to disperse them in a suitable liquid solvent and measure absorption using Beer-Lambert law^{7,8}. Though, such easy optical characterization fails in some case, for example when the processed liquid suspension is unstable.

The Kubelka-Munk model^{9–11}, originally derived for paintings¹², uses a simple diffuse reflectance to probe the absorption properties of solid-state samples. Due to its easy implementation for powders of particles, the model has been widely applied in scientific and industrial characterizations of materials such as paper^{13,14}, pigmented plastics¹⁵, human tissues¹⁶, teeth^{17,18} or pigment mixtures including iron oxide¹⁹. It was also applied to a range of plasmonic materials^{20–24}. However, one should not forget that the Kubelka-Munk formalism comes with specific hypotheses¹¹, such as a weakly absorbing medium necessary to minimize specular reflection. A careless use of the Kubelka-Munk formalism to highly absorbing medium, such as plasmonic particles around their localized surface plasmon resonance (LSPR), should be avoided. To the best of our knowledge, a detailed study on the conditions of application of Kubelka-Munk theory to plasmonic particles is missing from the current literature.

Therefore, in this work, we discuss the use of the Kubelka-Munk formalism and the validity of its hypotheses in a plasmonic context. We derive an analytical formula for computing the Kubelka-Munk function in the case of small plasmonic particles within the quasi-static approximation. This analytical derivation allows us to identify characteristic signatures in the Kubelka-Munk spectrum of plasmonic particles upon dilution in a suitable dielectric background. We produce different formulations of particles, i.e. indium-tin and molybdenum-tungsten oxides, and verify their plasmonic characteristics using diffuse reflectance spectrometry, according to the derived analytical model. These plasmonic particles are particularly interesting in the context of designing broadband optically-tunable materials, notably for electrochromic smart windows applications.

2. Kubelka Munk model for plasmonic materials

Optical properties of plasmonic particles processed as suspensions from colloidal synthesis approaches are classically determined through spectrophotometry. The obtained suspension is illuminated by an incident intensity I_0 while the emerging electromagnetic radiation of intensity $I < I_0$ is collected in a detector after going through an optical path *z* in the particulate medium (Fig. 1a)⁸.

Figure 1: (a) Experimental setup for (a) Beer-Lambert absorption measurements in liquid suspension and (b) Kubelka Munk model for plasmonic particles (in grey), with both undiluted and diluted configurations (diluting agent in blue) inside an integrating sphere.

The experimental situation can be modeled as a collection of particles, more or less uniformly distributed within the region $0 \le z \le d$ with a non-absorbing background (in blue in Fig. 1a), and a number of particles per unit volume *N*. In this case, scattering is considered incoherent, the separations between the particles being uncorrelated during the measurement. Therefore, one can deduce the well-known Beer-Lambert law⁸:

$$I(z) = I_0 e^{-\mu_{ext} z} \tag{1}$$

providing the intensity of attenuated light after a distance *z* with the attenuation coefficient $\mu_{ext} = NC_{ext} = NC_{abs} + NC_{sca} = 2(k + s)$ where C_{ext} , C_{abs} and C_{sca} are the extinction, absorption and scattering cross-section and *k* and *s* the absorption and scattering coefficients, respectively. Using the Beer-Lambert law, one usually characterizes the optical properties of a (plasmonic) material by its absorbance $A = -log(T) = \frac{\mu_{ext}d}{ln10}$ with $T = \frac{I(d)}{l_0}$ being the transmittance through the suspension. This model considers a single unidirectional energy flux. Therefore, equation (1) and the deduction of the absorbance are valid for small contribution from the scattering to the total attenuation, *i.e.* $NC_{sca}d = sd \ll 1$. This condition is generally met in plasmonic materials when the size *r* of the particles is smaller than the LSPR wavelength $\lambda = 2\pi/k'$ where *k'* is the wave vector inside the medium, hence neglecting scattering in the quasi-static limit, *i.e.* $C_{ext} \approx C_{abs}$ if $k'r \ll 1$.

