Amaterasu, the second most energetic (244 EeV) cosmic ray particle has been recently detected by the Telescope Array (TA) surface detector. The origin of the TA Amaterasu event is puzzling, as its arrival direction points back to a void in the local Universe, lacking conventional astrophysical ultra-high-energy (UHE) cosmic ray (CR) sources. Hence, we explore the possibility if this TA Amaterasu event could have originated from the decay of superheavy dark matter (SHDM) in the Milky Way. Such an origin also opens up multi-messenger detection channels in both UHE gamma-rays and UHE neutrinos. In this present work, using the TA Amaterasu event and the multi-messenger limits/sensitivities from various UHE telescopes, we place stringent constraints on the lifetime and mass of the SHDM. We find that the non-detection of the corresponding gamma-rays at the Pierre Auger Observatory (PAO) and the TA is in severe tension with the SHDM parameter space required to explain the TA Amaterasu event. Additionally, we extend the multi-messenger analysis to the future UHE gamma-ray and UHE neutrino telescopes such as PAO upgrade, GRAND 200k and IceCube-Gen2. We find that the bounds from the future neutrino telescopes will be able to compete with the present UHECR bounds. However, compared to the existing UHE gamma-ray bounds, the future PAO upgrade and the GRAND 200k gamma-ray detectors will improve the bounds on SHDM lifetime by at least one order of magnitude.

I. INTRODUCTION

The Telescope Array (TA) experiment has recently detected an ultra-high-energy cosmic ray (UHECR) event (named Amaterasu) of energy 2.44×10^{11} GeV which is the second highest energy UHECR ever detected [1]. The arrival direction (R.A.: $255.9 \pm 0.6^\circ$, Dec.: $16.1 \pm 0.5^\circ$) of this UHECR points back to a void in the local Universe rendering more questions than answers about its origin. As UHECRs above energy 5×10^{10} GeV propagating more than ~ 10 Mpc (mean free path) undergo energy losses due to the Greisen–Zatsepin–Kuzmin (GZK) effect [2–7], the likely source of this event is expected to be located within a distance of ~ 30 Mpc [1]. The TA collaboration [1] analysed a catalogue of gamma-ray sources to identify the probable source and found that the known sources were [8, 9] located at distances beyond 30 Mpc. One possibility could be that the primary UHECR is an iron nucleus at source, which might have undergone significant deflection in the extragalactic magnetic field (EGMF) during propagation to Earth [10–12]. Due to this, the actual source direction might be different than the arrival direction. Magnetic monopole has also been explored in the literature as a possible origin of the TA Amaterasu event [13–18]. Another possible explanation of the origin could be attributed to decaying superheavy dark matter (SHDM) in the Milky Way or

any local galaxy along the arrival direction. In this work, we examine if such a possibility of decaying SHDM in the Milky Way could give rise to the TA Amaterasu event.

Contrary to the conventional production of ultra-high-energy cosmic rays through the diffusive shock acceleration (bottom-up), dark matter (DM) decay into standard model (SM) particles has also been hypothesised as a top-down UHECR production mechanism (See review[7]). In order to produce the observed energy of the TA Amaterasu event via DM decay, energy-momentum conservation states that the DM particles should have mass larger than $\sim 5 \times 10^{11}$ GeV and can extend up to the energy scale ($10^{15} - 10^{16}$ GeV), close to the typical grand unified theory (GUT) scale [19–24]. Production of such SHDM may be possible via mechanisms such as vacuum or gravitational fluctuations in the early Universe during or after inflation [22, 25–39]. Note that UHECRs can also be produced in principle from self-annihilation of SHDM particles. However, the resultant flux is density squared suppressed [40]. Our analysis is based on the Galactic SHDM decay possibility, the extra-galactic component of the flux is found to be negligible in comparison to the the dominant contribution from Galactic DM halo [41].

SHDM particle (χ) in the Milky Way halo can produce UHECR protons (p), ultra-high-energy (UHE) gamma-rays (γ) and UHE neutrinos (ν) via the decay mode $\chi \rightarrow X\bar{X}$. Here, X and \bar{X} are the SM particle-antiparticle pairs [42]. For example, SHDM decaying via b quark channel can produce these UHE secondaries: $\chi \rightarrow b\bar{b} \rightarrow p\bar{p}$ or $\gamma\gamma$ or $\nu\bar{\nu}$. The resulting abundances of gamma-rays and neutrinos generally dominate over that of protons for specific choice of the decay channel. This is in disagreement with the UHECR composition measurements [43–45], that hint towards dominance of nucleon

¶ pm@jnu.ac.in

over gamma-rays and neutrinos. Note that abundances of different nuclei from protons to iron in the UHECR spectrum is still an unresolved issue [43–45]. Because of the disagreement with observations, SHDM scenarios for UHECRs are tightly constrained up to the maximum observed CR energy, $\sim 10^{11}$ GeV. The conventional UHECR spectrum is heavily suppressed around 10^{11} GeV due to the GZK effect and falls with energy as $\sim E^{-5}$ [46]. Thus, the region above this energy becomes invaluable for probing scenarios of SHDM.

The UHE gamma-ray and UHE neutrino fluxes associated with the conventional astrophysical UHECR flux are generally much smaller than that of the UHECR flux [4]. Whereas in SHDM scenarios, we expect them to be larger as mentioned above. This distinct multi-messenger characteristic can be a useful probe of UHECRs from SHDM and therefore, detection of UHE gamma-rays and UHE neutrinos becomes crucial. There are mainly two different telescopes, Pierre Auger Observatory (PAO) [43, 46–51] and TA [1, 44, 45, 52–54] currently operating and capable of detecting all the three components, UHECRs, UHE gamma-rays, and UHE neutrinos. The Yakutsk Extensive Air Shower Array can detect UHECRs and gamma-rays [55, 56], but its sensitivity is lower compared to TA and PAO. On the other hand, the IceCube experiment is also capable of detecting UHE neutrinos and holds sensitivity similar to that of PAO. The future telescope proposals such as Giant Radio Array for Neutrino Detection 200k (GRAND 200k) [57] and IceCube-Gen2 [58] and PAO upgrade [48] having much larger sensitivities compared to the current ones will provide us with unprecedented opportunities to conduct multi-messenger analysis at these extreme energies.

