Abstract

In this study, we investigate representations from paralingual Pre-Trained model (PTM) for Audio Abuse Detection (AAD), which has not been explored for AAD. Our results demonstrate their superiority compared to other PTM representations on the ADIMA benchmark. Furthermore, combining PTM representations enhances AAD performance. Despite these improvements, challenges with cross-lingual generalizability still remain, and certain languages require training in the same language. This demands individual models for different languages, leading to scalability, maintenance, and resource allocation issues and hindering the practical deployment of AAD systems in linguistically diverse real-world environments. To address this, we introduce CoLLAB, a novel framework that doesn't require training and allows seamless merging of models trained in different languages through weight-averaging. This results in a unified model with competitive AAD performance across multiple languages.

Index Terms: Multilingual Abuse Detection, Cross-Lingual Abuse Detection, Model Merging

1. Introduction

In today's digital era, online social media platforms, gaming communities, and digital environments have become indispensable aspects of modern life. Within these realms, audio plays a crucial role in facilitating real-time communication and fostering connections among users. However, alongside the advantages of audio communication in these settings, there is a growing concern regarding audio-abusive content (AAC). This refers to the malicious or inappropriate use of audio, encompassing behaviors such as verbal harassment, hate speech, and the dissemination of harmful or offensive material. The prevalence of AAC in digital spaces presents substantial challenges for both users and platform administrators.

Due to the challenges induced by AAC to online safety and well-being, audio-based abuse detection (AAD) has caught recent attention. While abuse detection in other modalities like text [1, 2] and visual [3, 4] content has garnered significant focus and development, AAD has not received comparable attention, despite its critical importance in safeguarding digital spaces. This gap underscores the urgent need for research and development efforts aimed at advancing AAD technologies to effectively mitigate the harmful impacts of audio-based abuse in online environments.

There has been growing interest in building effective AAD systems, for example, Gupta et al. [5] explored representations from VGG trained on AudioSet and multilingual wav2vec2 models with Fully Connected Network (FCN), GRU, and LSTM as classifiers. Further, Sharon et al. [6] showed that

AAD performance can be enhanced by fusing audio and ASR transcribed textual representations. On the other hand, Thakran et al. [7] showed that choosing the right acoustic cues by exploring multilingual and emotion recognition PTMs can lead to state-of-the-art (SOTA) performance in AAD without the need of textual representations also reverberated by Spiesberger et al. [8].

AAD has benefitted significantly from the availability of different PTM representations, particularly those adept at capturing paralinguistic cues effectively. However, representations from paralingual PTM [9] which has shown SOTA performance in related tasks to AAD such as speech emotion recognition (SER), speaker identification (SI), and so on, haven't been explored for AAD. In this work, we investigate representations from paralingual PTM for AAD and the first study to do so, according to the best of our knowledge. We hypothesize that these representations will capture verbal cues such as pitch, tone, and intensity much more effectively in comparison to representations of other PTMs for AAD. To validate our hypothesis, we present a comprehensive comparative study of five PTM (TRILLsson, Whisper, MMS, WavLM, x-vector) representations including paralingual, multilingual, monolingual as well as speaker recognition PTM which are SOTA in respective tasks and highly potential candidates for improved AAD.

We also conducted an investigation by combining PTM representations to explore their potential for complementary behavior for more improved AAD, akin to observations in other tasks such as speech recognition [10]. We further sought to address the challenge of AAC being present in diverse languages as realworld digital environments are linguistically diverse. This is a difficult task as a model trained in one language may perform poorly in others as pointed out by Spiesberger et al [8]. This gives rise to a necessity where individual models may be required for different languages. Maintaining separate models for each language not only increases complexity but also poses a significant challenge in terms of scalability, maintenance, and resource allocation for AAD systems. Moreover, it can lead to inconsistencies in performance across languages and hinder the seamless integration of AAD systems into multilingual environments. One way to solve this problem is to train model on the combination of different languages. However, this is not exactly a feasible solution, as training models on the combination of multiple languages will require substantial computational resources and also training data for different languages may not be available at the same time. To mitigate this, we propose, CoLLAB (CoLLABorative Approach for Multilingual Abuse Detection), a novel framework, that doesn't require training at all and enables seamless integration of models trained in various languages through the process of weight-averaging. This results in a single unified model that demonstrates competitive performance in AAD across multiple languages while comprising the same number of parameters as that of the models trained on individual languages. The proposed framework remains effective even in scenarios where training data for certain languages may not be available at the same time. Notably, **CoLLAB** offers the added benefit of operating in *Plug-in* mode, facilitating the seamless integration of models trained in various languages alongside those trained on ADIMA. This approach ensures consistent performance across upcoming new languages as well as previously seen languages.