However, for suspensions unstable because of their composition and/or processing method, this methodology using dispersed particles in a solvent may fail at correctly providing optical characterization of plasmonic particles. Nevertheless, a relatively direct optical measurement can still provide a characterization of the absorption properties of a particulate medium if one measures the diffuse reflectance of the particles being processed as powders, potentially from the proper filtration and/or evaporation/drying of the aforementioned unstable suspensions, using the Kubelka-Munk (KM) formalism^{11,25}. The later provides a direct link between the absorption coefficient k, scattering coefficient s and the measured diffuse reflectance R_{∞} as:

$$KM = \frac{k}{s} = \frac{(1 - R_{\infty})^2}{2R_{\infty}}.$$
 (2)

Using the above definitions for the absorption and scattering coefficients, the KM function is equal to $KM = \frac{C_{abs}}{C_{sca}}$. Provided that the scattering coefficient is constant¹¹, measuring the diffuse reflectance gives an easy way to access the absorption cross-section of a material. This is the reason why KM function is generally assimilated to (or confused with) an absorption spectrum.

Originally developed for characterizing paintings¹², special care should however be taken when used for characterizing plasmonic particles. A simple glance at equation (2) indicates that a vanishing scattering coefficient as for small particles – but not necessarily absorbing – would cause a divergence of the KM function, hence a wrong use of the equation (2) as is. A more detailed analysis requires recalling the underlying hypothesis of the KM model.

The KM model can be seen as an extension of the Beer-Lambert model because it considers energy flux in two opposite directions (Fig. 1b) rather than a unidirectional flux. We suppose a sample of powder of thickness d divided into infinitesimal layers of thickness dx relying on a substrate. The KM model is based on three hypotheses¹¹:

- (1) The particles inside the infinitesimal layer are considered as randomly distributed and with a size smaller than the thickness of the layer ($r \ll d$);
- (2) The sample undergoes diffuse irradiation;
- (3) The sample should display ideal diffuse reflection, *i.e.* reflection is isotropic, following Lambert cosine law^{26,27}. Therefore, we can neglect specular reflection R_{spec} in the total reflectance $R = R_{spec} + R_{\infty} \rightarrow R \sim R_{\infty}$.

The first hypothesis allows to consider the particle layer as homogeneous and avoids treating individual particles constituting the layer. Consequently, shapes and sizes of the particles can be non uniform²⁸. The sufficiently thick layer also ensures that one can neglect the reflectance coming from the substrate. This assumption is usually met in realistic experimental conditions.

The second hypothesis enables the isotropic distribution of scattering within the layer²⁹. In practice, no differences, within experimental errors, could be observed amongx three scenarios: (1) directive (45°) incident irradiation and directive vertical detection, (2) inside an integrating sphere, diffuse incident irradiation (*i.e.* the KM hypothesis) and vertical detection and (3) inside an integrating sphere, vertical incident irradiation and diffuse detection (our setup, as in Fig. 1b) ¹¹.

In case of low reflection/high absorption, which is the case around plasmonic resonance, the applicability of the KM model is questionable since the third hypothesis is not met. Specular reflectance for an interface separating medium 1 with refractive index n_1 and an absorbing medium 2 with refractive index $\widetilde{n_2} = n_2 + i\kappa$ is easily obtained using Fresnel formula^{30,31}. It yields for normal incident light:

$$R_{spec} = \frac{(n_2 - n_1)^2 + \kappa^2}{(n_1 + n_2)^2 + \kappa^2}.$$
(3)

At the limit of high κ , the specular reflectivity tends to one and R_{∞} is negligible. This remark is important for plasmonic systems which are highly absorbing at resonance. Therefore, directly applying the KM theory leads to unsuitable use of the model¹¹.

In order to counter this, using a dilution method enables to respect the KM hypothesis and properly characterize the absorption properties of the sample. It consists in grinding the absorbing powder and mixing it with a nonabsorbing standard such as LiF, NaCl, BaSO₄ or MgO, being added in excess so that it eliminates the original specular reflection. Consequently, the scattering coefficient of the mixture is almost solely determined by the scattering coefficient of the diluting agent ³². Using the pure diluting agent as reference for the reflectance measurements enables to neglect residual specular reflection as well as possible deviations from the isotropic scattering distribution in such a way that the measurements become independent of the experimental setup. Kortum explicitly demonstrated that the KM spectrum from undiluted anthraquinone does not resemble the "real" KM spectrum obtained by diluting anthraquinone in ethanolic solution³². The real spectrum is only recovered once the powder is sufficiently diluted in NaCl. The same behavior occurs for plasmonic particles as shown below. Therefore, such dilution method is a convenient experimental tool to optically characterize absorbing powder and should be considered as a sine qua non condition for using the KM model with plasmonic particles.