In this work, we for the first time consider the origin of the recent TA Amaterasu event in light of SHDM decay. We put multi-messenger constraints on the lifetime and mass of the SHDM using UHECR, gamma-ray and neutrino telescopes. We also account for the low energy UHECR spectrum detected by the TA. We consider different decay modes for SHDM as well as a wide range ($10^{11} - 10^{15}$ GeV) of SHDM mass. The constraints on the lifetime from gamma-ray non-detection limit of TA and PAO are found to be stronger than that of the UHECRs, discrediting the possibility of the TA Amaterasu event originating from SHDM decay. Furthermore, we also analyse the potential of the future telescopes mentioned above for probing SHDM lifetime through UHE gamma-ray and UHE neutrino detection. While future UHE neutrino detection are found to yield constraints comparable to that from UHECRs, UHE gamma-ray detection will lead to a few order of magnitudes improved constraints than that from UHECRs. Our constraints based on the TA Amaterasu event are consistent with those existing in the literature [31, 40, 41, 50, 59–76]. These works are based on various observations of UHECRs, UHE gamma-rays, and UHE neutrinos, but not the recent TA Amaterasu event.

The paper is organised as follows. In Sec. II, we de-

scribe the model adopted for flux calculation. In Sec. III, we present the results of our multi-messenger analysis for both present and future telescopes. Finally we summarize and discuss our main results in Sec. IV. The dependence of the results on various DM density profiles is discussed in Appendix A.

II. UHE FLUX FROM SHDM DECAY

In this section, we discuss the production of UHECRs, UHE gamma-rays and UHE neutrinos from the decay of SHDM and estimate the flux of these daughter particles. The SHDM particle, χ is considered to decay via the $1 \rightarrow 2$ process ($\chi \rightarrow X\bar{X}$) into various SM particles-antiparticle pairs. These SM particles and antiparticles can further produce other lighter particle-antiparticle pairs. In particular, we focus on the secondaries convenient for detection and further phenomenology, i.e., the UHECR protons (p), the UHE gamma-rays (γ) and the UHE neutrinos (ν).

The differential energy spectra, dN_i/dE (where, $i \equiv p, \gamma, \text{ and } \nu$) of these UHE final state particles depend on the SHDM mass (m_χ), lifetime (τ_χ) and the inclusive decay rate (Γ) of $\chi \rightarrow X\bar{X} \rightarrow i + \dots$ [42]. The flux of an observable particle i produced from DM decay depends on the differential energy spectra given by,

$$\frac{dN_i}{dx} = \frac{1}{\Gamma_0} \frac{d\Gamma}{dx} (\chi \rightarrow i + \dots). \quad (1)$$

Here, $x = 2E/m_\chi$ and $\Gamma_0 = 1/\tau_\chi$ is the inverse lifetime in the rest frame of χ [42]. The lifetime (τ_χ) and the mass (m_χ) of SHDM are considered to be the free parameters of the model and are constrained from the various observations of the UHE secondaries (p, γ , and ν).

In particular, the differential energy spectra (dN_i/dE) for different decay modes ($\chi \rightarrow X\bar{X} \rightarrow i + \dots$) are computed with the publicly available numerical code `HDMSpectra` [42]. `HDMSpectra` allows to compute energy spectra for a wide m_χ range, from the electroweak scale up to the GUT scale. The energy spectra are estimated by the fragmentation function, $D_a^b(x; \mu_Q, \mu_0)$ that gives the probability of an initial state a (e.g., $X\bar{X}$) at energy scale μ_Q evolving to a final state b (e.g., $p + \bar{p}$) at energy scale μ_0 with momentum fraction $x = 2E/m_\chi$ (see [42] for details).

Now, to estimate the total diffuse secondary particle flux from these SHDM decays one needs to include the contribution from all the SHDM distributed all over the Universe. In principle, the SHDM abundance over the Universe could be crucial. However, it turns out that the extra-galactic contribution is negligible in comparison to the secondary flux from SHDM decay in the Milky Way [41]. Thus, we focus on the diffuse flux of UHE protons, UHE gamma-rays and UHE neutrinos produced from the Galactic abundance of SHDM. The DM density in the Milky Way is expected to be the largest at the

FIG. 1. UHE flux fitted to different observations of TA for $m_\chi = 10^{12}$ GeV (solid) and $m_\chi = 10^{14}$ GeV (dashed). The decay channel is taken to be $\chi \rightarrow b\bar{b}$. *Left plot*: UHECR proton flux (blue curves) from SHDM decay fitted to the TA Amaterasu event (red data point) and the UHECR spectrum of TA (black data point). The UHECR flux above the energy of the TA Amaterasu event is taken to be constant (purple dotted). The flux fitting resulted in $\tau_\chi = 5.5 \times 10^{28}$ s and 7.5×10^{29} s for $m_\chi = 10^{12}$ GeV and $m_\chi = 10^{14}$ GeV, respectively. *Middle plot*: Integral UHE gamma-ray flux (magenta curves) from SHDM decay for the two m_χ values fitted to the upper limit on UHE gamma-ray flux from TA (black downward arrow). The resultant values of τ_χ are 3×10^{30} s and 8×10^{29} s, respectively. *Right plot*: UHE neutrino flux (green curves) from SHDM decay for the two m_χ values fitted to the upper limit on UHE neutrino flux from TA (black line). The corresponding values of τ_χ are 7×10^{25} s and 4.8×10^{25} s, respectively. The UHE neutrino flux constraint infers significantly small τ_χ values compared to that of UHE protons and UHE gamma-rays.

Galactic center and decreases as a function of the Galactocentric distance (R_{GC}). There are various models and simulations for the density profile of DM in the Milky Way [77–81]. In this work, we consider the Navarro-Frenk-White (NFW) profile [77] given by,

$$\rho_{\text{NFW}}(R_{GC}) = \frac{\rho_c}{(R_{GC}/R_c)(1 + R_{GC}/R_c)^2}, \quad (2)$$

where, ρ_c is the characteristic density at the characteristic scale $R_c = 11$ kpc and its value is determined by normalizing ρ_{NFW} with the DM density in the solar neighbourhood, $\rho_\odot = 0.43$ GeV cm $^{-3}$.