To summarize, the main contributions are three folds:

- A comprehensive comparative study of different PTM representations to investigate the efficacy of paralingual PTM representations for AAD and our results show that they achieve the topmost performance for different languages.
- We show that combining representations from different PTMs leads to improved AAD. See Section 4.3.
- We present, **CoLLAB** (Figure 1), a novel unified and collaborative framework that allows merging of models trained in different languages for achieving competitive performance across different languages for AAD.

For reproducibility of our experiments and as a reference for future studies to build upon **CoLLAB** for collaborative AAD, we will open source the codes and models built as part of our study after the double-blind review. As **CoLLAB** in *Plug-in* mode will allow merging of models trained by different researchers in different languages and making it in true sense a collaborative modeling framework for AAD. However, **CoLLAB** will expect that the researchers follow the same model architectures as given in this study. Kindly refer to Section 3 for further details.

2. Pre-Trained Representations

In this section, we discuss PTMs whose representations are used in our study. We utilize TRILLsson [11] as paralingual PTM that was derived from SOTA paralingual conformer CAP12 [9] through knowledge distillation. Unlike CAP12, TRILLsson is openly accessible and achieves SOTA performance in the NOSS benchmark. TRILLsson was trained on AudioSet and Librilight datasets, while CAP12 relies on the YT-U dataset, which potentially may include multilingual data. We employ TRILLsson¹ accessible via TensorFlow Hub and returns a vector of 1024-dimension size through aggregrating over time. We employ MMS [12] and Whisper [13] as multilingual PTMs in our study and they have shown SOTA in various downstream multilingual speech processing tasks. MMS was trained in over 1400 languages in a self-supervised manner while Whisper on 96 languages in a weakly-supervised manner. For monolingual PTM, we choose WavLM [14], which has achieved SOTA on SUPERB. Additionally, we consider x-vector [15], a SOTA time-delay neural network for speaker recognition. We have choosen x-vector as its representations have shown superior performance for related tasks such as SER [16], predicting shout intensity [17], depression detection [18] where capturing verbal cues such as pitch, intensity, tone, etc. are very important same as in AAD.

We experiment with MMS², Whisper³, and WavLM⁴ avail-

¹https://tfhub.dev/google/

able in Huggingface. We took x-vector⁵ from speechbrain [19] accesible through Huggingface. The input audio samples are sampled to 16kHz before passing through these PTMs and representations of 1280, 1024, 512-dimensional vectors for MMS, WavLM, x-vector are obtained respectively from the last hidden states through pooling average. For Whisper, we extract representations of 1280-dimension size from the encoder through average-pooling and discarding the decoder.

Figure 1: **CoLLAB**: Here, M_{Hi} , M_{Be} , M_{Ka} stands for models trained on Hindi, Bengali, Kannada respectively. **Left**: Models trained on ADIMA languages and weight-averaging of the models' weights for a single unified model; **Right (Plug-in Mode)** Model trained on external language, that can be integrated into **CoLLAB** and $M_{Plug-in}$ signifies the Plug-in model

3. CoLLAB

In this section, we present, **CoLLAB**, a novel framework for abuse detection across multiple languages. The proposed framework is shown in Figure 1.

CoLLAB operates under the assumption that models trained on different languages share a common architecture. This assumption enables seamless integration and collaboration among models trained in diverse languages within the framework. **CoLLAB** allows the merging of the trained models through weight-averaging. Let W_i represent the model weights for language i, where i = 1, 2, ..., n and n is the total number of languages. First, we normalize the weights of the models using L1 normalization given by \hat{W}_i .

$$\hat{W}_i = \frac{W_i}{\|W_i\|_1} \tag{1}$$

Normalizing the weights before averaging ensure fair representation, alignment of weight magnitudes, and stability in combining models trained in different languages. Then, we average the normalized model weights and the output is given by \overline{W} .

$$\bar{W} = \sum_{i=1}^{n} \hat{W}_i \tag{2}$$

This formulation (\overline{W}) ensures that the resulting unified model captures the collective knowledge from models trained in different languages while keeping the number of parameters the same as the individual models trained in the languages.

Figure 2: Downstream Model Architectures; Here, FCN stands for Fully Connected Network; Representation Fusion represents the model architecture for combination of PTM representations; We use either convolution or transformer block for the combination of PTM representations without intermixing them.

4. Experiments

4.1. Dataset

We use ADIMA [5] for our experiments and it contains 11,775 expert-annotated audio samples in ten Indic languages and spanning over 65 hours. It is evenly distributed across languages and comprises 5,108 abusive and 6,667 non-abusive samples from 6,446 unique Users.