Applying the dilution method to the KM model for plasmonic particles mixed with a diluent agent reaches

$$KM = \frac{k_{mix}}{s_{mix}} = \frac{k_{plas} + k_{dil}}{s_{plas} + s_{dil}} \cong \frac{k_{plas}}{s_{dil}}$$
(4)

where the indices \lim_{mix} , \lim_{plas} , \lim_{dil} stand for mixture, plasmonic and diluent agent respectively. We also assume that the diluent agent is non-absorbing ($k_{dil} \rightarrow 0$) and dominates the scattering coefficient of the mixture. The later assumption is further justified if the diluent is in coarse grain state (*i.e.* the size $r_{dil} > r_{plas} \rightarrow s_{dil} \gg s_{plas}$). Considering a constant scattering cross-section of the diluent agent $C_{sca,dil}$ ¹¹, one obtains

$$KM \cong \frac{N_{plas}C_{abs,plas}}{N_{dil}C_{sca,dil}}.$$
(5)

Therefore, one can now correctly relate the diffuse reflectance measurement to the absorption cross-section of the plasmonic particles measured once diluted, meeting KM hypotheses. Crucially, a trade-off must be reached between a sufficient density of plasmonic particles N_{plas} to have a measurable signal-to-noise ratio, and a not too high quantity to avoid specular reflection as discussed above.

Furthermore, one can provide an analytical formulation for the KM model for spherical plasmonic particles if one uses the electrostatic approximation ^{1,8}, valid when the size (here the radius) of the plasmonic particles is small compared to the vacuum wavelength $r_{plas} \ll \lambda_0$:

$$KM \cong \frac{8\pi^2}{\lambda_0} \left(\frac{1}{C_{sca,dil}}\right) \frac{f_{plas}}{1 - f_{plas}} r_{plas}^3 \sqrt{\varepsilon_{m,eff}} Im \left(\frac{\varepsilon_{plas} - \varepsilon_{m,eff}}{\varepsilon_{plas} + 2\varepsilon_{m,eff}}\right)$$
(6)

with f_{plas} being the filling fraction of plasmonic particles, related to the mass percentage of plasmonic particles used in the dilution $m_{plas}(\%)$ and the mass densities ρ :

$$f_{plas} = \frac{m_{plas}(\%)}{m_{plas}(\%) + \left(\frac{\rho_{plas}}{\rho_{dil}}\right) \left(1 - m_{plas}(\%)\right)}.$$
(7)

The small spherical plasmonic particles have a permittivity ε_{plas} embedded in an environment of permittivity ε_m (Fig1b). The latter can be approximated by the effective permittivity $\varepsilon_{m,eff}$ using a Bruggeman model³³ to consider the effect of the varying quantities of plasmonic and diluent constituents upon dilution. The resonance in the analytical KM function corresponds solely to the Frölich condition $Re\left(\varepsilon_{plas}(\omega)\right) = -2\varepsilon_{m,eff}$, *i.e.* the dipole surface plasmon resonance of the sphere. It should be noted that changing the diluting agent has a direct influence on the plasmonic absorption peak: an increased surrounding permittivity induces a shift of the absorption maximum. More details and discussion on the derived model can be found in SM1.

3. Kubelka-Munk formalism applied to plasmonic indium-tin oxide

3.a Analytical model for plasmonic ITO

To further characterize the trends of the KM model for plasmonic particles upon dilution, let us apply the analytical model (equation (6)) to indium-tin oxide (ITO) as state-of-the-art formulation allowing for NIR-modulating plasmonic electrochromism ${}^{4,34-38}$. We model here ITO nanoparticles of radius $r_{ITO} = 10nm$ and density $\rho_{ITO} = 7.18 \ g/cm^3$ diluted in LiF with $\rho_{LiF} = 2.64 \ g/cm^3$, $\varepsilon_{LiF} = 1.92^{-39}$. We use a Drude model for the permittivity of ITO (see details in SM2 and Fig. S1). Here, $C_{sca,dil}$ is considered as a scaling factor as discussed in SM1. One can clearly see three major characteristics of the effect of increasing dilution of plasmonic particles, *i.e.* decreasing m_{ITO} value, on the KM spectra (Fig. 2):

- (1) A red-shift of the peak of the KM function;
- (2) A diminution of the intensity of the KM function;
- (3) A broadening of the peak of the KM function.