Thus, given mass (m_χ) and lifetime (τ_χ) of the SHDM particle, the total flux, $\Phi_i(E, \theta)$ of the i^{th} secondary UHE particle ($i = p, \gamma, \text{ and } \nu$) along the line of sight can be expressed as,

$$\begin{aligned} \Phi_i(E, \theta) &= \frac{1}{4\pi m_\chi \tau_\chi} \frac{dN_i(E)}{dE} \int_0^{l_{\text{max}}(\theta)} \rho_\chi(l) dl \\ &= \frac{\rho_\odot R_{\text{SGC}}}{4\pi m_\chi \tau_\chi} \frac{dN_i(E)}{dE} \mathcal{J}(\theta), \end{aligned} \quad (3)$$

where,

$$\mathcal{J}(\theta) = \frac{1}{\rho_\odot R_{\text{SGC}}} \int_0^{l_{\text{max}}(\theta)} \rho_\chi(l) dl. \quad (4)$$

Here, R_{SGC} is the distance between the Sun and the Galactic center and is taken to be 8.34 kpc. This allows changing the line of sight coordinate (l) to the convenient Galactocentric coordinate (R_{GC}). The coordinate transformation from l to R_{GC} is given by $R_{GC} = \sqrt{R_{\text{SGC}}^2 - 2lR_{\text{SGC}} \cos \theta + l^2}$.

The flux over a solid angle, $\Omega = 2\pi(1 - \cos \theta)$ can be obtained by integrating out Eq. (4) from $\theta = 0$ to $\theta = \theta_{\text{max}}$. Thus the angle integrated total flux of the i^{th} secondary is,

$$\Phi_i(E) = \frac{\rho_\odot R_{\text{SGC}}}{4\pi m_\chi \tau_\chi} \frac{dN_i(E)}{dE} \mathcal{J}^{\theta_{\text{max}}}, \quad (5)$$

where,

$$\mathcal{J}^{\theta_{\text{max}}} = \frac{2\pi}{\Omega} \int_0^{\theta_{\text{max}}} \sin \theta d\theta \mathcal{J}(\theta). \quad (6)$$

As we are interested in the diffuse flux of UHECRs, UHE neutrinos and UHE gamma-rays, we integrate Eq. (6) over the entire solid angle, i.e., $\theta_{\text{max}} = \pi$ and obtain $\mathcal{J}^{\theta_{\text{max}}} \approx 2$. The dependence of the fluxes of UHE secondaries on a specific DM density profile can be estimated by calculating the $\mathcal{J}^{\theta_{\text{max}}}$ factor. Note that, a different choice of DM density profile other than the NFW profile leads to a negligible change in the UHE secondary fluxes, see Appendix A.

Now, this diffuse flux of the secondary particles can be obtained for different decay modes of χ , i.e., for different quarks, leptons and bosons for the X and \bar{X} combination (eg., $b\bar{b}$, W^+W^- , $\mu^+\mu^-$, $\nu\bar{\nu}$) in the decay process $\chi \rightarrow X\bar{X}$. In particular, the differential energy spectra $dN_i(E)/dE$ is estimated for these different decay modes.

To demonstrate the flux estimation for the UHECRs, UHE gamma-rays and UHE neutrinos, we consider the example of $\chi \rightarrow b\bar{b}$ mode using Eq. (5) with 100% branching fraction. The results are depicted in Fig. 1 together with the observational data and constraints of these UHE

fluxes from the TA experiment. We consider two specific choices of m_χ : 10^{12} GeV and 10^{14} GeV. The fluxes of all these UHE particles are inversely proportional (see Eq. (5)) to τ_χ . Rather than fixing the parameter τ_χ arbitrarily, we constrain the value of τ_χ in a phenomenological manner. τ_χ is estimated by normalising the SHDM derived flux of UHECRs, UHE gamma-rays and UHE neutrinos with the observed data or experimental upper limits on these fluxes. Since these fluxes as well as the observed flux/limits are all different from each other, they give rise to different values of τ_χ .

The left plot of Fig. 1 shows the observed UHECR spectrum data by TA in black dots. The red data point represents the flux of the recently observed TA Amaterasu event of energy 2.44×10^{11} GeV [1]. The flux for this TA Amaterasu event is obtained by dividing the total number of events by the total exposure of the telescope [1]. The uncertainties in the flux correspond to the propagated uncertainties. Importantly, for the energies higher than 244 EeV, we consider a conservative estimate that the maximum possible CR flux is not larger than the observed TA flux at the 244 EeV event, shown by the purple dashed line. This is contrary to the harder CR spectra suggestions at the highest energies [43, 82]. For these maximum limits, we show the upper limit of $p + \bar{p}$ flux for two different DM masses ($m_\chi = 10^{12}$ GeV and $m_\chi = 10^{14}$ GeV) considering the decay of DM into $b\bar{b}$ channel. This establishes the lower bound on DM lifetime, as indicated by Eq. (5). For the DM masses of 10^{12} GeV and 10^{14} GeV, the observational constraints fix the τ_χ at 5.5×10^{28} s and 7.5×10^{29} s, respectively. Note that the required energy for the TA Amaterasu event can not be created from SHDM with $m_\chi \lesssim 10^{12}$ GeV. This can be understood from the flux corresponding to $m_\chi = 10^{12}$ GeV in the left plot of Fig. 1 as the TA Amaterasu event lies on the high energy tail of this flux. For $m_\chi \lesssim 10^{12}$ GeV, the flux will fall off at energies smaller than the energy of the TA Amaterasu event. Similarly, there exists an upper limit for the SHDM mass. For example, the flux corresponding to $m_\chi = 10^{14}$ GeV is falling below the TA flux for our assumption of constant UHECR limit beyond the energy of the TA Amaterasu event. In particular, we find an upper limit on m_χ for this specific channel to be $m_\chi \sim 4 \times 10^{13}$ GeV.