4.2. Downstream Classifier

We experiment with two downstream networks (CNN, Transformer) extensively used in previous works [20, 10, 21, 22] for various speech processing tasks. The model architectures are shown in Figure 2. The extracted representations from the PTMs are passed through the networks. For CNN model, we build a convolution block that contains 1D-CNN layer and maxpooling layer followed by fully connected network (FCN). For Transformer model, we have used the same convolution block as used in CNN model followed by a transformer encoder [23] with number of the heads as 8. For combination of PTM representations, we pass individual PTM representations through Convolution/Transformer block as shown in Figure 2 and then concatenated and passed through FCN for final classification.

For the classification head, we use softmax activation function that outputs the probabilities pertaining to each class i.e abuse *vs* non-abuse. We train the models for 50 epochs using Rectified Adam as optimizer with a learning rate of 1e-3 and batch size of 32. We have also used early stopping and dropout for preventing overfitting. We use Accuracy and F1 (macro average) as metrics for evaluating our models. We use Tensorflow library for implementations. We use the official split given by [24] for training and testing our models. For models trained on individual PTM representations, trainable parameters of the models range between 4.2M to 10.5M and with combination of PTM representations it is between 8.4M to 11.3M.

4.3. Experimental Results

Within-language: First, we discuss the results obtained by training models with individual PTM representations shown in Table 1. The TRILLsson (Paralingual PTM) representations demonstrated the best performance across most languages, showcasing their effectiveness in capturing verbal cues crucial for AAD. Whisper representations followed closely, showing the second-best performance in most languages and leading in couples, likely due to exposure to diverse linguistic contexts during its pre-training. x-vector, WavLM, and MMS shows mixed performance. Amongst downstream networks, CNN shows better performance than transformer. Results with TRILLsson improve over previous works leveraging single PTM representations [24] and also [8], that uses handcrafted features for AAD. However, due to space constraints, we are not able to present the comparison table.

Table 2 shows the results when PTM representations are combined. We notice improvements in most instances compared to built on individual PTM representations. We experimented with the combinations where either TRILLsson and Whisper is present as these two PTMs showed the best performance individually. Combining TRILLsson and Whisper performed the topmost among all the other combinations showing the best complementary behavior.

Cross-lingual: The results are shown in Figure 3. We ex-

periment with only the best models from Table 1 (CNN with TRILLsson) and Table 2 (CNN with Whisper + TRILLsson). Despite these models achieving top performance when trained and evaluated in the same language, their cross-lingual performance is low. For example, models trained in Punjabi (Figure 3) perform poorly in most other languages and also models trained in other languages performs poorly in Punjabi. This low cross-lingual generalizability issue persists with both models trained with individual and combined PTM representations and calls for individual models to be trained in specific languages.

With CoLLAB: The scores obtained by the single unified model as a resultant of CoLLAB are presented in Table 3. We observe consistent performance across all the languages. This eliminates the need for training individual models for each language, thereby resolving scalability, maintenance, and resource allocation concerns. We also notice slight decrease in performance compared to models trained and evaluated in the same language (shown in D column in Figure 3) and we aim to look into this in future work. However, this presents a tradeoff, we have to incur for a single unified model that performs competitively across different languages as in real-world settings, we would want a model show relatively good performance across multiple languages and not in a individual language and performs poorly in other languages.

5. Conclusion

In this, we show that representations from TRILLsson (paralingual PTM) attain the topmost performance for AAD in comparison to other PTM (Whisper, MMS, WavLM, x-vector) representations. This performance is attributed to their effectiveness in capturing verbal cues such as pitch, tone, and intensity which are important attributes for AAD much more effectively than other representations. Additionally, we show that com-

Figure 3: Cross-lingual Evaluation Scores; Train, Test represents the language trained on and the languages tested on; Here, the values are accuracy scores and rounded off to two decimal points

bining PTM representations leads to further improvement in AAD performance. Despite this, challenges persist in achieving cross-lingual generalizability, with certain languages requiring language-specific training giving rise to scalability, maintenance, and resource allocation issues and hindering the practical deployment of AAD systems in linguistically diverse realworld scenarios. To address this, we propose **CoLLAB**, a novel framework that facilitates the merging of models trained in different languages and results in a single unified model exhibiting competitive AAD performance across different languages. Our work can guide future studies, firstly, in selecting the most suitable representations for AAD and secondly, act as a reference for the development of collaborative unified frameworks not only for AAD but also for related applications for deployment in linguistically diverse real-world environments.