Figure 2: Impact of dilution of plasmonic particles, here ITO, on KM function. Insets: values for $m_{ITO} = 10\%$ and $m_{ITO} = 1\%$.

The derived analytical model for the KM function is dominated by the absorption cross section of the plasmonic particles as seen in equation (6), specifically with the terms $r_{plas}^3 \sqrt{\varepsilon_{m,eff}}$ and $Im\left(\frac{\varepsilon_{plas}-\varepsilon_{m,eff}}{\varepsilon_{plas}+2\varepsilon_{m,eff}}\right)$. The effective permittivity of the surrounding medium evolves from being dominated by ITO ($\varepsilon_{ITO} < 0$ to the one of LiF ($\varepsilon_{LiF} > 0$ upon dilution. This increased effective surrounding permittivity causes the red-shift as the frequency of the plasmonic peak for small spherical particles is given by $\omega_0 = \omega_p/\sqrt{1+2\varepsilon_m}$ with ω_p the plasma frequency¹. This well-known result for absorption cross-section of plasmonic particles is illustrated in Fig. S2 (see SM2). The diminishing filling fraction of plasmonic particles once the mass percentage of those is lowered (equation (7)) upon dilution impacts the intensity. Lower number of plasmonic particles means lower k_{plas} and higher s_{dil} in equation (4), hence a globally diminishing intensity of the KM function. Finally, the broadening is related to the above mentioned Frölich condition for plasmonic resonance. If ε_m increases, $Re(\varepsilon_{plas})$ becomes more negative, and correspondingly, in a Drude model, $Im(\varepsilon_{plas})$ increases (see Fig. S1, SM2), resulting in a broadening of the peak.

The impact of other parameters, such as modifications of the radius of the plasmonic particles r_{plas} , the plasma frequency ω_p or the damping constant γ , on the analytical model of KM for plasmonic particles is further discussed in SM2.

One can wonder for which filling fraction of plasmonic particles the KM hypotheses are specifically met. There is no universal answer to this question¹¹. However, the present work can provide some guidelines. The main motivation of the dilution method was to meet the third hypothesis of the KM model, lowering the specular reflection and maximizing the diffuse reflectance. The quantity of plasmonic particles should be small enough to meet those criteria. It should be noted here that the second hypothesis of the KM model also supposes that particles are sufficiently separated from each other to neglect phase relations and interferences between the scattered waves²⁹. Furthermore, we used a model for an isolated plasmonic sphere¹ considering the

additive properties of the cross-sections, valid for incoherent scattering occurring once neglecting correlations between particles, *i.e.* at large interparticle separations. The above considerations lead to a quantity of plasmonic particles certainly below 50%. However, a too small percentage of plasmonic particles leads to a too low KM function because of the dominating s_{dil} factor causing small signal to noise ratio in experiments. Therefore, a threshold should be found. At this stage, we need more experimental considerations to further answer this question and confront the derived analytical model to verification.

3.b. Experimental verification for plasmonic ITO

To experimentally validate the proposed analytical KM model for plasmonic particles, ITO particles are fabricated through colloidal synthesis³⁸. Well dispersed and defined nanospheres are obtained, with a narrow diameter distribution averaging 5.5 ± 1.0 nm, based on transmission electron microscopy (TEM) images recorded using a TECNAI G² 20 operated at 200 kV and shown on Fig. 3a. Particles in the form of powder are then obtained by heating the suspension at 100°C until a dry solid is left. The sample is manually crushed in a mortar and diluted with LiF powder (at various %wt.) until a homogeneous mix is obtained, which is then transferred into a suitable holder for further optical characterization using UV-VIS-NIR spectrometry. Any extra powder is removed so that the surface of the sample is leveled with the holder.

Figure 3: (a) TEM image of ITO particles, (b) KM function of ITO particles using LiF as diluting agent.

Diffuse reflective measurements by UV–VIS–NIR spectrometry are performed on a Shimadzu 3600 Plus instrument using an integrating sphere (ISR-1503). Data is then post-processed using equation (2) to obtain experimental KM function. We performed 5 measurements, their mean value as well as the 99.75% confidence level are shown on Fig. 3b. The curve for $m_{ITO} = 100\%$ corresponds to undiluted ITO but does not fit the above explained KM hypotheses, so it should be considered carefully.