In the middle plot of Fig. 1, we show the upper limit on the integral UHE gamma-ray flux from the TA experiment [53, 54]. This upper limit comes from the non-detection of UHE gamma-rays. The solid and dashed magenta lines represent the gamma-ray flux for DM masses of 10^{12} GeV and 10^{14} GeV, the resultant τ_χ to maintain the TA gamma-ray upper limits are 3×10^{30} s and 8×10^{29} s, respectively. Again, the decay of DM is considered to be into $b\bar{b}$ final states. These values of τ_χ are significantly larger than those obtained from UHECR constraints. This is due to the fact that production of gamma-rays from $b\bar{b}$ annihilation is significantly enhanced compared to that of protons [42]. Similarly, in the right panel plot of Fig. 1, we show the TA's upper limit (black con-

tinuous line) on the UHE neutrino flux from the non-detection of UHE neutrinos in TA [83]. The solid and dashed green lines correspond to the flux of UHE neutrinos for the DM masses of 10^{12} GeV and 10^{14} GeV, respectively. The lifetimes for these two masses respecting the TA neutrino limits turn out to be 7×10^{25} s and 4.8×10^{25} s, respectively. Due to the poorer sensitivity of the neutrino detectors, the τ_χ limiting values from UHE neutrinos are at least 3 – 4 orders of magnitude smaller than the gamma-ray and UHECR constraints. Thus, the three UHE messengers give rise to different constraints on the SHDM lifetime and mass.

In all the three plots of Fig. 1, we do not take into account the contribution from the conventional astrophysical as well as extragalactic SHDM sources. For UHECRs, the contribution of the extragalactic SHDM component is found to be negligible [40, 41]. Whereas, the contribution of the conventional astrophysical component might be significant in the UHECR spectral energy range below the energy of the TA Amaterasu event, i.e., $\lesssim 10^{11}$ GeV [41]. However, considering a dominant fraction of UHECRs from the conventional astrophysical origin allows only a little fraction of UHECRs from SHDM. This results in stringent constraints on the production of UHECRs via SHDM decay in the DM mass range $\lesssim 10^{12}$ GeV and do not yield a conservative description of the constraints on SHDM lifetime. In order to avoid this, we consider that the UHECRs in this energy range are solely due to SHDM decay. This assumption gives rise to a lower bound on the SHDM lifetime. For UHE gamma-rays, the contribution of the extragalactic component is negligible in the energy range of our interest in comparison to the Galactic SHDM component. This is because UHE gamma-rays from extragalactic sources are attenuated severely due to pair production losses in the cosmic microwave background (CMB) and the extragalactic radio background during propagation to Earth [4, 41]. For UHE neutrinos, the contribution from extragalactic sources can be important as unlike gamma-rays, neutrinos do not suffer any propagation losses. Inclusion of extragalactic sources will result in lowering of the UHE neutrino flux from SHDM decay in the Milky Way which, in turn, will give rise to larger SHDM lifetime. In order to be consistent with the assumption for UHECRs above, we do not include the extragalactic neutrino flux in our analysis. Due to these assumptions, the constraints obtained on the SHDM lifetime from different messengers can be comprehended as the most conservative constraints. In the following, we discuss these constraints for present and future telescopes in detail and expand the description to different decay channels.

III. MULTI-MESSENGER CONSTRAINTS ON SHDM LIFETIME

In this section, we analyse the possibility that the TA Amaterasu event was produced via the decay of SHDM

FIG. 2. Constraints on SHDM decay rate for all possible two-body decay channels into SM particles derived from present UHECR data and UHE gamma-ray non-observation limits. Constraints from UHE neutrino non-observation limits are weak, hence not shown. The shaded regions above the curves in all the plots represent the excluded part of the parameter space. The blue curves show the constraints from the TA Amaterasu event together with the low energy UHECR data. The magenta (TA) and red (PAO) curves depict the constraints from non-observation of UHE gamma-rays. Constraints from different decay modes are distinct. The gamma-ray constraints are in general stronger than that of UHECRs. The vertically shaded grey regions depict the excluded range of m_χ for the TA Amaterasu event.

in the Milky Way. Following this, we place constraints on the lifetime/decay rate of SHDM. In order to derive the constraints in the energy band lower to the detected energy of the TA Amaterasu event, we consider the UHECR data detected by the TA. We also carry out a multi-messenger analysis on the SHDM decay rate considering the non-detection of UHE gamma-rays and neutrinos at various telescopes such as TA and PAO [49, 84]. Furthermore, we look into the SHDM lifetime probing capabilities of the various proposed future UHE telescopes. Below we present a brief discussion on the observational capabilities of different past and present telescopes as well as the capabilities of various future telescopes for detection of UHECRs, UHE gamma-rays and UHE neutrinos.

UHECR telescopes and measurements: UHECRs were discovered by the Akeno Giant Air Shower Array (AGASA) [85] and the High Resolution Fly’s Eye (HiRes) [86, 87] telescopes about a couple of decades

ago. In fact, HiRes had detected the most energetic (320 EeV) UHECRs till date [88]. Recent measurements of the UHECR spectrum above 0.1 EeV by the PAO [47] and TA [89] experiments agree well with these old measurements except for some disagreements regarding mass composition and spectral index at extreme energies. In this work, we focus on the UHECR spectrum measured by TA and also on the recent TA Amaterasu event. In future, the Giant Radio Array for Neutrino Detection (GRAND) [57] will complement these existing experiments and may provide us with useful insights into UHECR source properties.