Upon dilution in LiF, the three main characteristics of KM function presented in the proposed model are recovered, namely (1) the red-shift of the peak, (2) the diminution of the intensity and (3) the broadening of the peak of the KM function for a progressively lowered mass of plasmonic particles. Peak and FWHM values are

reported in SM3 (Table 1). The peak shifts from 1495 nm ($m_{ITO} = 90\%$) to 2040 nm ($m_{ITO} = 10\%$).

It could be wrongly deduced, by a simple glance at Fig. 3, that the noise attenuates with a lower quantity of ITO. This is not true, as it results from the attenuation of the KM signal (2). A normalized version of Fig. 3 is presented in SM 4 (Fig. S6). The noise above 1700 nm is due to the PbS NIR detector which is sensitive to any hot objects in the environment. Moreover, the diffuse reflectivity of the mixed powder is very small in that wavelength range for $m_{ITO} > 20\%$ (see SM4 Fig. S7), decreasing the signal-to-noise ratio.

In the following sections, we will consider m = 10% as a relevant threshold to verify the KM hypotheses and having sufficient signal to detect: the diffuse reflectance curve for m = 10% is well separated from the others, higher than the noise and with an intensity not close from zero.

All in all, the above results experimentally validate qualitatively the proposed analytical model and provide guidelines to properly apply the KM model to other plasmonic particles.

4. Application to molybdenum-tungsten oxides as emergent electrochromic materials

Interestingly, recent works have highlighted the occurrence of a largely-increased plasmonic absorption in other formulations of doped metal oxides, notably in oxygen-deficient molybdenum – tungsten mixed oxides being praised in photocatalytic applications. Specifically, Yin *et al.* have shown that the KM function of these $Mo_{1-y}W_yO_{3-\delta}$ – "MoWOx" – hybrids, presented KM intensities being 20 and 16 times larger than KM of parent formulations MoO_{3-x} and WO_{3-x}, respectively²⁴. They claimed that the enhanced absorption is a LSPR signal arising from vacancies in the crystal structure. They mainly studied the molar ratio of Mo:W = 1:1, but the 2:1 and 1:2 ratios presented red-shifted KM peaks as well as decreased peak intensities of about 20% and 50% vs. 1:1, respectively²⁴.

These "MoWOx" formulations further present noticeable interest as advanced electrochromic compounds (on-going studies), as they show enhanced electrochromic efficiency and dual-band selectivity towards both VIS and NIR wavelength ranges, highlighting the processed formulations as promising candidates for the development of "new generation" dual – band smart windows.

Therefore, we propose here to apply the KM formalism on these compounds to check the presence of plasmonic character.

We prepared MoWOx hybrids as well as parent oxides MoO_{3-x} and WO_{3-x} , adapting synthesis protocols from literature²⁴. Briefly, the materials are obtained through a single step solvothermal synthesis: 9 mmol of metallic powder precursors are dissolved in 11.5 mL of H₂O₂, then mixed with 69 mL of isopropanol and transferred into a 125 mL Teflon body, placed into a stainless-steel autoclave to be thermally treated for 1h at 160°C. For the MoWOx, 6 mmol of Mo and 3 mmol of W precursor are used (Mo/W : 2/1), while WO_{3-x} and MoO_{3-x} parent oxides are produced from 9 mmol of W and 9 mmol of Mo metallic powder, respectively. The obtained MoWOx particles present a peculiar "urchin-like" morphology (see TEM image in Fig. 4a), consisting in a solid core, with its surface covered by nanorods. These particles show average dimensions of $1.5 \pm 0.5 \mu m$. Parent oxides MoO_{3-x} and WO_{3-x} exhibit different morphologies, with MoO_{3-x} (Fig. 4b) presenting a feather-like morphology (elongated platelets of dimensions $1.9 \times 0.1 \times 0.05 \pm 0.5 \times 0.03 \times 0.01 \mu m$) while its W counterpart is found as aggregated nanospheres with an average diameter of $6.4 \pm 1.6 nm$ (Fig. 4c). It is interesting to note here that, although the shape, size and composition of the particles may be different, general conclusions and trends arising from the analytical model derived in section 2 are still valid, because those parameters are contained in equation 6, thus impacting the KM function.

Figure 4: TEM images of (a) MoWOx, (b) MoO_{3-x} and (c) WO_{3-x} particles. (d) KM function of undiluted MoWox particles and parent oxides MoO_{3-x} and WO_{3-x}. Inset: Zoom on KM function for parent oxides (e) KM function for MoWOx particles and parent oxides MoO_{3-x} and WO_{3-x} with 10% of mass percentage for the particles of interest.