UHE gamma-ray telescopes: There has been no detection of UHE gamma-rays in the PeV-EeV energy band till date, except for some Galactic sources slightly above PeV energies [90]. Various experiments such as Haverah Park [91], AGASA [92], Yakutsk [93, 94], AGASA+Yakutsk [95, 96], TA [53, 54], PAO [49, 84] have placed different upper limits on the UHE gamma-

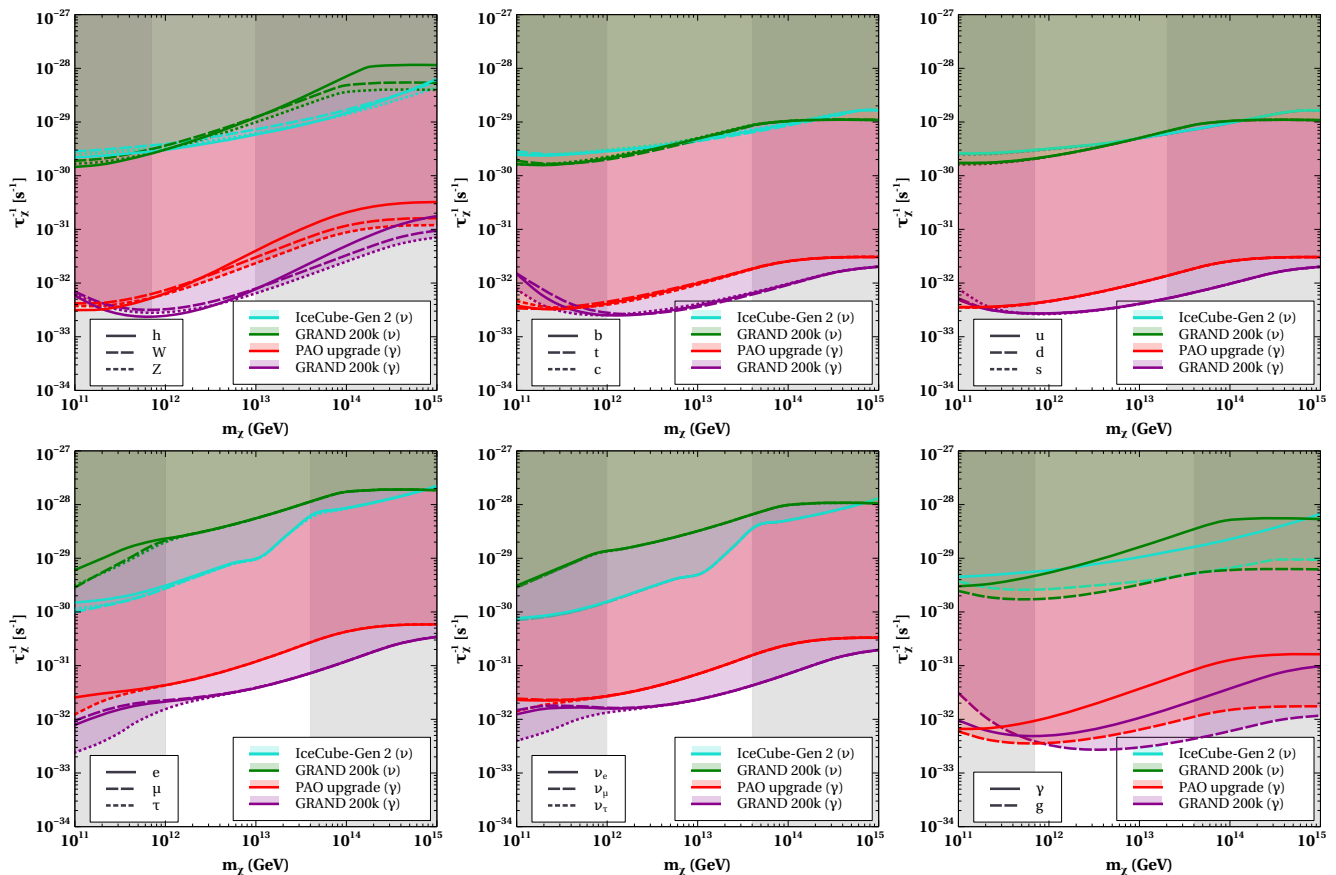

FIG. 3. Projected constraints on SHDM decay rate from future observation of UHE gamma-rays and UHE neutrinos for all possible two-body decay channels into SM particles. The shaded regions above the curves depict the parameter space which can be probed by the future UHE gamma-ray (PAO upgrade: red and GRAND 200k: purple) and UHE neutrino (IceCube-Gen2: cyan and GRAND 200k: green) telescopes. UHE gamma-ray observations will put stringent constraints on the SHDM lifetime. The vertically shaded grey regions depict the excluded range of m_χ for the TA Amaterasu event.

ray flux. Here, we focus on the recent upper limits from TA and PAO. In future, the GRAND 200k telescopes and the proposed upgrade of PAO surface detector (SD) [43] will either detect or put more stringent constraints on the UHE gamma-ray flux.

UHE neutrino telescopes: Similar to UHE gamma-rays, no UHE neutrinos have yet been detected in the past and presently running detectors such as Antarctic Impulsive Transient Antenna (ANITA) [97], IceCube [58], TA [83] and PAO [98]. Most of the theoretical [4, 99–109] and experimental [98, 110–112] upper limits of the UHE neutrino (astrophysical origin) flux are even below the sensitivities of some of the future telescopes such as Askaryan Radio Array (ARA) [113], Radio Ice Cherenkov Experiment Observatory (RICE) [114], and Square Kilometer Array (SKA) [115, 116]. However, the upcoming IceCube-Gen2 [58] and GRAND 200k [57, 117] experiments have significantly larger sensitivities and hold excellent potential of UHE neutrino detection. For the analysis regarding UHE neutrinos, we mainly focus on these two future experiments.