Studied particle	Dilution	Peak intensity [a.u.]	Peak wavelength [nm]
MoWOx	Undiluted This study	160	760
	Undiluted Yin ²⁴	130	655
	Diluted 10% This study	3.6	950
МоОз-х	Undiluted This study	5	929
	Undiluted Yin ²⁴	8	920
	Diluted 10% This study	1.8	927
WO _{3-x}	Undiluted This study	10	1485
	Undiluted Yin ²⁴	>10	>1400
	Diluted 10% This study	0.6	1450

Table 1: Comparison of KM peak intensities and peak wavelengths of MoWOx, MoO_{3-x} and WO_{3-x} particles studied in this work, compared to measurement from Yin *et al*²⁴. We also added diluted measurements with $m_{plas} = 10\%$.

First, let us compare, as Yin *et al.* did²⁴, the undiluted KM function of MoWOx hybrid and parent oxides MoO_{3-x} and WO_{3-x} (Fig. 4d and Table 1). The peak intensities are of 160 a.u. at 760 nm, 5 a.u. at 929 nm and 10 a.u. at 1485 nm, respectively. As comparison, Yin *et al.* reported KM peak intensities around 130 a.u. at 655 nm for MoWOx 2:1, 8 a.u. at 920 nm for MoO_{3-x} and above 10 a.u. and above 1400 nm (out of measurement range) for WO_{3-x}. Our results are therefore in good agreement with literature ones.

However, as explained above, a better comparison would be for a dilution with a mass of the studied species respecting the previously defined threshold, here of 10% compared to the LiF diluting agent, as reproduced on Fig. 4e. MoO_{3-x} peaks at 927 nm while WO_{3-x} peaks at 1450 nm. The KM function of MoWOx peaks at 950 nm with a doubled intensity compared to MoO_{3-x}, and six times increase compared to WO_{3-x}. The enhancement of absorption is clearly less spectacular than with undiluted samples but does correspond to fulfilled KM hypotheses. The broadband character of MoWOx is clearly evidenced, with enhanced contributions in both VIS and NIR ranges compared to parent oxides. No significant peak shifts are identified for parent oxides compared to undiluted species, while MoWOx appears red-shifted. This suggests a plasmonic behavior in NIR for MoWOx while low- or non-plasmonic character for parent oxides.

To verify this plasmonic property of MoWOx metal oxides, let us check if the KM spectra verify the three major criteria of the analytical model as presented in section 3. While the diminution of the KM signal upon dilution, *i.e.* criteria (2), is apparent on Fig 5a, the red-shift of the peak as well as its broadening are not obvious here. A normalized KM function is presented on Fig. 5b to better assess those characteristics.

The broadening (480 nm of FWHM) and the red-shift (+155 nm of LSPR maximum) are now clearly visible as reported data in SM5 (Table 2). We may further infer from those data that the dual-band electrochromic property arises from a combined effect of polaronic and plasmonic mechanisms⁴⁰. To further illustrate that hypothesis, we realized a fit of the experimental data for both $m_{MoWOx} = 100\%$ (undiluted) and $m_{MoWOx} = 10\%$ with a deconvolution of two Gaussian curves (Fig. 5c). The first Gaussian fits peak at respectively 735 nm for undiluted and 745 nm for $m_{MoWOx} = 10\%$, while the second ones peak at 1055 nm (undiluted) and 1350 nm (10%). It is consistent with an interpretation of a polaritonic behavior resulting in non-shifted peak contributions (first gaussian at lower wavelength) and a plasmonic behavior resulting in red-shifted peak contributions (second gaussian at higher wavelength).

Figure 5: (a) KM function of MoWOx particles upon dilution. (b) Normalized KM function of MoWOx particles upon dilution. (c) KM function for undiluted MoWOx $(m_{MoWOx} = 100\%, \text{ black curves})$ and diluted at 10% (green curves), with gaussian fits separating the global KM spectra in 2 components (gaussian fits 1 and 2 for each).