A. Present UHE telescopes

In this sub-section, we present the constraints on SHDM lifetime from different observations of UHECRs, UHE gamma-rays and UHE neutrinos and analyse the origin of the TA Amaterasu event. The constraints are obtained by normalising the flux of these particles with the experimental data or limits from non-observation. For UHECRs, we consider the spectrum measured by TA together with the recent TA Amaterasu event as depicted in the left plot of Fig. 1. Including the UHECR data from other experiments such as PAO, AGASA and HiRes will yield similar values of DM lifetime as the CR spectral shapes from these experiments are also very similar to that of TA. For the UHE gamma-rays, we take the upper limits on the flux from TA [53, 54] and PAO [49, 84]. Whereas for the UHE neutrinos, we consider the upper limits on the flux from PAO [98] and IceCube [58]. We consider a wide range of $m_\chi = (10^{11} - 10^{15})$ GeV and different two-body decay modes. For the decay modes, we take all the quarks (u, d, s, b, t, c), the gauge bosons (W, Z, γ , gluon), and the Higgs boson (h). The lower

limit of m_χ is chosen to be 10^{11} GeV as our primary goal is to analyse the origin of the TA Amaterasu event at 2.44×10^{11} GeV. On the other hand, the upper limit of $m_\chi = 10^{15}$ GeV is taken to be close to the GUT scale. For the given m_χ , we constrain the lifetime such that the UHE secondary particle observations, limits and sensitivities are satisfied. In particular, we follow convention of exclusion plots and constrain the inverse of the lifetime, i.e., τ_χ^{-1} rather than the lifetime (τ_χ). The constraints on τ_χ^{-1} as a function of m_χ for different decay modes are depicted in Fig. 2. The shaded regions above the curves depict the excluded part of the parameter space. The vertically shaded grey regions depict the excluded range of m_χ for the TA Amaterasu event as discussed in Sec. II.

In Fig. 2, the constraints on τ_χ^{-1} from TA's UHECR data, TA's gamma-ray flux upper limit and PAO's gamma-ray flux upper limit are shown by the blue, magenta and red curves, respectively. As the bounds from non-observation of UHE neutrinos are orders of magnitude smaller than the bounds from UHECR and gamma-rays, the neutrino bounds are not shown in Fig. 2. In the top panel, the left plot shows the bounds on SHDM lifetime obtained from $\chi \rightarrow hh$, W^+W^- , ZZ , the middle plot shows the bounds from $\chi \rightarrow b\bar{b}$, $t\bar{t}$, $c\bar{c}$, and the right plot shows the bounds from $\chi \rightarrow u\bar{u}$, $d\bar{d}$, $s\bar{s}$. Similarly, in the bottom panel, the left plot displays the bounds from the decay modes $\chi \rightarrow e^+e^-$, $\mu^+\mu^-$, $\tau^+\tau^-$, the middle plot from $\chi \rightarrow \nu_e\bar{\nu}_e$, $\nu_\mu\bar{\nu}_\mu$, $\nu_\tau\bar{\nu}_\tau$, and the right plot from $\chi \rightarrow \gamma\gamma$, gg . The excluded regions of the τ_χ^{-1} vs m_χ parameter in the plots correspond to flux larger than the experimental data or limits and hence disallowed.

There are some general features of all these exclusion plots coming for different decay channels. The bounds on τ_χ^{-1} from UHECR data for $m_\chi \lesssim 10^{13}$ GeV mimic the spectral shape of the UHECR spectrum for all decay modes, whereas above this energy they remain almost constant due to the constant flux assumption above energy of the TA Amaterasu event. If we consider the TA Amaterasu event only, the resulting constraints remain almost constant for all values of m_χ and are same as the constant values of τ_χ^{-1} for $m_\chi \gtrsim 10^{13}$ GeV.

The different channels also show some distinctions. The constraints from leptons are in general weaker than that of quarks or the bosons by about an order of magnitude. Therefore, the bounds on SHDM lifetime from the TA Amaterasu event can vary depending on the decay mode. However, within a specific family (quarks, leptons, bosons), the bounds do not differ significantly.

Regarding the constraints from UHE neutrinos, the present UHE neutrino telescopes such as IceCube, TA and PAO are not sensitive to the flux corresponding to τ_χ inferred by the TA Amaterasu event and therefore remains consistent with non-detection of UHE neutrino counterpart to the TA Amaterasu event. Interestingly, the gamma-ray sensitivities of the TA and PAO are close to the TA Amaterasu constrained SHDM gamma-ray flux. However, no such correlated gamma-ray flux has been detected by the TA and PAO collaboration. This

results in much stronger constraints from the gamma-ray upper limits of these telescopes than that of the UHECR data. Nevertheless, it is noteworthy that at the extreme values of m_χ , close to 10^{15} GeV for the quark channels the UHECR (Fig. 2, top middle and right plot) constraint is the strongest.

In all decay modes, for values of m_χ above $\sim 10^{13}$ GeV, the TA UHECR constraint curves cross the UHE gamma-ray constraint ones, opening a tiny parameter space supporting the SHDM origin of UHECRs. However, this inference is in conflict with the gamma-ray constraints from PAO except for the top left plot (bosonic decay modes) in Fig. 2. In this case, a small region above $m_\chi > 10^{14}$ GeV is still allowed. However, the allowed range of m_χ for the TA Amaterasu event is found to be between $\sim (10^{11.8} - 10^{13.6})$ GeV. Note the slight differences in the allowed mass ranges for different decay modes in the vertically shaded grey bands. Outside this range the SHDM decay can not explain both the TA Amaterasu event and the UHECR limit. Because, in this m_χ range, the constraints from the gamma-ray limits of TA and PAO disfavour the SHDM origin of TA Amaterasu event.

While considering the PAO limits one needs to be careful with the field of view (FOV) of the PAO (RA: 0 to 2π , Dec: $-\pi/2$ to $+\pi/4$). Indeed, the possible coordinate of the recent TA Amaterasu event (RA: 256° , Dec: 16°) is outside the FOV of PAO and can explain the non-detection of any correlated gamma-ray in PAO. In this scenario, the gamma-ray non-detection constraints from the TA turn out to be more crucial than the PAO constraint. Nevertheless, the values of τ_χ inferred by the TA Amaterasu event produce UHE gamma-ray flux larger than the present upper limit from the PAO. Hence, taking into account these multi-messenger constraints, we argue that the SHDM decay origin of the TA Amaterasu event is in severe tension.

The constraints extrapolated to higher m_χ values from the TA Amaterasu event allow a parameter space of $10^{-30} s^{-1} \lesssim \tau_\chi^{-1} \lesssim 10^{-29} s^{-1}$ for $m_\chi \gtrsim 10^{14}$ GeV, for SHDM originated UHECRs at the extreme energies of the spectrum. However, this UHE secondary flux being a diffuse flux, the PAO should also observe gamma-rays at similar energies. For instance, if we consider decay via the $b\bar{b}$ channel, the PAO can be expected to detect a UHE gamma-ray flux of about $(10^{-3} - 10^{-4}) \text{ km}^{-2} \text{ yr}^{-1} \text{ sr}^{-1}$ at $\sim 10^{20}$ GeV. Hence, future detection of UHECRs at or above this energy will be crucial for constraining UHECRs from SHDM decay. Finally, we also study the dependence of these constraints on the choice of Galactic DM density profile and find that the results are nearly independent of density profile choice (see Appendix A).

B. Future UHE telescopes

The above analysis shows that the observed UHECR data together with the experimental upper limits on the

FIG. 4. Constraints on DM lifetime/decay rate from both current and future experiments considering the DM decay via $b\bar{b}$ channel. The blue curve depicts the constraint from TA’s UHECR data. The cyan and green dashed curves represent the constraints from UHE neutrino sensitivities of IceCube-Gen2 and GRAND 200k, respectively. The magenta and red solid curves show the present constraints from UHE gamma-ray non-observation in TA and PAO, respectively, whereas, the red and purple dashed curves depict the projected reach of the upcoming telescopes PAO upgrade and GRAND 200k, respectively. While the constraints from current observations (blue, magenta, red solid curves) suggest $\tau_\chi \gtrsim 10^{30}$ s, future gamma-ray observations (red and purple dashed curves) will be able to probe τ_χ up to 10^{32} s. The vertically shaded grey regions depict the excluded range of m_χ for the TA Amaterasu event.

UHE gamma-ray and UHE neutrino flux put a strong constraint on the SHDM origin for the recent TA Amaterasu event. However, these stringent constraints do not completely rule out the possibility of a SHDM component in the UHECR spectrum. It might be possible that the SHDM component of the UHECR flux is smaller than that of the observed spectrum, eradicating detection in current telescopes and, therefore motivates us to look at the possibilities of the future telescopes. Detection of such a small flux requires more sensitive telescopes. The upcoming telescopes such as GRAND 200k, IceCube-Gen2 and PAO upgrade having larger sensitivities compared to the existing ones provide us with better opportunities to probe the SHDM through detection of UHE gamma-rays and UHE neutrinos. In the following, we discuss the potential of these future telescopes for constraining τ_χ and m_χ for the various two-body decay modes as considered above.

The constraints on the τ_χ for various decay modes

are obtained by normalising the computed fluxes from SHDM at the level of sensitivities (gamma-ray and neutrino) of the said telescopes. Fig. 3 shows the gamma-ray and neutrino bounds on the DM lifetime and mass for the different decay channels. For the gamma-ray constraints, we consider the sensitivities of the proposed PAO upgrade [43] and the GRAND 200k detector. The neutrino bounds are based on the UHE neutrino flux sensitivities of the IceCube-Gen 2 and the GRAND 200k detectors. The red and purple curves in Fig. 3 depict the constraints from gamma-rays in PAO upgrade and GRAND 200k, respectively. The constraints from neutrinos in IceCube-Gen2 and GRAND 200k are shown by the cyan and green curves, respectively. Overall, the constraints from the gamma-ray sensitivities are about two to three order of magnitudes stringent than that of the ones from neutrinos. Similar to bounds from the present experiments, the more stringent limits come from the quarks and gauge bosons decay channels as depicted in Fig. 3 for future telescopes. For gamma-rays, the constraints from GRAND 200k are found to be stronger than that of PAO for all decay modes. For neutrinos, the constraints from quarks and bosons channels are found to be similar for both the telescopes. However, for the leptonic channels the constraints from IceCube-Gen2 are stronger than that of GRAND 200k. This is because the energy spectra of the leptonic channels give rise to a peak at the energy close to the value of m_χ [42]. The constraints anticipated from UHE neutrino detection in both the future telescopes will be comparable to that from current UHECR data for $m_\chi \gtrsim 2 \times 10^{12}$ GeV. Therefore, the results from the future experiments will be crucial to put further and stronger multi-messenger constraints on the parameter space of SHDM.

IV. DISCUSSION AND CONCLUSION

In this work, we have analysed the possibility of the recently detected TA Amaterasu event, at 244 EeV to have originated from the decay of SHDM in the Milky Way. The arrival direction of this UHECR being a void in the local Universe makes it hard to explain its origin from the conventional astrophysical shock acceleration and opens up possibility of a SHDM origin. The analysis is carried out with a multi-messenger approach considering UHECR data from TA and upper limits on UHE gamma-ray and UHE neutrino flux from different experiments such as TA and PAO. For this, we have estimated the UHECR, UHE gamma-ray and UHE neutrino flux produced by SHDM decay with the NFW DM density profile for various SHDM decay channels and a wide range of SHDM mass. The constraints on these fluxes from the experimental data/limits have resulted in constraints on the SHDM lifetime or decay rates. While we have found an allowed SHDM mass range of $\sim (10^{11.8} - 10^{13.6})$ GeV for the TA Amaterasu event, the multi-messenger gamma-ray constraints from TA and PAO are in severe ten-

sion with the SHDM origin for the said TA Amaterasu event. However, these constraints indicate the possibility of UHECR flux at higher energies originating from heavier SHDM particles, i.e., $m_\chi \gtrsim 10^{14}$ GeV. In order to test the viability of such a scenario one would need more sensitive future telescopes such as PAO upgrade, IceCube-Gen2 and GRAND 200k.