To further discuss the occurrence of plasmonic behavior in metal oxide particles using the presented KM formalism, one can study the modification of the KM spectra with a different diluting agent. As expressed by our analytical formulation (equation 6) and shown in SM1, an increased electric permittivity background would cause a red-shift of the KM spectra. To illustrate this, we use BaSO₄ whose permittivity is $\varepsilon_{BaSo_4} = 265 >$ $\varepsilon_{LiF} = 1.924^{37}$. Here again, we check this affirmation with state-of-the-art ITO particles first (Fig. 6a) and indeed KM function for BaSO₄ appears red-shifted compared to LiF diluting agent, itself being red-shifted compared to undiluted KM spectra. Similar trends occur for MoWOx, further confirming its plasmonic behavior (Fig. 6b).

As the optical properties of MoWOx particles is supposed to result from oxygen vacancies, one might finally anneal the powder to suppress those vacancies. As seen on Fig. 6c, "stoichiometric MoWO_x" *i.e.* Mo_{1-y}W_yO₃ or "(Mo,W)O₃", resulting from substoichiometric MoWOx compounds being thermally annealed at 500°C for 12h under air (so to suppress the oxygen vacancies), has a severe drop in KM intensity This much less intense KM intensity of "stoichiometric MoWO_x" shows no significant trends with the dilution in LiF and BaSO4 (Fig 6d). Fully oxidized "stoichiometric MoWO_x" can then be considered as non-plasmonic.

Figure 6: KM function for undiluted and different diluting agents (LiF and BaSO₄) for (a) ITO and (b) MoWOx particles. (c) Comparison of KM spectra of MoWOx and MoWO₃ or "stoichiometric MoWOx". Insets: optical photographs of MoWOx (up) and (Mo,W)O₃ (down). (d) KM function for (Mo,W)O₃ being undiluted and using different diluting agents (LiF and BaSO₄).

6. Conclusions

In conclusion, we thoroughly investigated the application of a state-of-the-art model, the Kubelka-Munk formalism, to a specific problem of topical context, the optical characterization of plasmonic particles used for electrochromic applications. We highlighted the importance of using the dilution method to respect the original Kubelka-Munk hypotheses. An analytical model of KM ratio for plasmonic particles is provided within the limit of small particles (quasi-static approximation). This model allows to identify specific characteristics of the evolution of the KM function upon dilution, such as a red-shift and a broadening of the peak of the KM function as well as a diminution of the global absorption intensity of the KM function. Moreover, the KM function is also shown to red-shift when the diluting agent is changed to a higher dielectric environment. All those characteristics have been verified both numerically and experimentally on plasmonic ITO particles to assess the validity of the proposed analytical model. Moreover, it was applied to emergent doped metal oxides such as

MoWOx hybrids. Those MoWOx hybrids were compared to parent MoO_{3-x} and WO_{3-x} formulations, leading to ameliorated practice, and understanding in approaches of optical characterization of (non-)plasmonic particles. Those findings are notably useful in the context of electrochromic materials and could be applied to other electrochromic metal oxide formulation such as NiO or other shapes and structures. The present results are general enough to be applied to other plasmonic particles, beyond the present context of electrochromism.

Authors contribution

ML derived the analytical modelling helped by NDM and LH. FG carried out the sample fabrications under guidance and supervision of AM, JD, PC and RC, and optical measurements with advice from ML and NDM. NDM performed the Drude model analysis and the preliminary discussions on KM model. ML, FG, NDM, AM and LH analyzed all the data. LH, RC, ML and AM conceived the idea, suggested the designs, planned, coordinated and directly supervised the work. ML wrote the first draft of the manuscript, FG, AM and LH edited it and all authors contributed to the writing of the final version.

Acknowledgments

The authors acknowledge the support of the FRS-F.N.R.S. under the convention PDR T.0125.30 PLASMON_EC. M.L. is a Research Associate of the Fonds de la Recherche Scientifique – FNRS. This research used resources of the "Plateforme Technologique de Calcul Intensif (PTCI)" (http://www.ptci.unamur.be) located at the University of Namur, Belgium, which is supported by the FNRS-FRFC, the Walloon Region, and the University of Namur (Conventions No. 2.5020.11, GEQ U.G006.15, 1610468, RW/GEQ2016 et U.G011.22). The PTCI is member of the "Consortium des Équipements de Calcul Intensif (CÉCI)" (http://www.ceci-hpc.be). A.M. acknowledges University of Bordeaux and ICMCB, where he holds a Junior Professor Chair, for additional support and funding. The authors would like to acknowledge the discussions with Antoine Honet and Richard Ngamkam as well as fruitful interactions and longstanding collaborations with Michel Voué. Moreover, the authors warmly thank Jean-François Colomer for TEM images.