Therefore, we have also looked into the potential of these future telescopes to constrain the lifetime and mass of SHDM. All the results of our work are summarised in Fig. 4 for the decay mode $\chi \rightarrow b\bar{b}$. We show the bounds on τ_χ^{-1} from UHECRs (blue curve), UHE gamma-rays from TA (magenta curve), PAO (solid red curve), PAO upgrade (red dashed curve), GRAND 200k (purple dashed curve) and UHE neutrinos from IceCube-Gen2 (cyan dashed curve), GRAND 200k (green dashed curve). The constraints on lifetime from the TA UHECR data are found to be of the order of 10^{30} s for SHDM mass, $m_\chi \gtrsim 10^{13}$ GeV, whereas at lower masses the lifetime can be smaller. The constraints from gamma-ray upper limit of the TA data vary within an order of magnitude and found to be maximum of $\sim 3 \times 10^{30}$ s at around $m_\chi \sim 10^{12}$ GeV. The TA constraints (UHECR and UHE gamma-ray) alone allow for a small parameter space above 10^{14} GeV for the SHDM. However, the gamma-ray upper limit of PAO is about a factor of 3-4 larger and creates tension for the SHDM origin of the TA Amaterasu event. The future telescopes will be able to put much stronger constraints ($\gtrsim 10^{32}$ s) on the SHDM lifetime from gamma-ray observations as depicted by the purple dashed (GRAND 200k) and red dashed (PAO SD upgrade) curves. However, future UHE neutrino detectors such as IceCube-Gen2 (cyan dashed) and GRAND 200k (green dashed) will place constraints similar to the present UHECR derived limits (blue solid). These results vary substantially between different decay modes, we have done a detailed analysis for the different decay channels and found that the lepton channels to have the weakest constraints (see, Fig. 2 and Fig. 3).

To conclude, we have provided an updated estimate of multi-messenger constraints on the lifetime of SHDM by considering the recent TA Amaterasu event in conjunction with the TA UHECR data and non-observation of UHE gamma-rays and UHE neutrinos. While doing so, we have ensured consistency with the existing constraints in the literature [40, 41, 59, 61, 62, 73, 118]. Note that the constraints for heavier DM mass, i.e., $m_\chi > 10^{12}$ GeV are not very robust due to the lack of data (UHECRs, UHE gamma-rays and UHE neutrinos) at energies above $\sim 10^{11}$ GeV. For harder UHECR flux anticipated from SHDM [41] or conventional diffusive acceleration [43, 82], the resulting constraints on the lifetime for $m_\chi \gtrsim 10^{12}$ GeV will be smaller than the ones obtained in this work. Nevertheless, such shorter lifetimes for the SHDM are not supported by UHE gamma-ray observations and do not impact the conclusion of this work.

Appendix A: Dependence on DM density profile

We have performed the analysis on SHDM decay considering the NFW DM density profile in the Milky Way throughout the paper. For completeness of the analysis, it is crucial to understand the variation of the results for different DM profiles. Therefore, in this appendix, we present an analysis on the dependence of our results on different DM density profiles. Other than the NFW profile, here we take two other DM profiles - Einasto [79] and Burkert [81]. The equations for DM energy density for these two profiles are

$$\rho_{\text{Ein}}(R_{\text{GC}}) = \rho_c \exp \left[-12.5 \left(\left(\frac{R_{\text{GC}}}{R_c} \right)^{0.16} - 1 \right) \right], \quad (\text{A1})$$

$$\rho_{\text{Bur}}(R_{\text{GC}}) = \frac{\rho_c R_c^3}{(R_{\text{GC}} + R_c)(R_{\text{GC}}^2 + R_c^2)}, \quad (\text{A2})$$

respectively.

To illustrate the effect of different DM profiles, we compute the constraints on SHDM lifetime from TA's UHECR observation for the DM profiles discussed above. The results are shown in Fig. A.1. In the top panel of A.1, we show the DM energy density in the Milky Way as a function of Galactocentric distance for the different DM profiles. These DM profiles give different $\mathcal{J}^{\theta_{\text{max}}}$ values in equation (5). While for NFW profile, $\mathcal{J}^{\theta_{\text{max}}}$ takes value of 1.99, for Einasto and Burkert profiles, its value is 2.08 and 1.95 respectively. This variation of $\mathcal{J}^{\theta_{\text{max}}}$ gives a maximum of around 7% changes in SHDM lifetime depending on the DM profile as shown in the bottom plot of figure A.1. Hence, the dependence of the constraints on the DM profile is negligible.

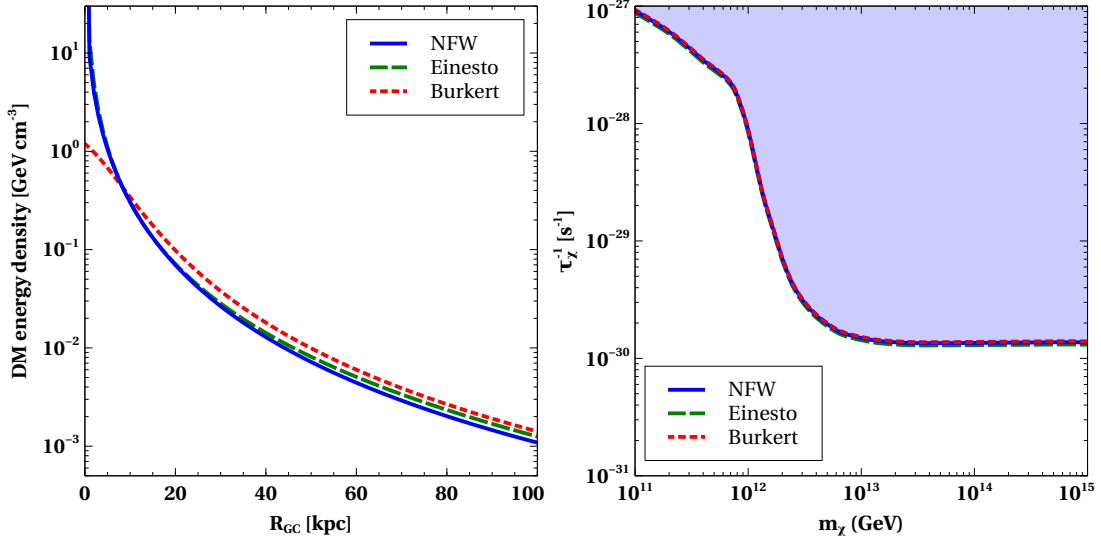

FIG. A.1. *Top plot:* DM energy density vs Galactocentric distance for three different DM profiles. *Bottom plot:* Constraints on DM lifetime from UHECR vs DM mass for different DM profiles considering $b\bar{b}$ channel. The constraints are nearly independent of the DM profiles.
